Overall, D2 Drilling Campaign was completed 91 days ahead of the planned campaign duration, including rig movement and an additional workover activity. This excellent performance was achieved through evaluations and improvement meeting conducted for each well to be drilled, including post-drilling meetings, pre-spud meetings, and stuck pipe prevention meetings with the involved service companies. The detailed drilling time for each well can be seen in Figure 2.

Out of the 11 activities performed, 8 were executed successfully ahead of the planned schedule. Among the 3 activities that slightly exceeded the planned time, one was the workover operation, which unexpectedly required more time despite no significant technical problems. Meanwhile, the other two activities, drilling well #2 and #9, faced challenges due to a fishing job in well #1 and a stuck pipe incident that necessitated a sidetrack in well #9.

2.2 Drilling Depth Performance

The success rate of the well depth in reaching its target is 99%. The success rate of the drilling depth describes the comparison between the actual and planned cumulative depth. Eight wells succeeded to reach or even exceed their target depth. Only two wells did not achieve the target depth due to a stuck pipe that left a fish in hole for

well #2 and the drillstring weight almost reached the tensile strength of drillpipe for sidetracking in well #9, making the hole cannot be drilled deeper.

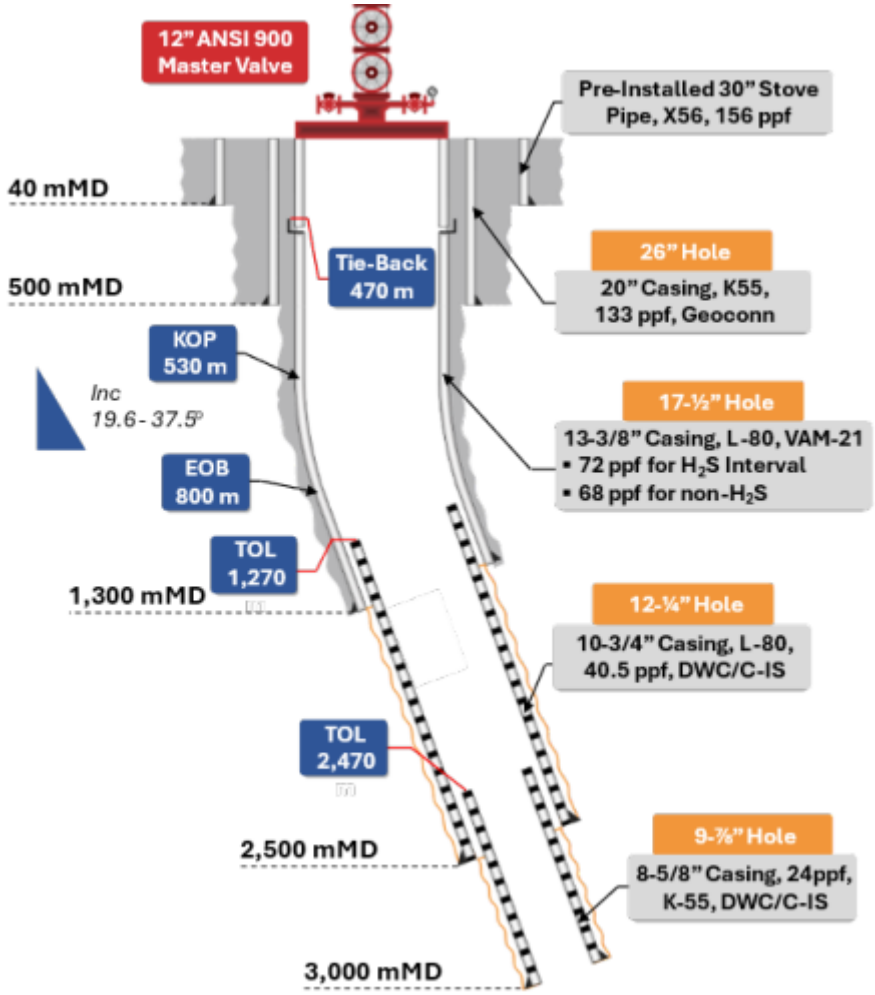

Figure 1: Typical Well Schematic of D2 Drilling Campaign.

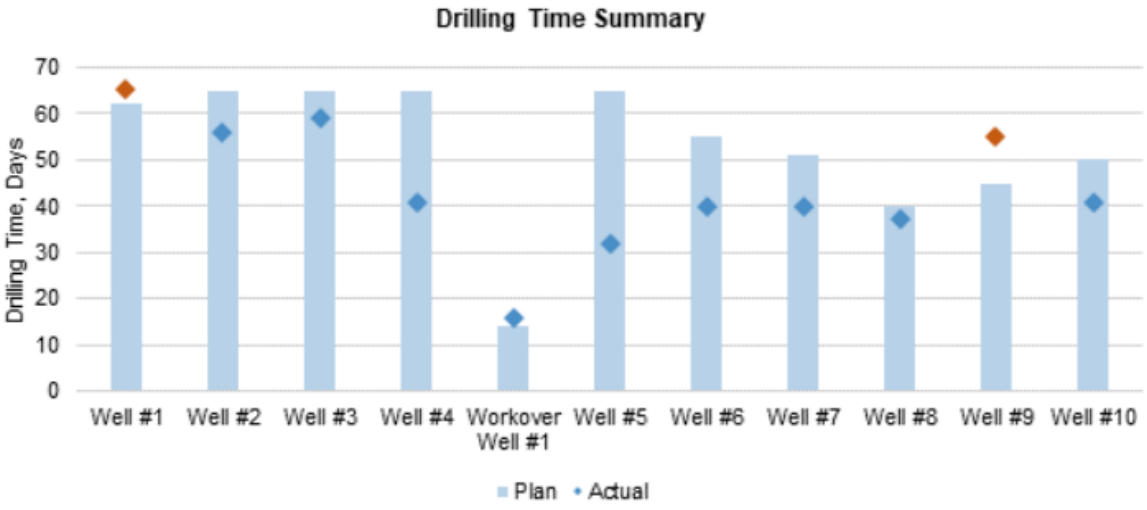

Figure 2: Drilling Time Summary Chart.

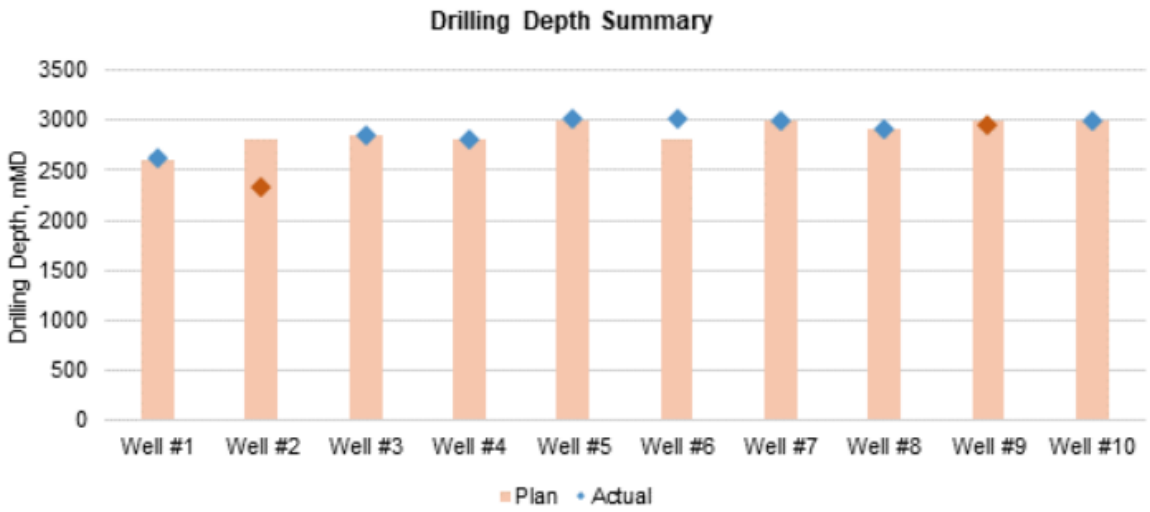

Figure 3: Drilling Depth Summary Chart.

2.3 Drilling Cost Performance

The cost efficiency of drilling correlates with the success of the two previous parameters. The cumulative final drilling cost incurred during the D2 Drilling Campaign remains below the planned cost, reaching only 95%. From all 11 operations, 7 wells succeeded to achieve final cost below the planned.

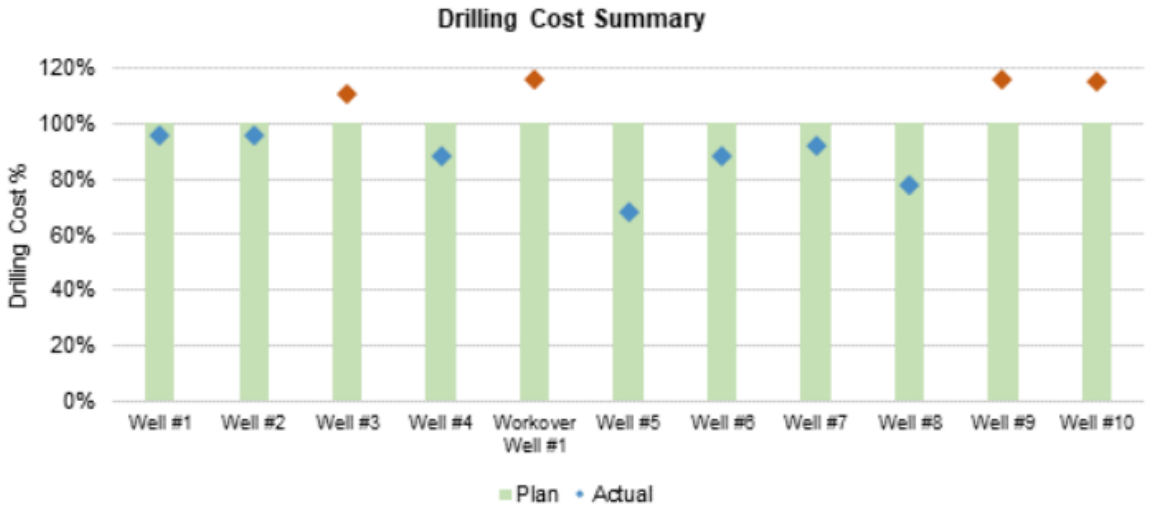

Figure 4: Drilling Cost Summary Chart.

When compared to the allocated investment, the drilling expenses are even lower at 86%. This translates to a significant 14% savings, which is commendable. The average cost rate per depth in D2 Campaign is 2,038 USD/m. Furthermore, the six producer wells drilled are estimated to generate power up to 97 MW collectively, resulting cost rate at 670,599 USD/MW. This rate is below the planned rate at 1,000,000 USD/MW.

2.4 Overall Drilling Performance

The drilling performance of Dieng 2 campaign is measured with Drilling Depth, Rate of Well Completion (ROWC), Cost per Meter (CPM) and Non-Productive Time (NPT) Parameters. Drilling depth is the deepest bit depth of the last wellbore instead of the last casing run depth. Below is the summary of ROWC, CPM and NPT of D2 Campaign. The benchmark data is gathered from 224 geothermal wells in Indonesia from another geothermal operator companies.

- **ROWC** is the average of depth deepening in a day and stated in m/day. The higher the value, the better the drilling performance. The average ROWC of D2 Campaign is 61.19 m/day, much better than the average ROWC of geothermal drilling in Indonesia in 45 m/day (drilling data by EBTKE interval 2009-2022).

- **CPM** is the average final cost (without movement cost) spent per meter drilled and stated in USD/m. The lower the value, the better the drilling performance. The average CPM of D2 Campaign is 2,038 USD/m, much better than the average CPM of geothermal drilling in Indonesia in 2,700 USD/m (drilling data by EBTKE interval 2009-2022).
- **NPT** is the time spent for unplanned operation (based on GDE's rules) experienced compared to the total drilling time. Low NPT value means good drilling execution. The average NPT value of D2 campaign is 8.35%, lower than the maximum NPT target at 10%.

Figure 5 shows the ROWC, CPM ad NPT record of each well in D2 Drilling Campaign.

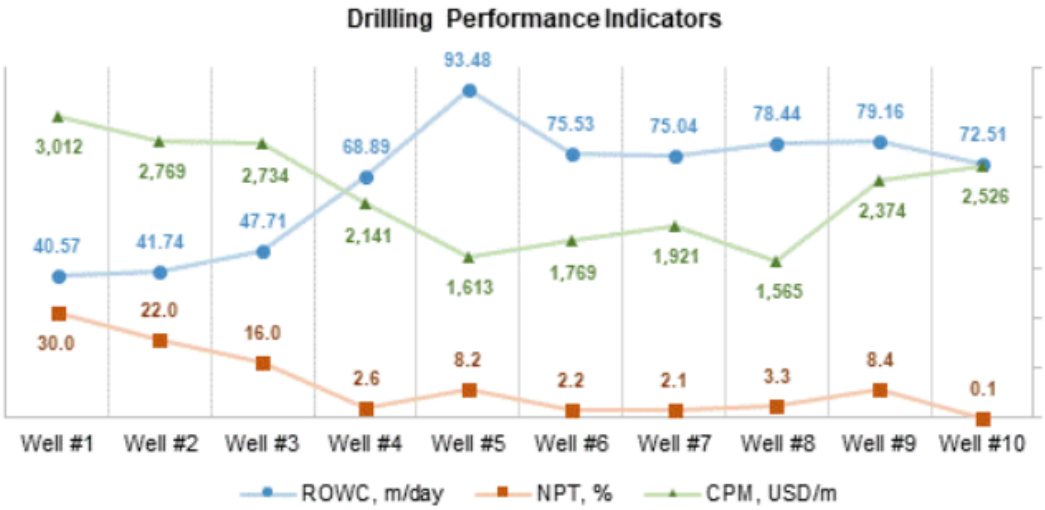

Figure 5: Drilling Performance Indicators Chart.

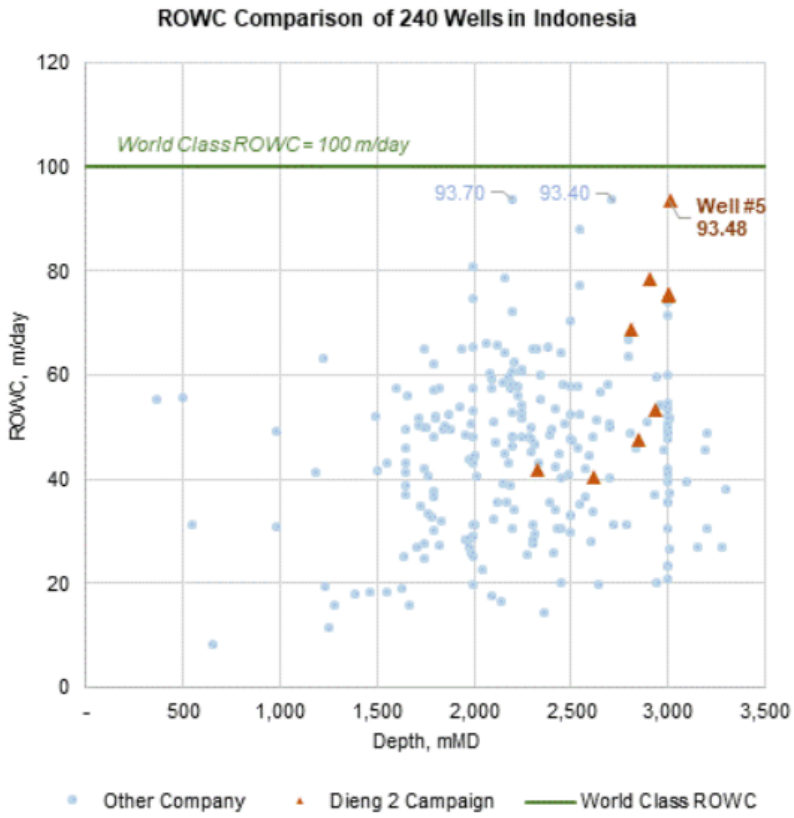

Figure 6: ROWC Comparison of 240 Geothermal Wells in Indonesia.

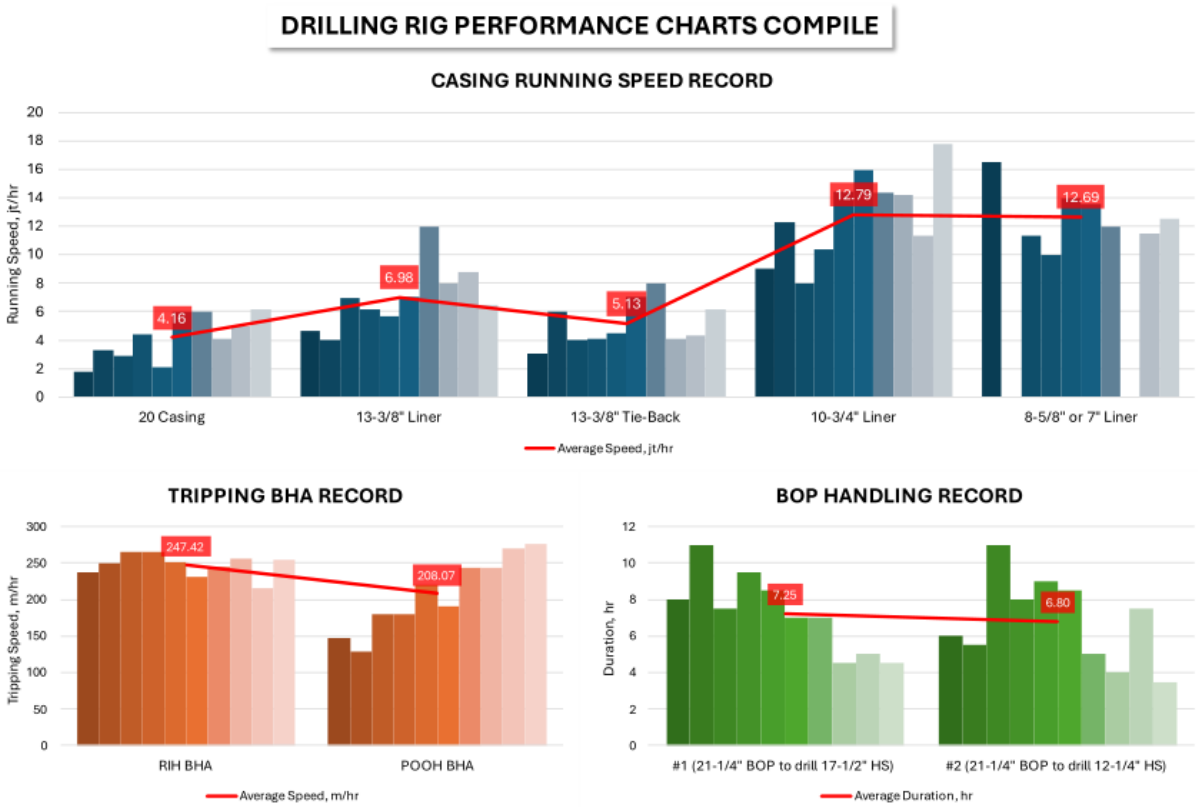

Figure 7: Drilling Rig Performance.

Excellent drilling campaign has been performed during Dieng 2 Project in term of ROWC, CPM, and NPT. By taking attention to the ROWC, it is important to note that 8 out of 10 wells recorded value above 45 m/day. The only 2 wells that were not reaching 45 m/day are the 2 first drilled well when the learning curve was just being started. The peak of ROWC value was gained in the Well #5 with 93.48 m/day. The decreasing trend value of CPM from the first well to the last well demonstrates an outstanding learning curve. From NPT side, 7 out of 10 wells record NPT value below 10% to qualify the drilling operation objective. The last well records only 0.1% of NPT which shows once again a good learning curve.

2.5 Other Achievements

During the D2 Drilling Campaign, several other outstanding achievements were attained in terms of safety and drilling operations. Some of these accomplishments are:

- Zero Recordable Accident in 1,362,474 hours (702 days) without incident as the commitment of Geo Dipa Energi for safety operation.
- Second best ROWC in Indonesian geothermal drilling record with 93.48 m/day in Well #5 as shown in Figure 6.
- Long 12-1/4" open hole section at Well #7 with 1,471 m and was successfully running 10-3/4" perforated liner to bottom.
- High daily Rate of Penetration (ROP) at Well #5 with 324 m drilling depth progress in a day.

3. VALUABLE LESSON LEARNED AND DRILLING STRATEGY

Here are some of the key factors that significantly contributed to the success of drilling operations in Dieng, particularly in terms of drilling timeline, cost efficiency, and operational excellence.

- The selection of high-quality service companies with high qualification, especially for the drilling rig provider which demonstrated by rapid duration of mobilization, moving/skidding, demobilization, tripping time, BOP handling, casing running and also the low value of Non-Productive Time (NPT). The drilling rig performance is shown in Figure 7.
- Efficient contract value resulting from grouping several service companies into a single rig bundling within the semi-IPM contract scheme.

- Competent planning and operational supervision achieved by highly skilled office drilling team that has been involved in several drilling campaigns previously and the selection of highly experienced man power or field drilling team to execute the plan.
- Appropriate drilling fluid design which was achieved by conducting Inhibitive Tests. This test provided a solution to address bit balling issues caused by sticky clay. This involved using a drilling fluid formulation combining KCl, PHPA, and lubricant, resulting in high penetration rates and eliminating the need for frequent bit and BHA trips for cleaning.
- Performance-based drill bit selection system. Three drilling bit providers were participated in D2 drilling campaign and evaluated based on maximum drillable depth, cost per foot, and rate of penetration (ROP).

4. CONCLUSION

GDE has successfully completed their first ever drilling campaign as an Indonesian geothermal operator, Dieng 2 Drilling Campaign, for the supply of steam to the new Dieng 2 Power Plant. The drilling campaign was completed 91 days ahead of schedule, achieving 99% of the planned drilling depth and saving 5% of the planned costs. Beyond the technical aspects, GDE also recorded 1,362,474 hours (702 days) of Zero Recordable Accidents, demonstrating their commitment to safety. Another achievement from this drilling campaign was achieving the second-best Rate of Well Completion (ROWC) in Indonesia with a rate of 93.48 m/day during the drilling of Well #5. Additionally, they successfully drilled the longest 12-1/4” open hole section in Indonesia at Well #7 (1,471 m) while successfully running 10-3/4” perforated liner to the bottom. Well #5 also had the best daily Rate of Penetration (ROP) with 324 m of drilling depth progress in a single day. These successes were attributed to various efforts, including selecting high-quality services with high qualifications, efficient contract value, competent planning and supervision, appropriate drilling fluid design, and a performance-based drill bit selection system.

Keywords: : production well, scaling, hole cleaning, acidizing

ABSTRACT

Production well 8C4, operational for five years, experienced a significant decline in performance, from 55 kg/s at 14.7 bar to 55 kg/s at 9.6 bar. Analysis of routine fluid samples revealed that calcite oversaturation occurred when temperatures exceeded 140°C within the wellbore. In response, an intervention involving jetting and acid treatment was initiated. Leveraging completion test data and insights from pre-job testing, the intervention strategy was tailored for optimal results. The implementation of the acid jetting treatment yielded promising outcomes, with a notable 65% increase in steam production.

1. INTRODUCTION

Well 8C4 was fully drilled in 2009, reaching a depth of 1755 meters with big hole configuration. Loss of circulation began at 1189 meters, and the injectivity index is in the range of hundreds (kg/s/bar). The reservoir fluid is in a compressed liquid state with a temperature of 264℃. During a separator flow test, it was confirmed that the well produces fluid at a rate of 120 kg/s at 15.2 bar pressure, with a flowing enthalpy of 1100 kJ/kg. Since 2012, the well has been supplying steam to a power plant. The specific configuration of the well is detailed in Figure 1.

1.1 Production trend

In 2012, the initial production from the well was impressive, yielding 468 tons per hour of total mass flow at 13.9 barg, which generated 9.87 megawatts of electricity. By 2017, production had decreased to 188 tons per hour of total mass flow at 9.32 barg, resulting in 3.44 megawatts of electricity. Despite the reduction in production rate over the years, the flowing enthalpy and static reservoir pressure have remained stable, indicating sustained performance without decline.

The deliverability output curve, modeled elliptically, effectively illustrates the discharge performance of the well. Despite consistent reservoir pressure and flowing enthalpy, significant drops in production occurred between 2012 and 2013, as well as between 2013 and 2014. However, from 2014 to 2017, there were no major fluctuations in production levels. This stable phase in production contrasts sharply with the earlier years, as depicted by the elliptical model on the deliverability output curve in Figure 2.

The high Calcite Scaling Index as seen in Figure 3, caused calcium scale deposition when the well produced exceeded 140°C, prompted a Go-Devil survey (sizes 8", 5", and 3") in the UBL-8/C4 well. During the survey, soft tagging was observed at a depth of 859 mMD. Subsequent analysis revealed a severe reduction in liner diameter, from 10 inches to 3 inches (Hastriansyah, 2018). A small sample retrieved by the Go-Devil was dissolved in hydrochloric acid (HCl) for analysis. X-ray diffraction conducted on a neighboring well at a depth of 845 mMD confirmed the presence of calcite scale.

1.2 Pressure and Temperature Measurement

Downhole pressure and temperature are routinely monitored in production wells whenever feasible. Figure 4 illustrates the PT profile between 2010 and 2016, showing no significant decline in either pressure or temperature.

2. HOLE CLEANING

A hole cleaning operation involving a jetting tool and acidizing was scheduled for well 8C4. Due to the continuous operation of the well, an integrity check could only be conducted as part of the hole cleaning procedure. As part of this process, a basic well condition survey was introduced, which included deploying a go-devil, a scale catcher, conducting injection PTS (Pressure, Temperature, and Spinner), and performing a gross permeability test throughout the well cleaning program.

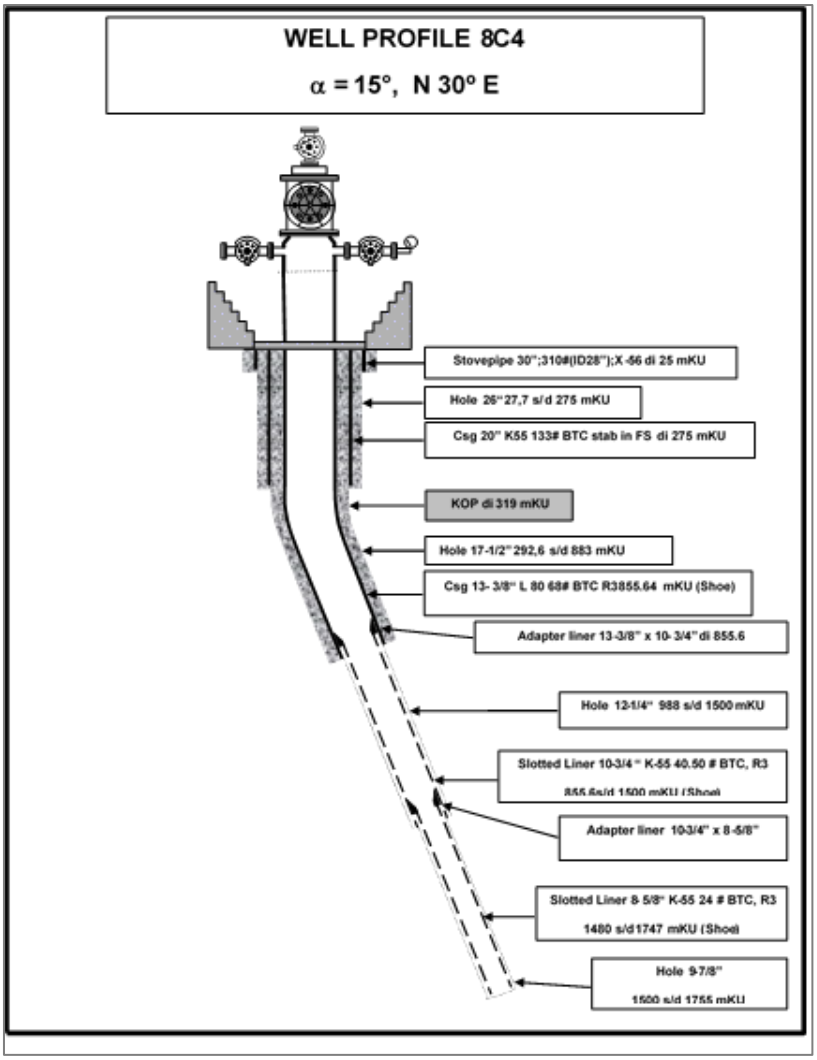

Figure 1: Well Configuration 8C4.

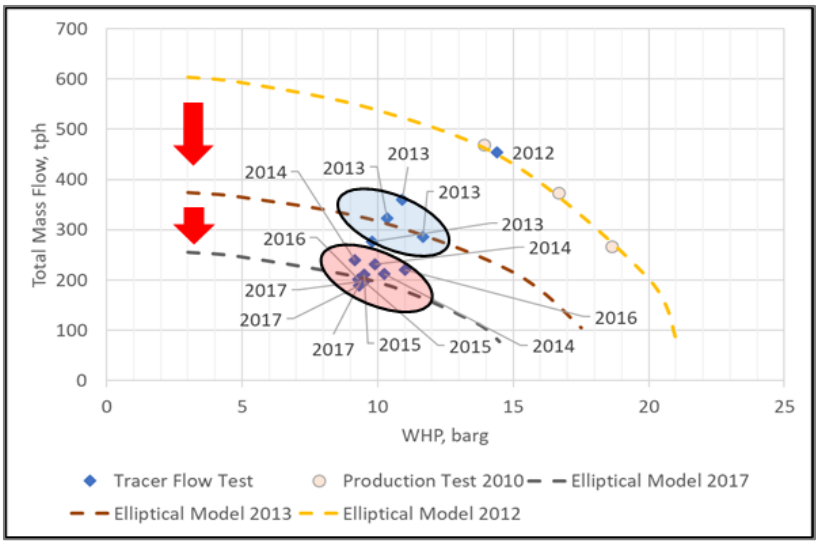

Figure 2: Deliverability Output Curve 8C4.

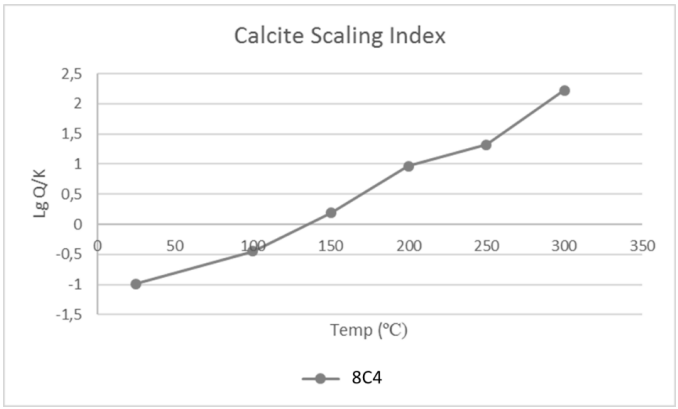

Figure 3: Well 8C4 Calcite Scaling Index.

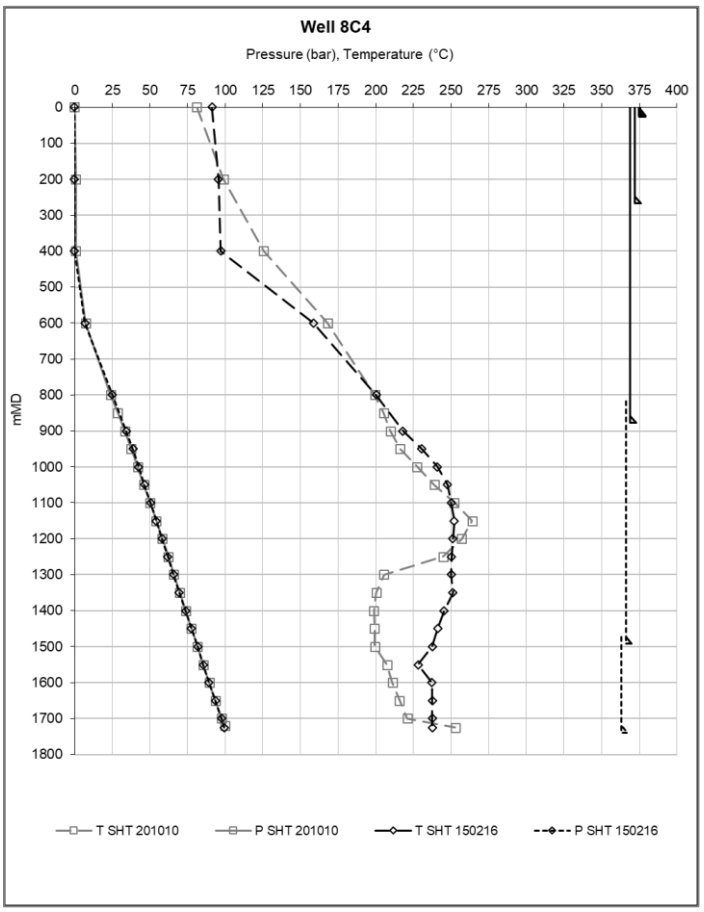

Figure 4: Well 8C4 Shut In P&T Profile.

2.1 Acid Design

For sandstone acidizing operations, the preferred acid type is mud acid, which combines hydrochloric acid (HCl) and hydrofluoric acid (HF). The acid should demonstrate a solubility range of 50% to 70% based on laboratory testing, ensuring effective dissolution of mineral deposits within the sandstone formation (see Table 1 for Acid Design in well 8C4**)**. During operations, a coiled tubing with a diameter of 2-7/8 inches is utilized, allowing for precise acid delivery. The total injection rate is maintained at 10 barrels per minute (bpm), optimizing the treatment process to enhance reservoir permeability and production efficiency.

Permeability is directly correlated with volume, highlighting the need to consider its implications. For high permeability reservoirs, the suggested fluid volumes range from 160 gal/m to 500 gal/m for preflush (PF) and 250 gal/m to 500 gal/m for main flush (MF). Additionally, the reaction's harmful effects on metal must be considered. Acidic fluids (AF) can be used to produce HF solutions and are less toxic than HF, as liquids are safer to handle and reduce the need for manual handling. AF exhibit moderate to high solubility with minerals such as feldspar, illite, smectite, chlorite, calcite, and kaolinite.

Table 1: Acid Design.

Type	Product	Volume
Pre-Flush	9% HCl	200 gal/m
Main Flush	14% HCl – 22% Ammonium Fluoride	400 gal/m
Post Flush	Water	400 gal/m
Additive	Corrosion Inhibitor Iron Control Agent Friction Reducer	

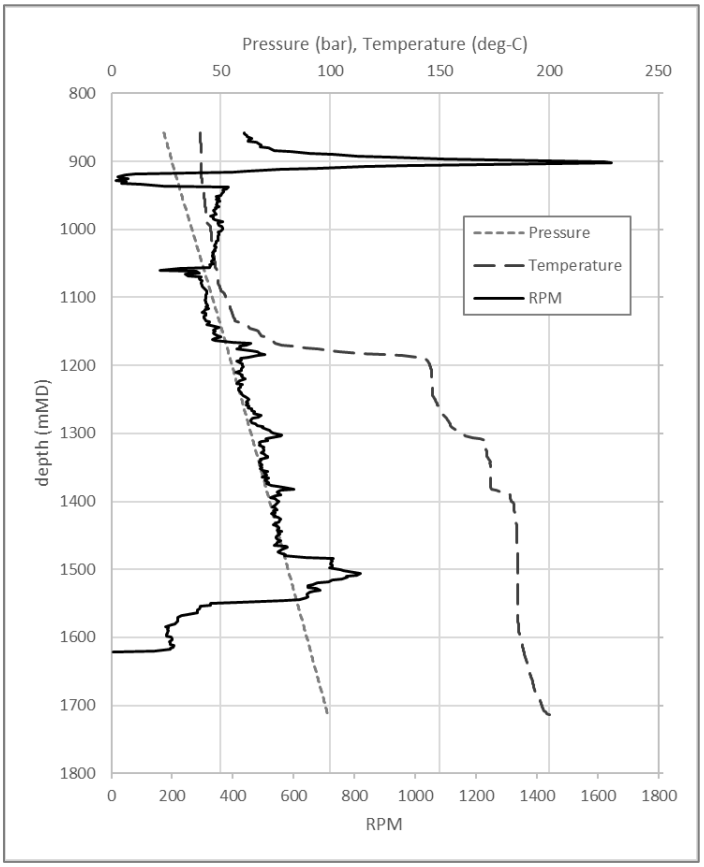

Figure 5: Injection PTS data.

Table 2: Acidizing Result Comparison.

	Total flow (tph)	Steam flow (tph)	Generation (Mwe)
Pre acid	188	28	**3.4**
Post acid	392	46	**5.7**

Corrosion inhibitors play a crucial role in protecting coiled tubing and wellbore from corrosion. Iron control agents are essential for reacting with dissolved metal ions to prevent solids precipitation, thereby maintaining the integrity of the system. Additionally, friction reducers are utilized to decrease injection pressure in coiled tubing, enhancing the efficiency and safety of the injection process.

2.2 Acidizing Operation

The process begins with Step I, where quenching is conducted at a rate of 10 BPM (barrels per minute). In Step II, the equipment is run into the hole until it reaches the target depth. However, the operation cannot penetrate below 896 meters. To address this, acid is pumped using a jetting nozzle, successfully achieving penetration. In Step III, acid is injected at a rate of 5 BPM, with annulus water being pumped at the same rate. Unfortunately, the

injection PTS data (Figure 5) exceeds the maximum temperature for the corrosion inhibitor, necessitating the dumping of acid at 1100 mMD.

3. CALCULATION, RESULT, AND DISCUSSION

The results of the operation were a mix of significant improvements and some drawbacks. On the positive side, steam flow improved by an impressive 165% (see Table 2), and discharge performance recovered, approaching the levels specified in the Output Curve Model from the year 2012 (Figure 6). However, there was a reduction in enthalpy, which decreased from 1026 kJ/kg to 980 kJ/kg. This indicates a slight decline in the energy content per unit mass, which might impact the overall efficiency despite the gains in flow and discharge performance.

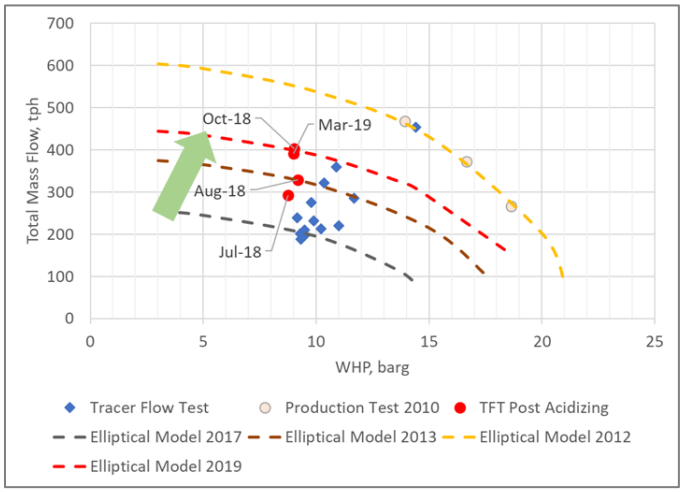

Figure 6: Deliverability Curve After Acidizing.

4. CONCLUSION

Well UBL-8/C4 had calcite scaling deposition in the wellbore and fine migration problems. Acidizing stimulation using Sandstone Acid was successfully performed in this geothermal well, which recovered its discharge performance. Consequently, the steam production of UBL-8/C4 increased by 1.65 times, from 27.5 ton/hr (3.4 MWe) to 45.5 ton/hr (5.7 MWe).

ACKNOWLEDGEMENT

The authors wish to thank the management of PT Pertamina Geothermal Energy Tbk. for the permission to publish this paper. Discussion with Reservoir team members are very much appreciated.

Keywords: Geothermal, Multicriteria Decision-Making, Production Optimization, Analytical Hierarchy Process

ABSTRACT

Geothermal power plants in Indonesia generally have a capacity of around 55 MWe. The steam from the production well is transported to the power plant through a steam gathering system. However, natural decreases in the production well's capacity can be occurred due to several factors such as wellbore and reservoir issues. Monitoring various factors can help identify these issues, guiding future planning for well optimization program such as optimizing WHP, well investigation, well intervention, workover or drilling programs to maintain production capacity. This paper explores a data-driven approach to prioritize well optimization activities in geothermal field "X" using the Analytical Hierarchy Process (AHP). AHP is a multicriteria decision-making tool that enables the consideration of various factors influencing such as wellhead pressure, steam flow, cost and lesson learn of production optimization. The methodology involves identifying these key criteria, constructing pairwise comparison matrices to quantify their relative importance, and deriving weightings for each factor. Subsequently, different well of are evaluated based on their impact on the weighted criteria. Finally, an AHP-based developed for decision analysis aimed at establishing an overall priority ranking of nine production wells and support management decisions regarding the next production optimization strategies.

1. INTRODUCTION

Geothermal power plants play a crucial role in Indonesia's energy sector. As one of the prominent companies engaged in energy production in Indonesia, PT. XYZ has been actively involved in sustainable energy generation. One of its geothermal fields is responsible for extracting steam and brine from geothermal reservoirs and transporting them to the power plant for electricity generation. The Geothermal "X" Field has nine production wells, and monitoring and mantaining the production capacity of these wells is essential for sustained energy production. Many factors like wellbore integrity, reservoir depletion, and operational challenges can lead to a natural decline in the production capacity of geothermal wells over time (Dewi et al., 2020). To address these challenges, Production enhancement activities, such as well workovers, interventions, and drilling new wells, play a crucial role in maintaining the production capacity of the Geothermal "X" Field.

Based on the company's historical data, the pany has i activities to minimize the gap between target and realization, and has shown a positive trend in closing this gap, as shown in Figure 1. However, after 2021, the gap has widened.

According to the other data, the gap between the target and realization for electricity generation from the Geothermal "X" Field had exhibited a positive trend in closing until 2021. However, this gap has widened after 2021. Additionally, the gap in the equivalent availability factor decreased to 16.1% in 2021 but has since become wider, indicating the need for the company to implement measures to increase steam supply and close this gap, as shown in Figure 2.

To address this challenge, the company needs to develop a comprehensive strategy to prioritize its well optimization efforts. The Analytical Hierarchy Process (AHP) is a multi-criteria decision-making tool that can be effectively utilized to evaluate and prioritize different well optimization techniques based on their impact on key criteria such as wellhead pressure, steam flow, cost, and success ratio from the past of production enhancement such as workover, well intervention, additional/upgrading facilities. Therefore, this study aims to apply the Analytical Hierarchy Process (AHP) to analyze the decision-making process in prioritizing well optimization activities for the Geothermal "X" Field to maintain its production capacity. By ishing an overall priority ranking of production wells, the company can effectively manage resources and prioritize activities such as workover, well interventions, or additional/upgrading facilities. This will ultimately contribute to ensuring the long-term inability of its by existing assets, which is assumed to be more attractive than drilling a new well.

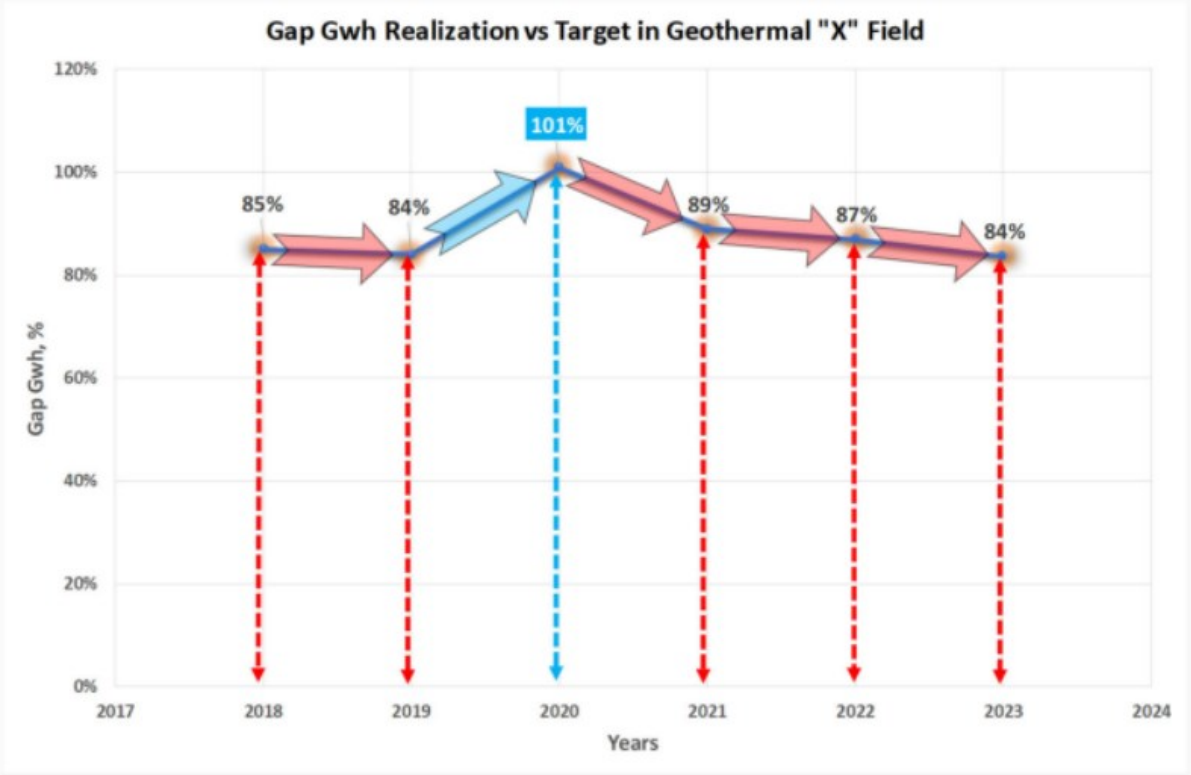

Figure 1: Gap Analysis Gwh Target vs Realization in "X" Field (PT.XYZ, 2024).

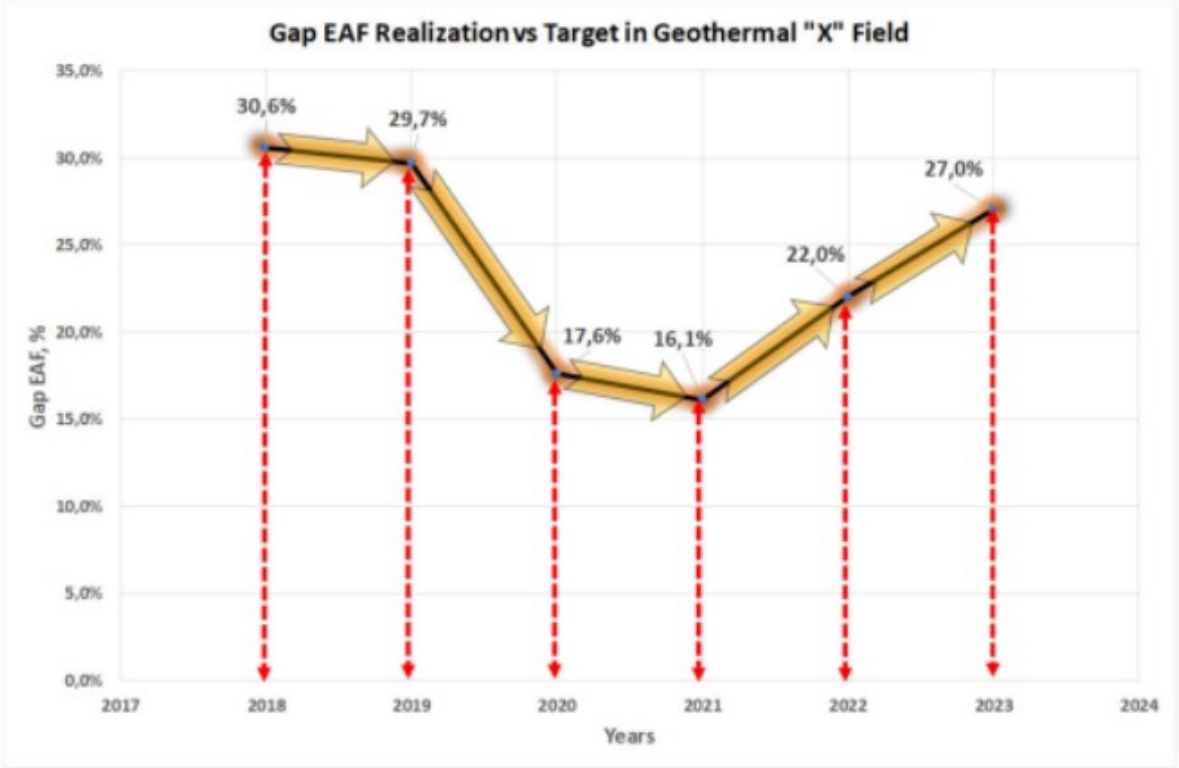

Figure 2: Gap Analysis Equivalent Availability Factor (EAF) in Geothermal "X" Field (PT.XYZ, 2024).

2. Literature Review

2.1 Analytic Hierarchy Program (AHP)

Decision analysis is based on axiomatic decision theory and it incorporates! insights from the study of decision-making (Cui et al., 2021). Multi-Criteria Decision Making (MCDM) is a comprehensive, multidimensional approach to address decision-making challenges across various fields, seeking the most favorable alternative by considering all relevant criteria. This method employs powerful tools to analyze complex decision-making problems in different domains (Afandi, 2018). The Analytical Hierarchy Process (AHP) is a traditional MCDM techni that bines both qualitative and quantitative analyses (Liu et al., 2020). It helps in the overall selection process by breaking down a complex issue into a hierarchical structure of goals, criteria, and alternatives (Sharma & Gandhi, 2008). AHP organizes and analyzes complex decisions, allowing decision-makers to compare and prioritize different alternatives based on multiple, often conflicting criteria. It is particularly effective in situations involving subjectivity and is well-suited for problems where decision criteria can be organized hierarchically into sub-criteria (Tuzmen & Sipahi, 2011). Developed by Thomas Saaty in the 1970s, AHP involves several steps (Emawan et al., 2021): constructing a hierarchical model with the objective, alternatives, and evaluation criteria; assigning weights to the criteria through pairwise comparisons; synthesizing judgments to establish priorities; assessing the consistency of these judgments using an ratio; and making the final decision based on the results. For example, a study by Simorangkir & Pratama (2023) integrates AHP with the whale optimization algorithm to determine the best energy source and important components before optimizing them. Febrianto et al. (2022) used AHP to select the right training material for mechanics, finding that the highest -ranked option was the Komatsu model unit with preventive maintenance training materials. Similarly, Budiman & Pratama (2022) employed AHP to decide which secondhand plastic injection molding machine to purchase, concluding that the Potenza PT350 was the best option to meet customer demand with a 300-ton capacity.

To make comparisons, we need a scale of numbers that indicates how many times more important or dominant one element is over another element as shown in Table 1.

Table 1: Scale Instrument for Pairwise Comparison Data Collection Method, Tools & Technique Interpretation.

Intensity of Importance	Definition
1	Equal Importance
3	Moderate Importance
5	Strong Importance
7	Very Strong Importance
9	Extreme Importance
Intensities of 2, 4, 6, and 8 can be used to express the level of intermediate values	

The AHP assigns a weight to each evaluation criterion based on the decision maker's pairwise comparisons. A higher weight indicates greater importance of the corresponding criterion. For each criterion, AHP then scores the options according to the decision maker's pairwise comparisons of the options relative to that criterion. A higher score reflects better performance conceming the specific criterion. Finally, AHP combines the criteria weights and option scores to determine a global score for each option, resulting in an overall ranking. The global score for an option is a weighted sum of the scores it received for all criteria.

2.2 Criteria Parameter

The main criteria parameters in the Analytical Hierarchy Process (AHP) include:

a. Wellhead Pressure (WHP)

Wellhead pressure is a crucial indicator of the well's production capacity (Qin et al., 2013), monitoring and maintaining wellhead pressure is essential for sustained energy production (Carson & Mansure, 1982). Declining wellhead pressure can be a signal of reservoir depletion or well integrity issues, requiring optimization measures (Al-Dulaijan et al., 2013). In this study, the tools and technique to enhance the quality of user's judgement is the gap between actual condition and average wellhead pressure within a year data approach.

b. Steam Flow

Steam flow rate is another critical parameter in maintaining the power plant's energy production. The steam flow rate from a production well directly impacts the power generation capacity of the geothermal power plant. Optimizing steam flow is critical for maintaining the overall production capacity. According to Dwikorianto et al., (2010), the steam flow rate is a key parameter in geothermal power plant operations, as it determines the

amount of electricity that can be generated. Maintaining and optimizing the steam flow from production wells is essential for sustaining the power generation capacity of the geothermal fi field. In this study, the tools and technique to enhance the quality of user's judgement is using the gap between actual steam flow and the target flow rate data approach.

c. Cost

The cost associated with well optimization activities is a crucial consideration in the decision-making process. This includes the costs of well workover, well intervention, or additional/ upgrading facilities. The cost factor should be evaluated in terms of the financial impact and feasibility of the proposed optimization measures. Selecting the most cost-effective solutions that can effectively improve production capacity is essential for maintaining the overall profitability and sustainability of the geothermal operations. In this study, the tools and technique to estimate the cost is based on the three- point estimation PERT (Program ion and Review Technique) approach. This involves optimistic, pessimistic, and most likely cost scenarios to obtain a more accurate and realistic cost estimate for the well optimization activities.

d. Success Ratio

The success ratio of the well optimization activities is another important criterion in the decision-making process. The success ratio of production enhancement activities, such as well workovers, well interventions or additional/upgrading facilities, is a critical factor in the decision making process for prioritizing well optimization efforts. The success ratio reflects the historical performance and effectiveness of these activities in improving well productivity and maintaining production capacity. A high success ratio indicates that the proposed optimization measures are more likely to achieve the desired outcomes, making them more attractive options for the company to prioritize. Conversely, a low success ratio may suggest the need for more thorough evaluation or alternative approaches to ensure the long-term sustainability of the geothermal operations. In this study, the tools and technique to measure the success ratio is based on the historical data of past production enhancement activities and or well investigation data in the Geothermal "X" Field and or well investigation data. User judgement will rely on this data to enhance the quality of input of this Analytical Hierarchy Process (AHP) Application.

3. METHODOLOGY

Methodology of this research is combining data quantitative and qualitative approach which is a conceptual framework of this study can be shown at Figure 3.

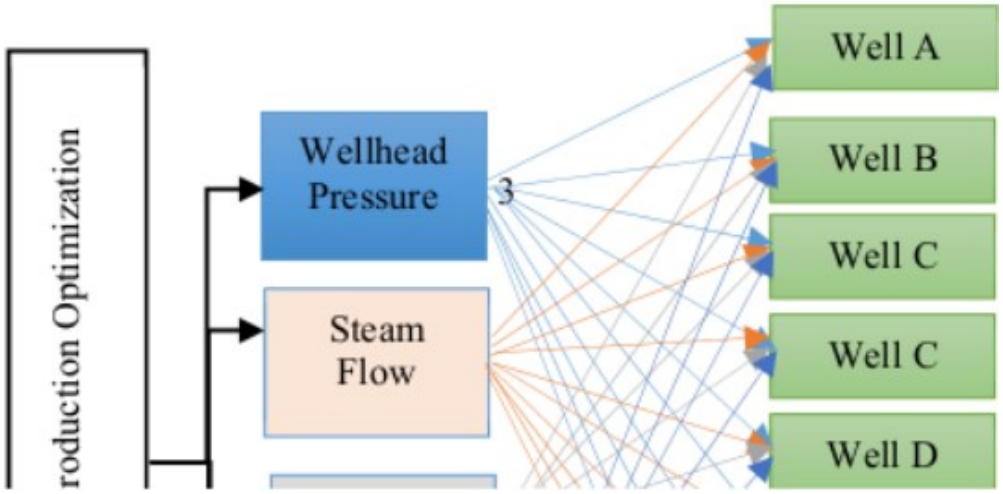

Figure 3: Conceptual framework AHP Well Intervention Priority in "X" Field at PT. XYZ.

Based on those conceptual frameworks, the data collected in this study was created in Table 2. Most of data is based on expert judgement, data analytical, and three-point estimation PERT that come from **unpublished check sheets** owned by an expert in PT. XYZ. The result from expert will interpreted to the level of Fundamental Scale for Pairwise Comparisons either linear regression if using data driven for tools & technique interpretation or verbal judgement if using expert judgement (Saaty, 1987).

Table 2: Data Collection Method, Tools & Technique Interpretation.

No.	Level Judgment	Tools & Technique Interpretation	Remarks
1	Wellhead Pressure	Expert Judgement	
2	Steam flow	Expert Judgement	
3	Cost	Expert Judgement	
4	Success Ratio	Expert Judgement	
5	Wellhead Pressure comparison each alternative	Data Analytical	Gap of WHP Actual vs Average 1 year calculation by Users compare with each alternative
6	Steam flow comparison each alternative	Data Analytical	Gap of Steam Flow Actual vs Average 1 year by Users compare with each alternative
7	Cost comparison each alternative	Three-point estimation PERT	Gap Based on judgement users for pessimistic, optimistic and most likely in regards cost of well treatment compare with each alternative
8	Success ratio comparison each alternative	Data Analytical	Expert Judgement based on historical well for well treatment, well investigation and or well surveillance data compare with each alternative

4, RESULT AND ANALYSIS

4.1 Result of Decision Criteria

Based on tools & technique interpretation from Table 2, the result of level importance in decision criteria can be shown in Table 3.

Table 3: Result Pairwise Comparison in Decision Criteria.

	Cost	Steam flow	Success Ratio	WHP
Cost	1.0	1.0	0.1	1.0
Steam flow	1.0	1.0	0.1	2.0
Success Ratio	9.0	9.0	1.0	9.0
WHP	1.0	0.5	0.1	1.0

According to Table 3, the priority and level consistency shown acceptable as per Table 4.

Table 4: Result the Priority and Level Consistency in Decision Criteria.

Decision Criteria	Priority	Consistency Ratio	Degree of Consistency
Cost	0.083	0.023	Acceptable
Steamflow	0.102		
Success Ratio	0.744		
WHP	0.072		

4.2 Result of Alternative and Overall Goal

After decision criteria, the next step evaluation is to get overall goal based on decision criteria compare with all alternatives. Based on Table 2, the result of level importance, consistency ratio and degree of consistency for WHP, Steam Flow, Cost, and Success Ration can be shown in Table 5, Table 6, Table 7, and Table 8, respectively.

Table 5: Result of WHP in Comparison Each Alternative.

Well	A	B	C	D	E	F	G	H	I	Consistency Ratio	Degree of Consistency
A	1.0	9.0	7.0	9.0	9.0	9.0	9.0	6.0	5.0	0.026	Acceptable
B	0.1	1.0	0.3	1.0	1.0	1.0	1.0	0.3	0.2		
C	0.1	3.0	1.0	4.0	4.0	4.0	4.0	0.5	0.3

4. CONCLUSION

Production optimization is a critical task for geothermal companies to optimize and continuously improve on their assets. The AHP approach allows the company to systematically evaluate and prioritize the production well optimization options based on key criteria such as wellhead pressure, steam flow, cost, and success ratio. The final result of the Analytical Hierarchy Process tells us that the top 3 wells that need to optimization are Well B, Well I, and Well A. However, if the company needs to maximize its capacity and the cost still feasible, it may add Well C and Well G as shown in the Table 9 as alternative solutions.

Optimizing Performance of LP-Separator and Brine ORC Using Brine Reinjection System (BRS) Pumps in the 15 MW Combined Double Flash and Binary System at PT. Sorik Marapi Geothermal Power

Keywords: Optimizing, Brine Reinjection System (BRS) Pump, LP-Separator, Brine ORC

ABSTRACT

The 15 MW Combined Double-Flash and Binary system utilizes 2-phase geofluid (steam and brine) from two production wells, Well T-01 and Well T-02, with a steamfield facility consisting of an HP-Separator, LP-Separator, and Brine Reinjection System (BRS) Pumps (BRSP-01 and BRSP-02), and a power plant facility consisting of a Steam Expander (SE-07), Steam ORC (ORC-16), and Brine ORC (ORC-15). The Double-Flash system uses the hot brine from the first separation by the HP-Separator to be re-flashed (second separation) using the LP-Separator to produce additional steam. Meanwhile, the Binary system uses the exhaust steam from SE-07 for ORC-16 and the hot brine from the LP-Separator for ORC-15. ORC-15 utilizes the heat from the brine after the second separation from the LP-Separator to heat the working fluid (R245fa) using heat exchanger equipment (pre-heater and evaporator) to vaporize the working fluid and drive the working fluid expander to generate electricity. The operation of the LP-Separator and ORC-15 is connected to the operation of the BRS Pump. The brine from the HP-Separator is pumped to the LP-Separator using BRSP-01, and the brine from the LP-Separator is pumped to ORC-15 using BRSP-02. The BRS Pump is a brine pump used for pumping hot brine at a specific pressure and brine rate, controlled by a variable frequency drive (VFD). This allows the operator to regulate the discharge pressure and brine rate entering the LP-Separator and ORC-15. Thus, the operator can optimize the process using the BRS Pump to achieve optimal pressure and brine rate settings to produce an optimal steam fraction (steam rate) in the LP-Separator and optimal power generation from ORC-15. Additionally, a higher discharge pressure will make the brine more saturated, and the SSI value will be lower than without using the BRS Pump, reducing the potential for scaling formation along the brine line from the HP-Separator to the LP-Separator and the brine line from the LP-Separator to the ORC-15 Outlet. By optimizing BRSP-01, the LP-Separator steam fraction value will increase by 0.6629% to 3.1080% (using BRSP-01) compared to 3.0875% (without BRSP-01). This results in a total power generation increase of 0.0604% to 11466.2443 kW (using BRSP-01) compared to 11459.3174 kW (without BRSP-01). Optimizing BRSP-02 will increase the power generation of ORC-15 by 0.5774% to 1409.7176 kW (using BRSP-02) compared to 1401.6246 kW (without BRSP-02. Furthermore, the potential for scaling formation along the brine line from the HP-Separator to the LP-Separator can be minimized because the discharge pressure is above the saturation pressure, i.e., 8.94 barg (Pressure saturation is 6.61 bar), and the SSI value decreases by 0.0534% to 1.1238 (using BRSP-01) compared to 1.1244 (without BRSP-01). Along the brine line from the LP-Separator to the ORC-15 Outlet, the discharge pressure is 17.32 barg (Pressure saturation is 4.30 bar), and the SSI value decreases by 0.2749% to 1.3460 (using BRSP-02) compared to 1.3497 (without BRSP-02).

1. INTRODUCTION

The Combined Double Flash and Binary system is a advance geothermal energy conversion system that combines double flash and binary conversion systems. The double flash system performs a flashing process or separation of steam and brine from a 2-phase geofluid through two separation stages. The 2-phase geofluid from the production well undergoes the first separation (first flash/separated) using an HP-Separator. The brine from the HP-Separator, which still has a high temperature and contains steam fraction, holds the potential to produce additional steam for the steam expander/turbine. Therefore, the brine undergoes a second separation process using an LP-Separator (second flash/separated). The binary system is a power generation system that uses heat from brine or steam to transfer heat to a working fluid (secondary fluid) using heat exchanger equipment (preheater and evaporator). This process produce vapor from the working fluid, which drives the working fluid expander/turbine to generate electricity.

The 15 MW system in Sorik Marapi using the Combined Double Flash and Binary system, utilizing geofluid from two production wells, Well Production T-01 and T-02. Geofluid from the production wells flows to the HP-Separator for the first flash process. The brine from the HP-Separator is then directed to the LP-Separator for the second flash process, transported using the Brine Reinjection System (BRS) Pump or BRSP at a specific pressure

and flow rate. The BRSP can be controlled by the operator as the pump motor is equipped with a variable frequency drive (VFD), allowing the frequency of the BRSP to be set according to the discharge pressure and system flow rate. After the second flash, the brine from the LP-Separator is not immediately reinjected but instead directed to the Brine ORC (Binary System) or ORC-15. The brine from the LP-Separator still has a high temperature and can be utilized as a heat source for heat transfer with the working fluid in ORC-15. The brine from the LP-Separator is directed to ORC-15 using BRSP-02, with the pressure and flow rate adjusted to match the working pressure and flow rate of ORC-15. Afterward, the brine from ORC-15 flows to the reinjection system line.

From the explanation above, the BRSP plays a crucial role in the operation of the 15 MW Combined Double Flash and Binary system, particularly for the LP-Separator and Brine ORC. This is because the BRSP functions to maintain the pressure and flow rate of brine along the brine line. Therefore, using the BRSP allows optimization of the output from the LP-Separator and Brine ORC by determining the optimal discharge pressure from BRSP-01 and BRSP-02 entering the LP-Separator and Brine ORC. The discharge pressure at the LP-Separator will control the inlet of the LP-Separator, resulting in different steam fraction values for each pressure setting. By optimizing the discharge pressure with BRSP-01, the most optimal steam fraction value can be achieved. An optimal steam fraction will produce an optimal steam rate and ultimately generate the most optimal power from the Steam Expander (SE-07) and Steam ORC (ORC-16). Furthermore, optimizing ORC-15 using BRSP-02 will determine the optimal discharge pressure to achieve optimal power generation from ORC-15. In addition to achieve optimal thermodynamic processes, BRSP optimization also influences the potential for scaling formation in the brine line from the HP-Separator to the LP-Separator (BRSP-01) and the brine line from the LP-Separator to ORC-15 (BRSP-02). Scaling potential in the brine line is affected by the pressure and temperature of the brine line. The brine line temperature will indicate the saturation pressure, where if the pressure line is below the saturation pressure, the brine will have the potential to undergo flashing, increasing silica concentration due to the brine becoming more concentrated and raising the SSI value. Therefore, the pressure line must be maintained above the saturation pressure to keep the brine in a saturated state, reducing the flashing process and minimizing the scaling potential in the brine line. Using the BRSP, the brine line pressure can be stably set above the saturation pressure, reducing the potential for scaling in the brine line.

Optimizing discharge pressure and flow rate using BRSP for the LP-Separator and ORC-15 is crucial for maximizing total power generation and reducing the potential for scaling formation in the brine line, ensuring the entire system operates optimally. Therefore, this paper will explain the optimal BRSP discharge pressure values for optimizing the output of the LP-Separator and Brine ORC using thermodynamic simulation methods. The optimization results will compare the values with and without using BRSP in the 15 MW Combined Double Flash and Binary system at Sorik Marapi.

2. BASIC THEORY

2.1 Double Flash

In this system, two geofluid separation processes are used the HP-Separator and LP-Separator. Additionally, two types of steam expanders/turbines are employed the HP-Steam Expander and the LP-Steam Expander, which are coupled with a single generator.

2.1.1 Steam Fraction Analysis of LP-Separator

The brine from the discharge of the BRSP-01 (6), which still has a hot temperature, will flow to the LP-Separator (7) to extract additional steam from the hot brine that can still be flashed because it still has a steam fraction (x7). The thermodynamic process that occurs in stage 6-7 is isenthalpic, where there is no enthalpy loss in the process. Therefore, the formula for this process is as follows:

$$h_6 = h_7 \quad (1)$$

At the LP-Separator (7), the steam fraction value (x_7) is given by:

$$h_6 = h_{f7} + x_7 . h_{fg7} \quad (2)$$

$$X_7 = (h_6 - h_{f7})/h_{fg7} \quad (3)$$

2.1.2 Steam Rate and Power Generation of LP Steam Expander

Steam rate from LP-Separator can calculate with this equation

$$m_{lps} = (1 - x_2) . x_7 . m_{total} = m_8 \quad (4)$$

And to calculate the brine rate from LP-Separator use this equation

$$m_{lpb} = (1 - x_2) . (1 - x_7) . m_{total} = m_{11} \quad (5)$$

The power output by the two stages is quantified through the mass flow rate, as well as the amount of brine for reinjection and the amount of waste heat from the condenser. The isentropic efficiency and power of the LP-Steam Expander can be expressed in the same way as the single-flash turbine.

$$\eta_{lpt} = (h_9 - h_{10})/(h_{10} - h_{10s}) \quad (6)$$

$$W_{lpt} = m_s \,.\, (h_8 - h_5) = (1 - x_2) \,.\, x_7 \,.\, m_{total} \,.\, \eta_t \,.\, (h_8 - h_{5s}) \quad (7)$$

2.2 Brine Organic Rankine Cycle (ORC)

2.2.1 Heat Transfer

The analysis of the heat exchanger where the geothermal brine transfers some of its thermal energy to the working fluid is another straightforward application of the principles of thermodynamics and mass conservation. Considering the entire package as the thermodynamic system, the governing equation is:

• Brine ORC (Stage a/u – c/w dan Stage 13a/13b – 14a/14b: heat transfer)

$$m_{brine} \,.\, (h_{13a/13b} - h_{14a/14b}) = m_{wf\ exp.1/exp.2} \,.\, (h_{a/u} - h_{c/w}) \quad (8)$$

$$m_{wf\ exp.1/exp.2} = m_{steam}.(h_{13a/13b} - h_{14a/14b})/(h_{a/u} - h_{c/w}) \quad (9)$$

2.2.2 Power Generation

With the usual assumptions of negligible potential and kinetic energy terms, along with steady, adiabatic operation, the power is determined from

• Brine ORC (Stage a/u – b/v: Isentropic)

The brine from BRSP-02 LP-Separator (13) will transfer heat to the working fluid, causing it to undergo a phase change into vapor with high thermal energy content. At this stage, an isentropic process occurs, and the applicable formula is as follows:

$$W_{t\ exp.1/exp.2} = m_{wf} \,.\, (h_{a/u} - h_{b/v}) = m_{wf} \,.\, \eta_t \,.\, (h_{a/u} - h_{b/v}) \quad (10)$$

2.3 Brine Reinjection System (BRS) Pump

The Brine Reinjection System (BRS) Pump, or BRSP, is a centrifugal pump used to pump hot brine from the HP or LP-Separator to the next system. BRSP consists of BRSP-01, which pumps hot brine from the HP-Separator to the LP-Separator, and BRSP-02, which pumps brine from the LP-Separator to the Brine ORC and the reinjection system.

2.3.1 Basic theory of Centrifugal Pump

An increase in the fluid pressure from the pump inlet to its outlet is created when the pump is in operation. This pressure difference drives the fluid through the system or plant. The centrifugal pump creates an increase in pressure by transferring mechanical energy from the motor to the fluid through the rotating impeller. The fluid flows from the inlet to the impeller center and out along its blades. The centrifugal force hereby increases the fluid velocity and also consequently transforming the kinetic energy in to pressure.

2.3.2 Thermodynamics Pump Theory

In the HP-Separator, there are centrifugal pumps named BRSP-01, which function to increase the pressure of brine from the HP-Separator to the LP-Separator. Besides that, centrifugal pump also use to increase pressure of the brine from LP-Separator to Brine ORC using BRSP-02.

2.3.3 Stage 3-6 (BRSP-01: Isentropic) and Stage 11-13 (BRSP-02: Isentropic)

The brine from the HP-Separator (3) enters the suction of the BRSP-01 and then pumped towards the LP-Separator. This Brine Pump functions to pump the hot brine towards the LP-Separator with a controlled pressure and flow rate according to the system's requirements. The enthalpy value of the brine entering the LP-Separator is the enthalpy value at stage 6 (discharge), which is the brine that has been pumped, not the enthalpy value at stage 3 (suction).

The brine from the LP-Separator (11) enters the suction of the BRSP-02 and then be pumped towards the Brine ORC. This Brine Pump's function is to pump the brine to the Brine ORC by increasing the pressure according to the working pressure inlet of the Brine ORC, ensuring that the brine remains saturated and will reducing the potential formation of silica in the Brine ORC, although not significantly. The enthalpy value of the brine entering the Brine ORC is the enthalpy value at stage 13, not the enthalpy value at stage 11.

The definition of pump efficiency is similar to that of a turbine, but the numerator is the isentropic work. Here is the formula to determine the enthalpy value at discharge of the BRSP (6 and 13):

$$h_{6/13} = h_{f3/11} + (h_{6s/13s} - h_{f3/11})/\eta_{BRSP-01/02} \quad (11)$$

The isentropic value of the Brine Pump (6s) can be determined using the following formula:

$$h_{6s/13s} = h_{f3/11} + v_{3/11}(P_{6s/13s} - P_{3/11})$$

Where v3/11 is the specific volume of the brine at the suction of the BRSP-01/02, which can be determined using the density value of the brine.

$$v_{3/11} = 1/\rho_{f3/11} \quad (12)$$

2.4 Scaling Potential in Brine Line

2.4.1 SSI Analysis

The essential parameter in terms of silica deposition is silica saturation index (SSI). SSI is the ratio between the concentration of silica in solution and the solubility of amorphous silica under the same conditions, or if formulated.

$$SSI = concentration\ of\ silica\ in\ solution\ /\ concentration\ solubility\ of\ amorphous\ silica \quad (13)$$

The SSI parameter can be used to estimate the probability of silica scaling as follows:

- If SSI > 1, the fluid is in a supersaturated condition, and silica deposition is possible.
- If SSI = 1, the fluid is in a saturated condition.
- If SSI < 1, the fluid is in an undersaturated condition, thus silica deposition is unlikely to occur

2.4.2 Pressure Saturation and Flashing Process

Geothermal fluids can exist either in liquid or vapor depending on the pressure and temperature conditions affecting them. The fluid remains in a liquid state only at a specific pressure, its temperature is below the boiling point or saturation temperature. The fluid exists in vapor at a specific pressure, its temperature exceeds the boiling point of water or saturation temperature.

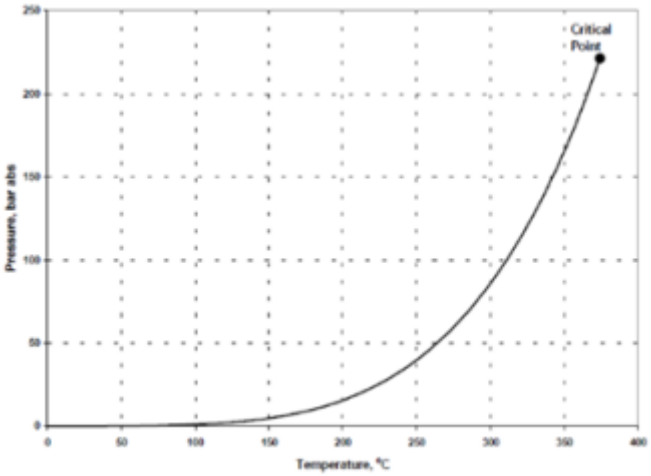

Figure 1: Relationship between Saturation Temperature and Pressure.

The curve in Figure 1 is called the saturation curve. Above the saturation curve, where the temperature is higher than the saturation temperature, only vapor phase exists within the system. In this state, the vapor is called superheated steam. Below the saturation curve, where the temperature is lower than the saturation temperature, only liquid phase exists within the system. In this state, the liquid phase is referred to as compressed liquid.

3. METHODOLOGY

3.1 Working Process

The working process implementation in this paper is as follows:

a. Creating Process Flow Diagram (PFD) and T-S Diagram
b. Data Collection:
   - Steam Field Data (Production Well Data, HP-Separator, BRSP-01, LP-Separator, and BRSP-02)
   - Power Plant Data (SE-07, Steam ORC (ORC-16), and Brine ORC (ORC-5))
   - TFT data (Steam Rate and Brine Rate)

c. Thermodynamics Analysis (Fluid Properties and Heat & Mass Balance)
   - Optimizing using BRSP-01 for LP-Separator and BRSP-02 for Brine ORC
   - Steam field Analysis
   - Power Generation Analysis (SE-07, Steam ORC (ORC-16), and Brine ORC (ORC-16))
   - Pressure saturation analysis
   - SSI Analysis

d. Result Discussion

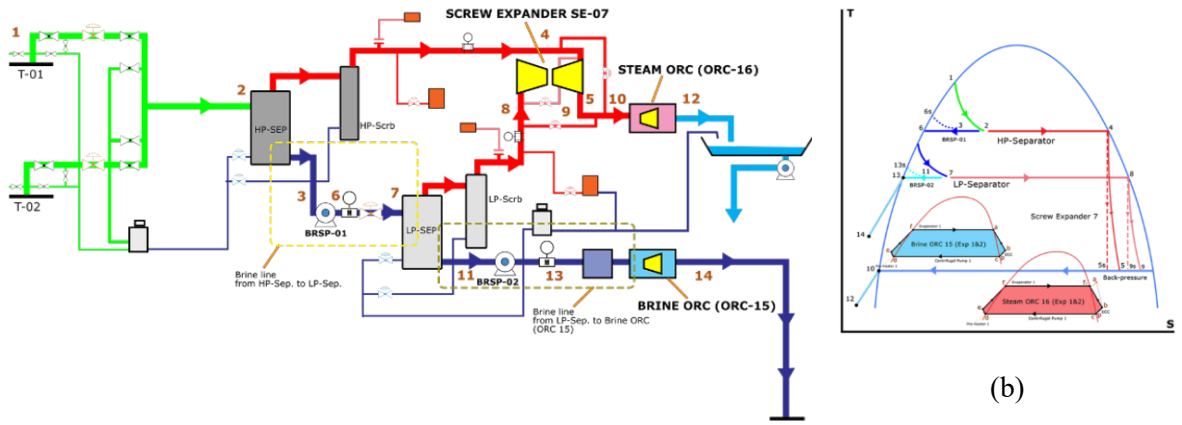
3.2 Thermodynamics Properties

The geofluid from the Production Well is in the form of two-phase steam and brine, the Water Saturated thermodynamics properties are used. In determining thermodynamics properties for steam and brine, the author uses NIST Reference Fluid Thermodynamic and Transport Properties—REFPROP Version 9.1 The working fluid used in Steam ORC and Brine ORC is Refrigerant R245fa, and the thermodynamic properties of R245fa are determined using data from NIST Reference Fluid Thermodynamic and Transport Properties—REFPROP Version 9.1 The air humidity use in Evaporative Cooling Condenser (ECC) Analysis especially Air Cooler, and the thermodynamic properties of Air Humidity are determined using data CoolProp-Version 6.4.1.0.

4. DATA

4.1 Process Flow Diagram (PFD)

4.1.1 Process Flow Diagram of Double Flash



(a) (b)

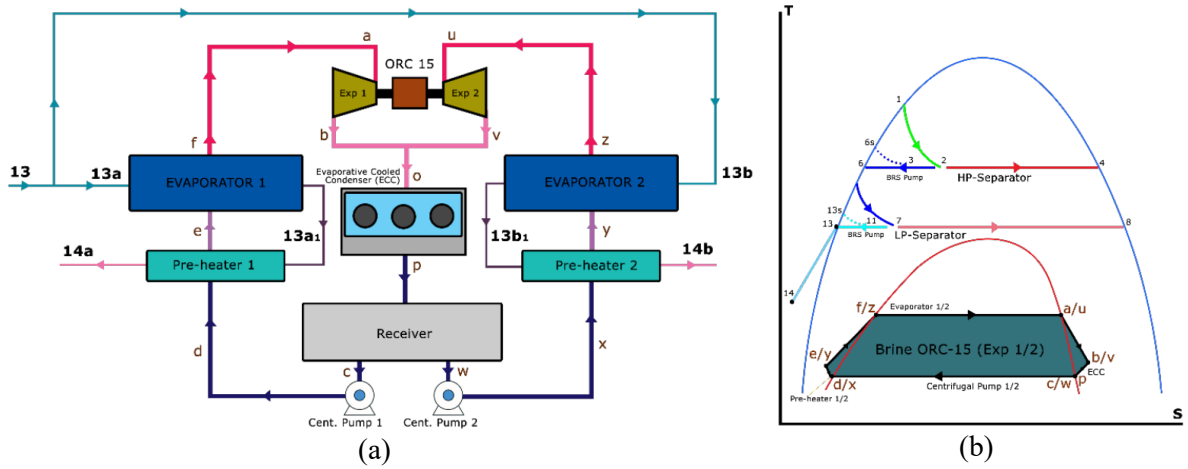
Figure 2: Combined Double Flash and Binary (Steam ORC and Brine ORC): Process Flow Diagram (a) T-S Diagram (b).

(a) (b)

Figure 3: Steam Expander (SE-07) (a) Steam ORC (ORC-16) (b).

Figure 2 illustrates this process starting from the Production Well (1) such as T-01 and T-02, where two-phase geofluid flows to the HP-Separator (2) for steam-brine separation. The steam separated from the HP-Separator and HP-Scrubber (2) will flow to the HP Steam Expander-generator (4) to generate electricity and the brine from the HP-Separator (3) will enter the suction of the BRSP-01 and then pumped towards the LP-Separator (7) for double flash process to extract additional steam from the hot brine that can still be flashed because it still contains a steam fraction (x7). The steam separated from the LP-Separator and LP-Scrubber flows to the LP-Steam Expander to generate electricity again and the brine from the LP-Separator (11) will enter the suction of the BRSP-02 and then pumped towards the Brine ORC (13).

4.1.2 Process Flow Diagram of Brine ORC



(a) (b)

Figure 4: Brine ORC: PFD (a), T-S Diagram (b).

Figure 5: Brine ORC (ORC-15).

Figure 4 illustrates the process where brine discharged from BRSP-02 at the LP-Separator is pumped with a pressure around 17 barg towards the Brine ORC. This brine retains a high temperature value around 145°C and a high enthalpy value (hf), indicating its potential for heat transfer with the working fluid to generate electricity again. There are three main processes: the Brine in ORC-15 process, which is the hot brine pumped by BRSP-02. The second part is the Binary loop Exp-1, which is the binary system for Exp-1 consisting of states a-f, and the third part is the Binary loop Exp-2, which is the binary system for Exp-2 consisting of states u-z. And finally the process will continuesly and make a thermal cycle. For condensing vapor R245fa in ORC-15 using Evaporative Cooled Condenser (ECC) especially Air Cooler.

4.1.3 Process Flow Diagram of BRSP

In Figure 6, it shows a simple process flow diagram of the Brine Reinjection System (BRS) Pump (BRSP) in the 15 MW Combined Double Flash and Binary (Brine ORC) system. Here, the hot brine separated from the HP-Separator flows towards the suction of BRSP-01 (Stage 3), which then pumps it towards the LP-Separator (Stages 6-7) with a specified discharge pressure and flow rate. BRSP-01 functions to pump the hot brine towards the LP-

Separator while controlling the pressure and flow rate using a Variable Frequency Drive (VFD) to adjust the pump frequency and discharge control valve. Before entering the LP-Separator, the inlet pressure to the LP-Separator is controlled by a control valve (CV) to lower the pressure, thereby initiating the second flashing process in the LP-Separator. Subsequently, the brine separated from the LP-Separator flows to the suction of BRSP-02, which then pumps it towards the Brine ORC (ORC-15) (Stages 11-13) and further into the reinjection system. Thus, from the diagram above, there are three types of brine lines: the brine line from the HP-Separator to the LP-Separator, the brine line from the LP-Separator to Brine ORC-15, and the brine line from the Outlet ORC-15 to the reinjection system. BRSP-02 functions to pump the brine to ORC-15 by increasing the

pressure according to the inlet working pressure of ORC-15, ensuring the brine remains in a saturated condition and minimizes the potential formation of silica in the Brine ORC, albeit not significantly. BRSP-02 is essential for increasing the pressure in the line, as the Brine ORC (ORC-15) reduces pressure due to the heat transfer process between the brine and the refrigerant in the heat exchanger (preheater and evaporator). Therefore, BRSP will maintain the pressure in the reinjection system above the saturation pressure.

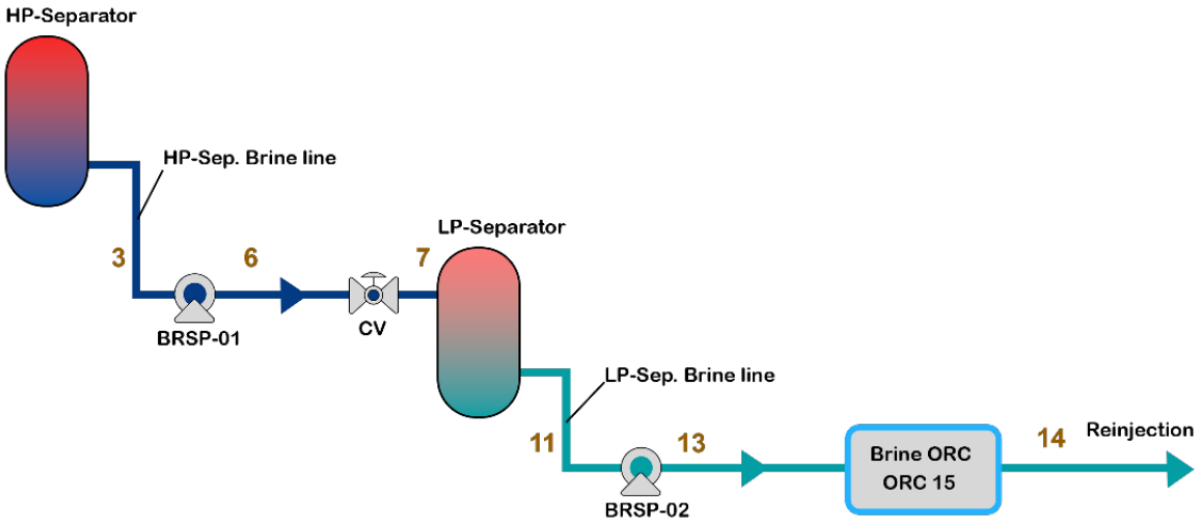


Figure 6: PFD BRSP-01 dan BRSP-02.

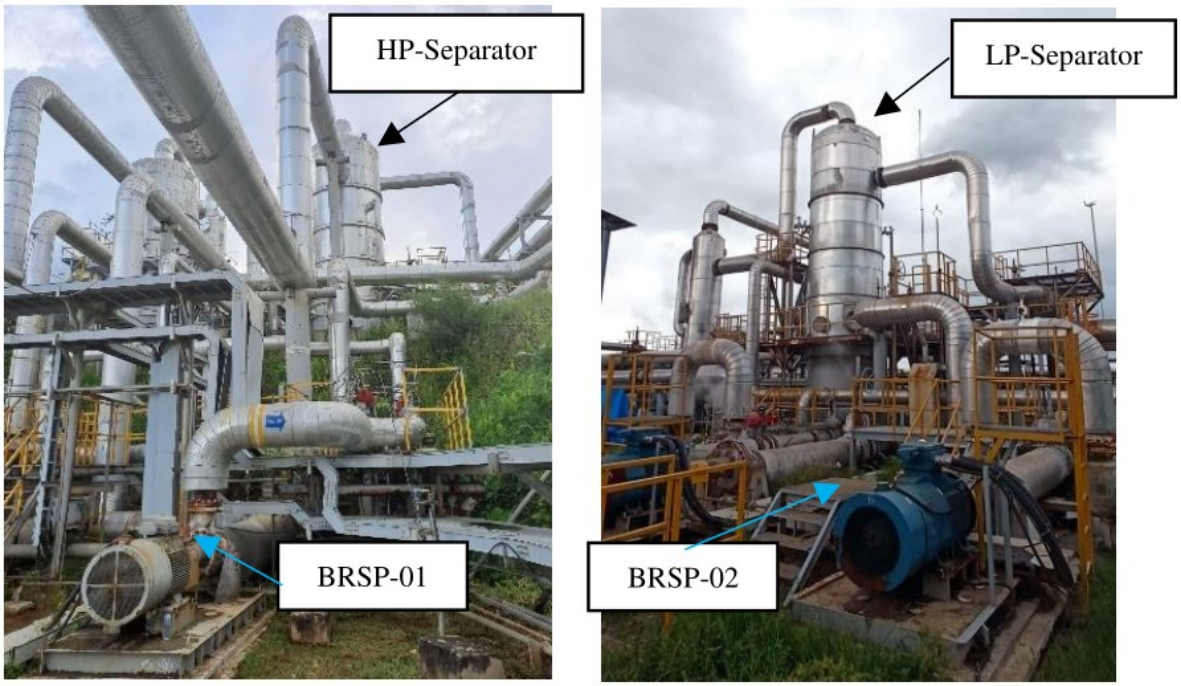

Figure 7: HP-Separator and BRSP-01 (a); LP-Separator and BRSP-02 (b).

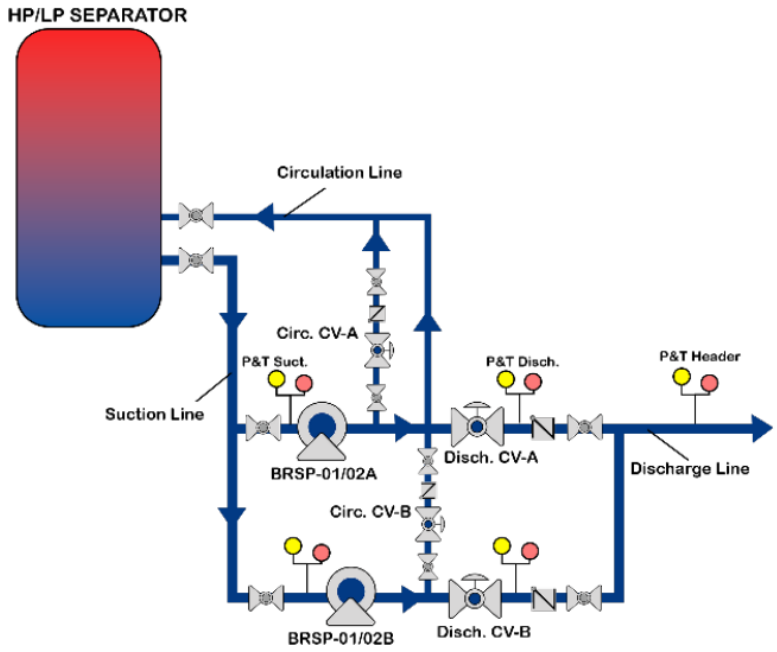

Figure 8: Configuration of the Brine Reinjection System (BRS) Pump (BRSP).

In Figure 8, it illustrates the configuration of the Brine Reinjection System (BRS) Pump equipment. BRSP of The HP and LP-Separators operate in parallel, requiring two BRSP pumps to ensure redundancy: while one BRSP (a) is running, the other BRSP (b) remains on standby. Additionally, in cases where the Brine ORC requires a higher brine consumption and the Brine Reinjection System Pump (BRSP) is operating with insufficient brine flow, a second BRSP will be activated alongside the first to increase the brine rate, thereby meeting the higher brine consumption demands of the Brine ORC. This setup allows for seamless backup in case of issues with one BRSP, facilitating maintenance without disrupting the system. Additionally, there are three main lines in the BRSP: the suction line, discharge line, and circulation line. The suction line transports brine from the HP/LP-Separator to the suction of BRSP-01/BRSP-02. The discharge line serves as the brine discharge line from the BRSP, pumping brine to either the LP-Separator or Brine ORC system. The circulation line pumps brine back to the HP/LP Separator under certain process conditions, such as during separator level decreases or during BRSP changeovers. To control brine flow within the BRSP system, control valves (CVs) are employed, namely the Discharge CV and Circulation CV. These CVs facilitate easy changeover of BRSP operations by operators. Moreover, to prevent backflow during BRSP changeovers, check valves are installed in the discharge and circulation lines. For monitoring operational parameters, Pressure and Temperature transmitters are integrated into the BRSP system.

4.2 Operation Data

The data processed for calculations in this paper is the actual operational data based on Fluid Collection and Reinjection (FCRS) data in August 2022. The FCRS data are shown in Table 1, 2, and 3. The specification and operation data of BRSP are shown in Table 4, 5, and 6.

5. RESULT

5.1 Heat and Mass Balance of LP Separator, Brine ORC and BRSP

Table 7 shows the Heat and Mass balance and SSI analysis of the brine line system from HP-Separator to LP-Separator, brine line from LP-Separator to ORC-15, and brine line from Outlet ORC-15 to the reinjection system.

Table 7 shows that stage 6 represents brine entering the LP-Separator using BRSP-01 with a discharge pressure of 9.94 bar, a temperature of 162.76 ℃, and a brine rate of 112.83 kg/s. The brine enthalpy entering the LP-Separator is 687.65 kJ/kg (stage 6). By comparing stage 6 with stage 3 as the suction of BRSP-01, it can be seen that the enthalpy value of stage 6 is higher than stage 3 (687.22 kJ/kg). This is due to the increased discharge pressure of BRSP-01. For the brine line from the LP-Separator to ORC-15, there is also a difference between stage 11 and stage 13. At stage 11, as the brine suction of BRSP-02, the discharge pressure is 4.79 bar, the temperature is 146.30 ℃ with 616.23 kJ/kg brine enthalpy value. At stage 13, as the brine discharge of BRSP-02, the discharge pressure is 18.32 bar, the temperature is 146.58 ℃, and the brine rate is 109.32 kg/s. The brine rate of the LP-Separator is lower compared to the HP-Separator because part of the steam content from the HP-Separator brine rate has been separated, thus reducing the brine rate flowing to ORC-15. The enthalpy value entering ORC-15 as

the heat source for heat transfer is 618.33 kJ/kg (stage 13). This enthalpy is used by ORC-15 to heat the working fluid, which is the R245fa refrigerant. Meanwhile, the temperature of the brine line, after its heat has been utilized by ORC-15, will drop to 72.39 ℃ with a pressure of 8.80 bar and a brine enthalpy of 303.10 kJ/kg.

5.2 Optimizing Using Brine Reinjection System (BRS) Pumpa (BRSP)

5.2.1 Optimizing BRSP-01

The optimization of BRSP-01 involves optimizing the discharge pressure of BRSP-01 at the HP-Separator so that the inlet pressure before the CV LP-Separator operates around 9-10 barg. With such discharge pressure and CV LP inlet pressure, the brine enthalpy value at the inlet of the LP-Separator will increase due to the increased discharge pressure. Therefore, based on thermodynamic calculations, BRSP-01 can enhance the steam fraction in the LP-Separator.

a. Optimization of LP-Separator

Figure 9 shows that by optimally operating the discharge pressure of BRSP-01 for the inlet pressure before the CV LP-Separator with a recommended pressure of 9.94 bar, the steam fraction will increase from 3.08753% (with a BRSP-01 suction pressure of 7.19 bar) to 3.10800%, or an increase of 0.66299%. The increase in steam fraction means that the steam rate produced by the LP-Separator ill increase from 3.4836 kg/s (12.5412 t/h) to 3.5067 kg/s

(12.6243 t/h), or an increase of 0.0831 t/h. The results of this optimization calculation are very feasible to apply, as the current operating system still has potential for further optimization, considering that the BRSP-01 specification can operate at a pressure of 4 MPa (40 bar) and the working pressure of the LP-Separator is 1.1 MPa (11 bar). Although the output of the LP-Separator does not increase significantly, with this discharge pressure, the BRSP-01 and LP-Separator can operate optimally according to equipment specifications. This increase in steam rate will cause the brine rate of the LP-Separator to decrease from 100.2889 kg/s (361.0397 t/h) to 100.2058 kg/s (360.7405 t/h). This is because, with a higher discharge pressure, the steam flashing from the brine will increase, resulting in a lower brine rate entering ORC-15 compared to the brine rate of the HP-Separator.

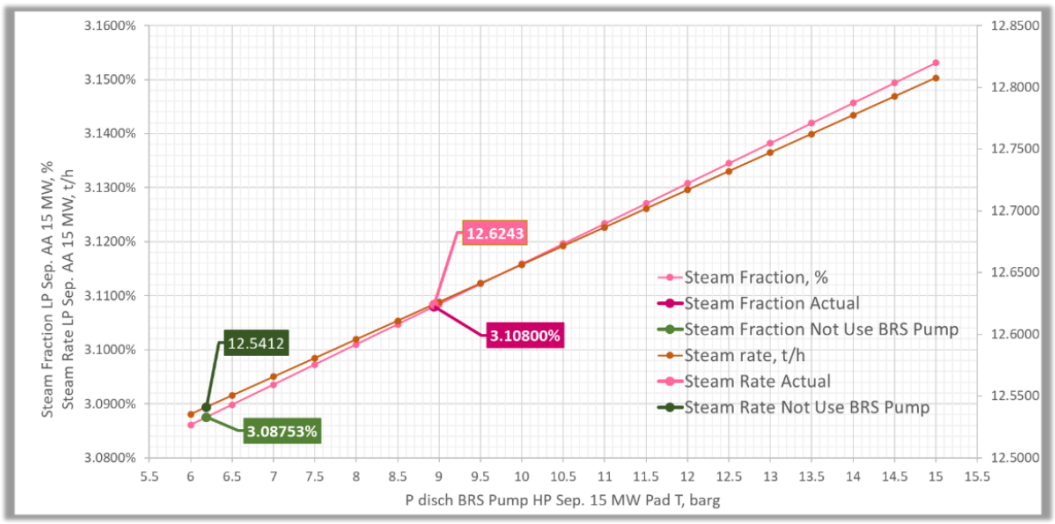

Figure 9: Optimizing BRSP-01: Steam Fraction and Steam Rate Analysis of LP-Separator.

b. Optimization of Power Generation

With the increase in steam fraction from the LP-Separator, the power generation from Steam Expander-07, Steam ORC (ORC-16), and Brine ORC (ORC-15) will change. This can be seen from the graph results in Figure 10. SE-7 will increase from 5427.6233 kW to 5430.9453 kW (an increase of 0.0612% or 3.3320 kW), resulting in an increase in Thermal Efficiency from 4.21485% to 4.21743% and Utilization Efficiency from 14.61649% to 14.62544%. Meanwhile, the power generation of ORC-15 will decrease from 1410.0154 kW to 1409.7176 Kw (a decrease of 0.0211% or 0.2987 kW), resulting in a Thermal Efficiency of Brine ORC of 4.1016% and a Utilization Efficiency of 15.2697%. As for the power generation of ORC-16, it will increase from 4621.6787 kW to 4625.5815 kW (an increase of 0.0844% or 3.9028 kW), resulting in a Thermal Efficiency of Steam ORC of

5.4199% and a Utilization Efficiency of 71.0551%. From the results, an increase in steam fraction will lead to higher power generation in both the Steam Expander (SE-07) and the Steam ORC (ORC-16) due to the increased steam supply rate. However, this increase in steam rate will result in a decrease in the brine rate, thereby reducing the brine supply to the Brine ORC (ORC-15) and consequently lowering its power generation. The changes in power generation will directly affect the thermal efficiency and utilization efficiency. As power generation increases, both thermal efficiency and utilization efficiency will rise, and vice versa.

c. Pressure Saturation Analysis of Brine Line

With optimal discharge pressure, the brine will become more saturated and can reduce the flashing process along the brine line due to pressure loss along the pipe. This can decrease the silica concentration and the SSI value.

The saturation pressure of the brine line from the HP-Separator to the LP-Separator is 6.63 bar with a brine line temperature of 162.76 ℃, and the operating pressure of BRSP-01 is 9.94 bar. Based on the graph in Figure 11, the operating pressure of BRSP-01 will operate at a pressure above the saturation pressure, thus keeping the brine in a saturated condition. However, if the operating pressure of the brine line falls below the saturation pressure, flashing will occur in the brine, making it more concentrated due to the steam flashing out from the brine. This will cause the silica concentration and SSI to increase, especially since the brine line will experience pressure loss along the line. Therefore, the brine line pressure must be maintained above the saturation pressure using BRSP-01. If the brine line pressure suddenly drops below the saturation pressure, hammering will occur. This happens due to the sudden flashing of the brine. The subsequent hammering effect is very dangerous as it can damage the brine line facilities.

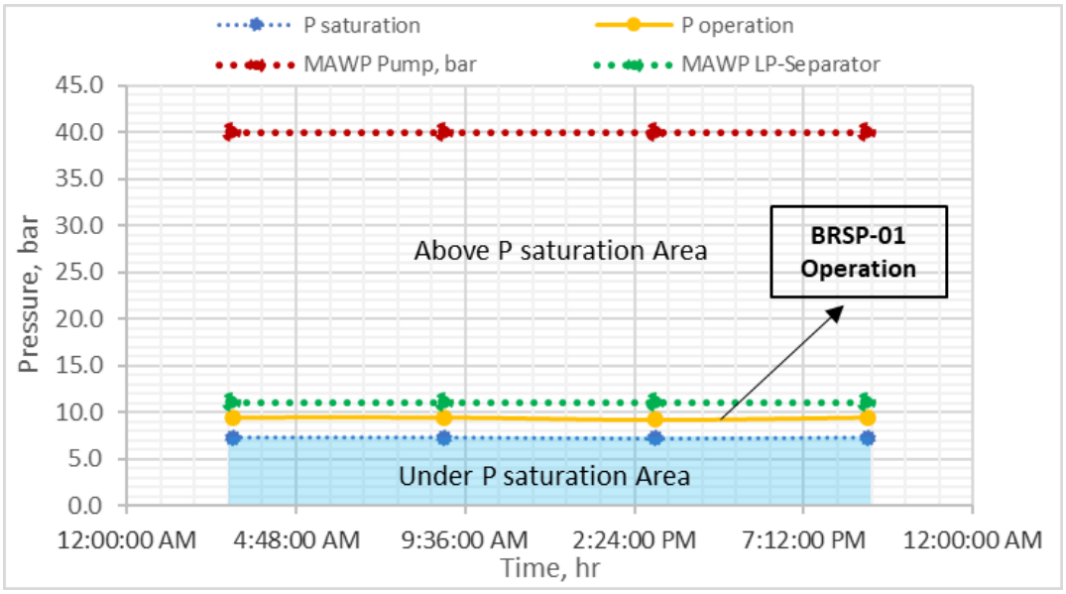

Figure 11: Optimizing BRSP-01: Pressure Saturation Analysis.

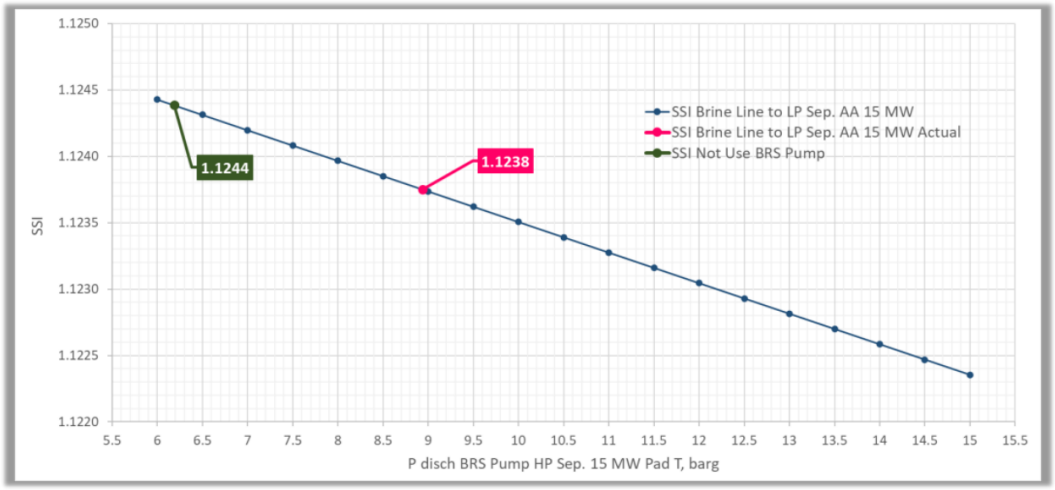

Figure 12: SSI Analysis of Brine Line from HP-Separator to LP-Separator.

d. SSI Analysis

The SSI analysis of the brine line from the HP-Separator to the LP-Separator is shown in Figure 12. In Figure 12, it is shown that with a discharge pressure of BRSP-01 of 8.94 barg, the SSI value decreases from 1.1244 without BRSP-01 (with a BRSP-01 suction pressure of 6.19 barg) to 1.1238, a decrease of 0.0006 (0.0534% decrease). This decrease in SSI is due to the increased discharge pressure, which leads to an increase in brine enthalpy. With the increase in brine enthalpy, the temperature rises from 162.10 ℃ to 162.76 ℃. Additionally, one of the factors influencing silica concentration is temperature; higher temperatures result in higher silica concentration calculations (Amorphous Silica Index). Thus, compared to the silica concentration sample (Silica Solution), the SSI value decreases. Conversely, if the brine line temperature decreases, the SSI value increases, and the potential for scaling also increases. Despite the optimization of BRSP-01 resulting in a slight decrease in the SSI value, it can still significantly reduce the potential for scaling along the brine line, considering the pressure loss from the HP-Separator to the LP-Separator. With BRSP-01, the SSI value in the brine line remains stable (does not increase) due to reduced pressure loss, thereby reducing the potential for scaling in the brine line.

5.2.2 Optimizing BRSP-02

BRSP-02 Optimization involves optimizing the discharge pressure of BRSP-02 at the LP-Separator so that the inlet pressure of Brine ORC (ORC-15) can operate around 17-19 barg. With this discharge pressure and ORC-15 inlet pressure, it will increase the brine enthalpy value at the inlet of ORC-15 as a heat source due to the increased inlet pressure. This, in thermodynamic and heat transfer calculations, can enhance the power generation of ORC-15.

a. Optimization of Power Generation

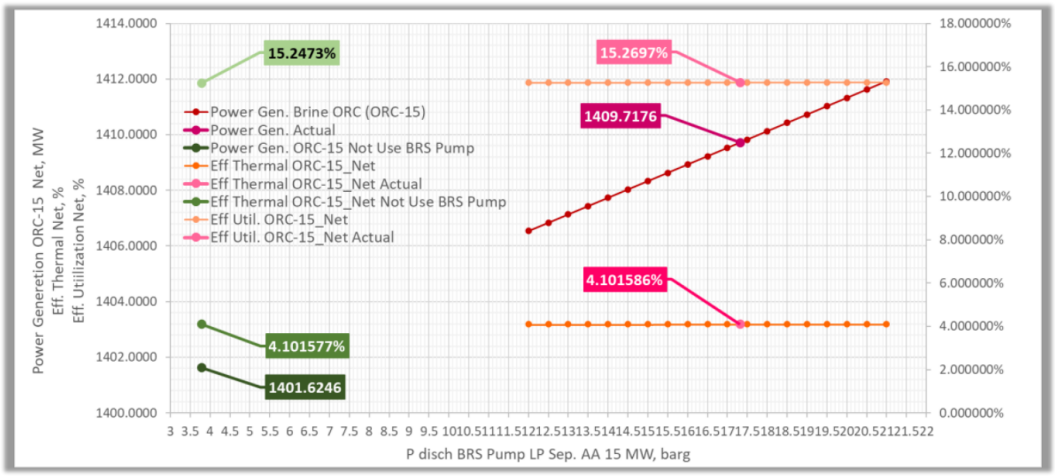

Figure 13: Optimizing BRSP-02: Power Generation ORC-15.

With the optimization of BRSP-02, the power generation of ORC-15 will increase by approximately 0.5574%, from 1401.6246 kW to 1409.7176 kW (Figure 13), an increase of 8.0930 kW. This results in the Thermal Efficiency of Brine ORC increasing from 4.101577% to 4.101586% and the Utilization Efficiency increasing from 15.2473% to 15.2697%. With BRSP-02 optimization, it is possible to maintain stable power generation of ORC-15 despite a decrease in brine rate due to the increased steam fraction from the LP-Separator after the previous optimization of BRSP-01. This optimization calculation shows promising application potential because BRSP-02 is not yet operating optimally, given its MAWP of 3 MPa (30 bar) and the working pressure inlet of ORC-15 at 2 MPa (20 bar). These specifications indicate that there is still room to optimize the processes of BRSP-02 and ORC-15 according to their respective working pressures.

b. Pressure Saturation Analysis of Brine Line

The saturation pressure of the brine line from the HP-Separator to the LP-Separator is 4.34 bar with a line temperature of 146.58 ℃, while the operating pressure using BRSP-02 is 18.32 bar. With this operating pressure, according to Figure 14, the pressure is above the saturation pressure, meaning the brine is in a saturated condition, thereby preventing flashing of the brine before it enters ORC-15. If flashing occurs in the brine before entering ORC-15, the brine will become more concentrated due to the steam released from the brine, leading to an increase in silica concentration and SSI values. Additionally, the heat transfer processes in the preheater and evaporator of ORC-15 will reduce the pressure and temperature of the brine line, further increasing silica concentration and SSI values after exiting ORC-15. Therefore, to minimize scaling formation in the preheater and evaporator, the inlet pressure of ORC-15 must be maintained above the saturation pressure so that silica concentration does not increase

before entering ORC-15. Meanwhile, the saturation pressure of the brine line from the outlet of ORC-15 to the reinjection system is 0.35 bar with a line temperature of 72.39 ℃, and the operating pressure is 8.8 bar. With this operating pressure, the pressure is above the saturation pressure, ensuring the brine remains in a saturated condition.

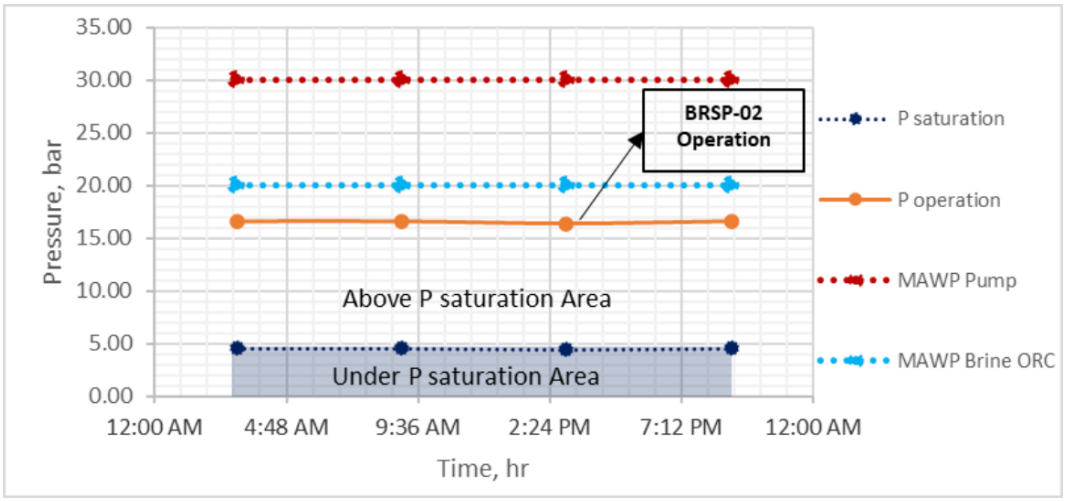

Figure 14: Optimizing BRSP-02: Pressure Saturation Analysis.

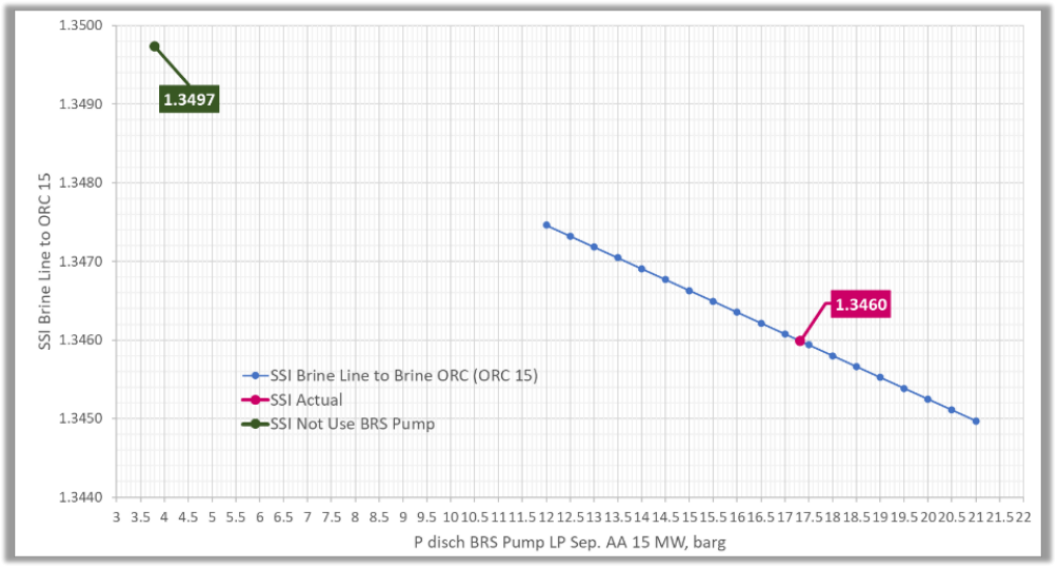

Figure 15: SSI Analysis of Brine Line from LP-Separator to Brine ORC (ORC-15).

c. SSI Analysis

The SSI value on the brine line from the LP-Separator to ORC-15 is 1.3497, which is higher compared to the SSI value on the brine line from the HP-Separator to the LP-Separator, which is 1.124. This is because the brine rate from the LP-Separator is lower compared to the brine rate from the HP-Separator due to the steam being flashed back by the LP-Separator. Additionally, the temperature of the brine line with BRSP-02 is lower compared to the temperature with BRSP-01, at 146.58 ℃ compared to 162.10 ℃ (BRSP-01). This lower brine rate and temperature will cause the brine to become more concentrated, leading to a higher silica concentration and consequently increasing the SSI value compared to BRSP-01.

With BRSP-02 optimization, it can maintain the SSI value of the brine line stable and prevent it from increasing. In Figure 15, it shows that with a BRSP-02 discharge pressure of 17.32 barg, it will reduce the SSI value from 1.3497 with the brine line pressure without BRSP-02 (BRSP-02 suction pressure) of 3.79 barg to 1.3460, or a decrease of about 0.0037 (a decrease of 0.2749%). The temperature rises from 146.30 ℃ to 146.58 ℃. Although this reduction in SSI value is not very significant, it can still reduce the potential for scaling formation both in the brine line at the ORC-15 inlet and in the loop heat exchanger pipes (pre-heater and evaporator). Once the brine has absorbed its heat, the pressure and temperature of the ORC-15 outlet towards the brine line reinjection system

will decrease to 8.80 barg and 72.39 ℃. With this decrease in temperature, the SSI value will increase compared to the ORC-15 brine line. Therefore, BRSP-02 plays a crucial role in maintaining the brine line pressure above saturation pressure to prevent an increase in SSI values in the brine line reinjection system.

5. DISCUSSION

Optimizing the Brine Reinjection System (BRS) Pump (BRSP) can enhance the total power generation generated by the 15 MW Combined Double Flash and Binary System. Additionally, maintaining the brine line pressure above saturation pressure can minimize the potential for scaling formation. BRSP-01 is a pump designed to transfer brine from the HP-Separator to the LP-Separator at a specific discharge pressure. Optimizing BRSP-01 will impact the total power generation of the combined SE-07 power generation, Steam ORC (ORC-16), and Brine ORC (ORC-15).

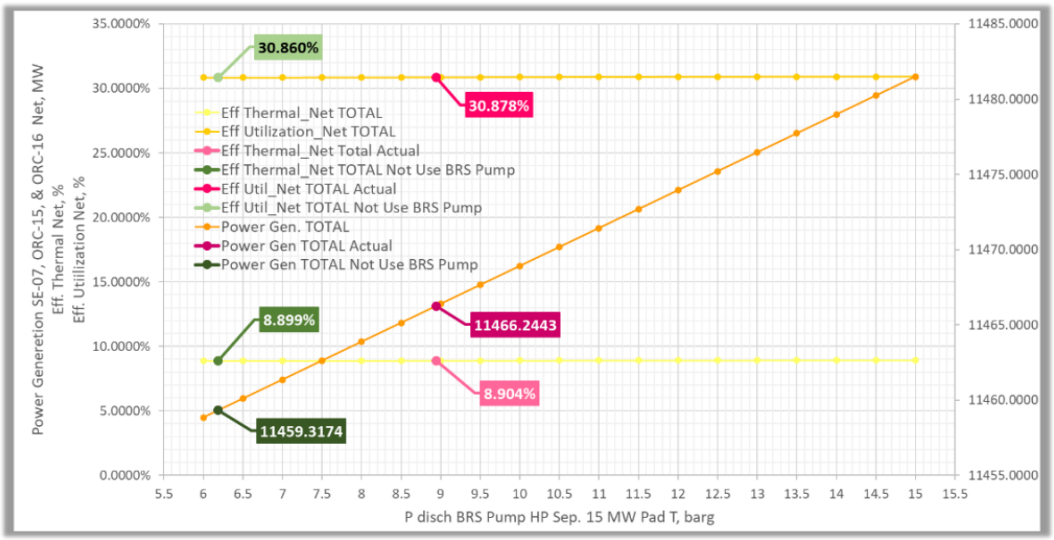

Figure 16: Optimizing BRSP-01: Total Power Generation of SE-07, ORC-15, and ORC-16.

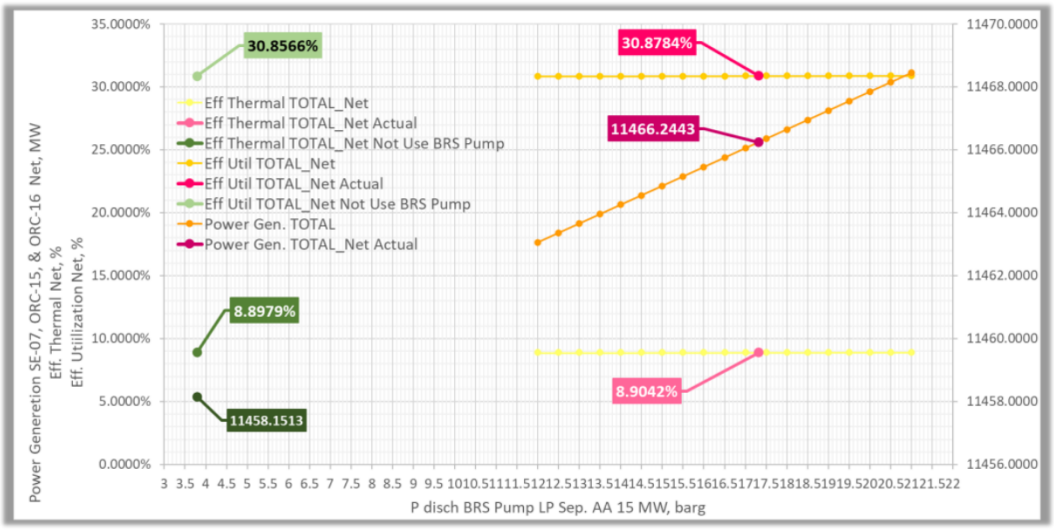

Figure 17: Optimizing BRSP-02: Total Power Generation of SE-07, ORC-15, and ORC-16.

Based on Figure 16, the differences in total power generation, thermal efficiency, and utilization efficiency can be observed between operation pressures without BRSP-01 and with BRSP-01. Using BRSP-01 at an operation pressure of 8.94 barg results in a total power generation of 11466.2443 kW. This value is higher compared to operating without BRSP-01, which yields 11459.3174 kW. The increase in total power generation with BRSP-01 compared to without BRSP-01 is 0.0604% or approximately 6.9269 kW. With the increase in total power generation, the total thermal efficiency will also rise from 8.899% to 8.904%. Similarly, the total utilization efficiency will increase from 30.860% to 30.878%. Although the increase in total power generation with a discharge pressure of 8.94 barg is not significant, the discharge pressure can still be increased since the maximum

working pressure before the CV LP-Separator is 11 barg, indicating further optimization potential with a higher discharge pressure from BRSP-01 to achieve greater total power generation.

In addition to optimize BRSP-01, this system also needs to be optimized with BRSP-02. Because as the steam fraction from the LP-Separator increases, the brine rate from BRSP-02 will decrease. Based on Figure 17. Above, the differences in total power generation, thermal efficiency, and utilization efficiency can be observed between operation pressures without BRSP-02 and with BRSP-02. Using BRSP-02 at an operation pressure of 17.32 barg results in a total power generation of 11466.2443 kW. This value is higher compared to operating without BRSP-02, which yields 11458.1513 kW, an increase of approximately 8.0930 kW. The increase in total power generation with BRSP-02 compared to without BRSP-02 is 0.0703%. With the increase in total power generation, the total thermal efficiency will also rise from 8.8979% to 8.904%. Similarly, the utilization efficiency will increase from 30.8566% to 30.8784%. Although the increase in total power generation is not significantly with a discharge pressure of 8.94 barg, the discharge pressure can still be increased since the maximum working pressure inlet Brine ORC (ORC-15) is 20 barg.

In addition to influence total power generation, the optimization of BRSP-01 and BRSP-02 can also minimize scaling potential in the brine line from HP-Separator to LP-Separator, from LP-Separator to Brine ORC (ORC-15), and from the outlet of ORC-15 to the reinjection system.

Figure 18 shows the SSI values for each brine line in this system. The SSI value for the brine line from HP-Separator to LP-Separator using BRSP-01 is 1.1238 with a temperature of 162.76 ℃. This value is lower compared to not using BRSP-01, which is 1.1243 with a temperature of 162.70 ℃. Next, the SSI value for the brine line from LP-Separator to ORC-15 using BRSP-02 is 1.3460 with a temperature of 146.58 ℃. This value is lower compared to not using BRSP-02, which is 1.3496 with a temperature of 146.30 ℃. Meanwhile, the SSI value for the brine line from the outlet of ORC-15 to the reinjection system is 3.1862 with a temperature of 72.39 ℃. With SSI values above 1 for each brine line, scaling potential remains present. Optimizing BRSP is not significantly the primary method to prevent scaling formation, but BRSP functions to maintain the brine line in a saturated condition so that scaling potential does not increase due to pressure and temperature drops along the brine line. To effectively prevent scaling in the brine line, the optimal method currently is to maintain the brine line temperature above 180 ℃. At this temperature, the SSI value would be < 1 or within the no scaling potential area. However, because the 15 MW system uses a Combined Double Flash and Binary conversion system where the heat from brine is maximally utilized for electricity generation, it causes the brine line temperature to remain low (<100 ℃). The lower the Brine ORC outlet temperature, the greater the power generation obtained. This means that more heat from the brine is transferred to the working fluid, which will increase the SSI value to greater than 1, and the potential for scaling formation becomes higher. With this conversion system, increasing the brine line temperature by more than 100 ℃ is challenging. If the outlet temperature of Brine ORC increases, it indicates suboptimal heat transfer, resulting in decreased power generation of Brine ORC and potential issues such as scaling in the loop pipe heat exchangers (pre-heater and evaporator). Therefore, the most effective current method to prevent scaling in the brine line is to use additional chemical treatment such as scale inhibitors injected into the brine line before entering LP-Separator and Brine ORC.

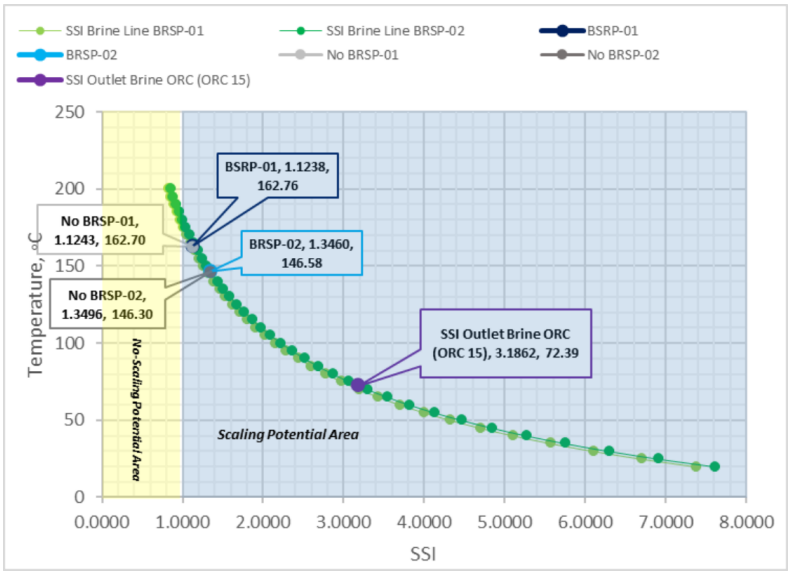

Figure 18: Optimizing BRSP-01 and BRSP-02: SSI Analysis.

6. CONCLUSION

The conclusions in this paper are as follows:

1. By optimizing BRSP-01, the brine enthalpy discharge value will increase based on the increase in discharge pressure, from 687.22 kJ/kg (P suct: 6.19 barg) to 687.65 kJ/kg (P disch: 8.94 barg). Meanwhile, the brine enthalpy value for BRSP-02 optimization increases from 616.23 kJ/kg (P suct: 3.79 barg) to 618.33 kJ/kg (P disch: 17.32 barg).
2. The steam fraction produced by the LP-Separator will increase from 3.08753% to 3.10800% using BRSP-01. Thus, the steam rate of the LP-Separator increase from 3.4836 kg/s (12.5412 t/h) to 3.5067 kg/s (12.6243 t/h), and the brine rate decrease from 100.2889 kg/s (361.0397 t/h) to 100.2058 kg/s (360.7405 t/h).
3. Total power generation will increase from 11459.3174 kW to 11466.2443 kW (a 0.0604% increase) with BRSP-01 optimization, while with BRSP-02 optimization, ORC-15 power generation will increase from 1401.6246 kW to 1409.7176 kW (a 0.5574% increase), resulting in total power generation increasing from 11458.1513 kW to 11466.2443 kW (a 0.0703% increase).
4. The saturation pressure of the brine line from HP-Separator to LP-Separator is 6.63 bara (Temperature: 162.76 ℃) with BRSP-01 operating pressure at 9.94 bara, while the saturation pressure of the brine line from LP-Separator to Brine ORC is 4.34 bara (Temperature: 146.58 ℃) with BRSP-02 operating pressure at 18.32 bara, and the saturation pressure of the brine line outlet from Brine ORC to the reinjection system is 0.35 bara (Temperature: 72.39 ℃) with reinjection system operating pressure at 8.8 bara.
5. The SSI value for the brine line from HP-Separator to LP-Separator decrease by 0.0534%, from 1.1244 (without BRSP-01) to 1.1238 (using BRSP-01) with temperature at 162.76 ℃, while the SSI value for the brine line from LP-Separator to ORC-15 decrease by 0.2749%, from 1.3497 (without BRSP-02) to 1.3460 (using BRSP-02) with temperature at 146.58 ℃, and the SSI value for the brine line from ORC-15 to reinjection system increase to 3.1862 due to the outlet temperature dropping to 72.39℃.
6. Optimizing BRSP-01 and BRSP-02 will increase the steam fraction and total power generation, albeit not significantly. By optimizing the discharge pressure, BRSP-01 and BRSP-02 operation can be optimized, enhancing the output of the LP-Separator and Brine ORC. Meanwhile, the SSI values will decrease, albeit not significantly, as BRSP helps maintain pressure above saturation and prevents SSI values from rising due to pressure and temperature drops along the brine line.

ACKNOWLEDGEMENT

The author would like to express sincere gratitude to Mr. Richard Alexander for his generous support throughout the research process and for his invaluable guidance, expertise, and contributions to this paper.

ABSTRACT

The Indonesian government continues to set optimistic targets for Geothermal expansion in terms of capacity and ratio of geothermal to electrical energy sources, while the reality remains lower than the aim. The absence of geothermal exploration is not due to a scarcity of new opportunities; there are plenty of fresh prospects waiting to be explored, but rather is due to longer time and higher expense. In the most cases, the time and cost efficiency of new prospect investigation is still a big challenge, with exploration taking more than 6 years and resulting in substantial costs, making the project's economics less appealing. Exploration drilling is a crucial activity that has contributed to inefficiency in terms of time and expense; it is a complicated issue, and the Indonesia market has yet to develop a best practice to address the challenge of effective and efficient exploration drilling. In theory, slim-core hole drilling is one of the best methods for conducting effective and efficient exploration drilling because it is a compact operation that requires very little preparation and support, it can provide the most critical information for reserve confirmation, and it has the lowest cost impact to get out of the concession. However, in the case of recent exploration drilling, the drilling time is significantly longer than the target time, the actual cost exceeds the budget, and the success ratio is low in comparison to the objectives, and as a result, Indonesia geothermal practitioners are beginning to question the use of slim-core hole drilling exploration solutions. This paper, based on the author's and the exploration drilling team's direct experience with one of the most recent slim-hole exploration drillings in Indonesia, will attempt to share the best practices and lessons learned, as well as insight into coring activity and improvement plan to increase the probability of success. By implementing the best practices and mitigating lessons learned, the success ratio of slim-core hole to meet the objectives will increase. Based on the recent slim hole drilling, most of them were targeting in the range of 60 days of drilling time and approximately USD 1.2 million in drilling costs, which have a good chance of being met if the best practices and lessons learned are implemented. The combination of the improvement plan and learning curve reduction strategy may result in the slim-core hole being more effective and efficient, the drilling days less than 60 days and the drilling cost less than USD 1 million can be easily accomplished. With the historical of slim-core hole drilling in Indonesia, it is not an invention, it only requires innovation to become a viable option.

1. INTRODUCTION

1.1 Indonesia Geothermal Exploration

Geothermal exploration continues to be significantly lower than the expected target, resulting in new geothermal in term of the number and capacity are not achieved. The exploration took longer time for the execution and most of them have a longer an idle time in between the stages that's impacted to the project economic, there are a lot an invisible and indirect cost keep piled up during the slow progress, and with the idle time will delay the return of the investment if the project is feasible and decided to be continued to the development stage, if the project is not feasible, the idle time will extend the sunk cost duration and it has huge concern for the investor on their investment. A longer time for the investment return combined with the uncertainty of possible total investment cost are a big concern for the investor to enter the geothermal market, or to continue and add their investment in geothermal industry.

The reserve confirmation is the exploration aim, refer to SNI 6009 – 2017 in Figure 1, the process will start with speculative and hypothetic study and then follow with reserve assessment to identify a possible reserve, to simulate a probable reserve and to calculate a proven reserve.

Figure 2 illustrates an example of geothermal exploration with prolonged execution process. It took more than twenty (20) years to complete the reserve confirmation, starting with an early study for project financing, followed by a geoscience study, and ending with initial and additional exploratory drilling. And the latest status of this concession is waiting for development execution. if just reflecting to this case and there isn't an innovation to

bring the process become time effective and cost efficient, and then Indonesian geothermal growth always behind the expected.

GEOTHERMAL RESERVE CONFIRMATION (REF SNI 6009-2017)

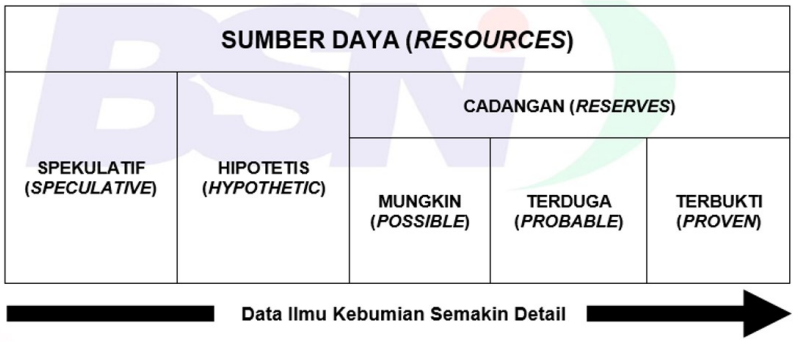

Figure 1: Geothermal reserve confirmation (Ref SNI 6009-2017).

CASE EXAMPLE – EXPLORATION PREPARATION TO EXECUTION

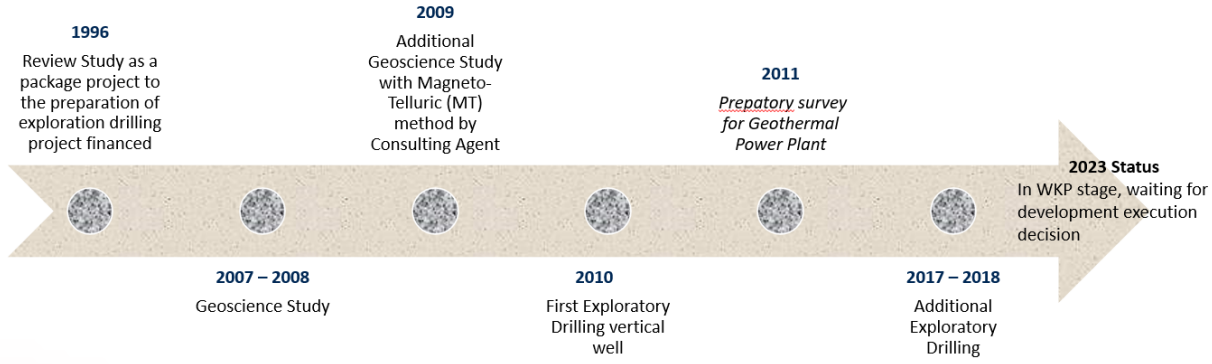

Figure 2: An example of geothermal exploration with prolonged execution process.

The innovation to bring the efficiency with an effective exploration should be able to demonstrate the reserve, to get as much sub surface information as feasible, the probable reserve in a timely and cost-effective manner, and reduce the cost impact to get out of the concession.

Given that exploration drilling is the ultimate activity for reserve confirmation in geothermal projects, it's crucial to adopt options that ensure cost efficiency, time effectiveness, and provide key information for reserve confirmation. Using slim-core hole drilling, in the theory, can a viable option for exploration drilling, offering a less expensive, compact, and lean approach to gather initial subsurface data and confirm the reserve.

1.1 Indonesia Geothermal slim-core hole historical performance

A slim-core hole is not a something new for Indonesia Geothermal exploration as illustrated in Figure 3 for the historical summary, back to the early state of Indonesia geothermal Industry in between 1994 – 1998, two (2) big geothermal fields in Indonesia, Sarulla and Darajat had performed slim-core hole exploration drilling campaign with a good result in term of performance and reserve confirmation. In Sarulla, in between approximately 1994 until 1997, from nine (9) exploration wells were drilled, Six (6) were slim-core hole wells with three (3) of them were deviated well. With the limited information of those wells, and only having the final well schematic from the old well report, so there is no information about the days and cost, however there is an interesting information for the well depths were in the range 6662 ftMD or 2029 mMD to 8000 ftMD or 2436 mMD which are deeper than the target depth of all exploration wells that's recently drilled and planned to drill.

Darajat has a good documentation on the slim-core hole drilling performance, referred to riza et all, proceeding 20th NZ Geothermal Workshop 1998 publicity, within two years, six (6) slim-core holes successfully drilled with a good performance to meet the objectives. The project was very successful obtaining a valuable sub surface information to answer the probable reserve in a timely and cost-effective manner and adopted the best practices from other previous project in Sarulla to reduce the learning curve while keep continuing capture the best practices and lesson learned to improve the learning curve. The well depths were in the range of 4402 ftMD or 1340 mMD and 7578 ftMD or 2308 mMD, with the average drilling time was 61 days includes with two wells were experienced the stuck pipe and sidetracked. The program was started with DRJ S1 drilling, the drilling was

completed in 51 days for 4402 ftMD and 1,340 mMD, it was a good starting for the first well that's revealed the project team capability to manage the learning curve, on the next well the performance continuously improved, the number of drilling days is improved along with the well depth deeper, even for two wells that experienced with stuck pipe and end up with sidetrack, it's indicated the team had significant lesson learned on the second event, the decision to solve the problem more faster and efficient in the second well if compare than the first well, in DRJ S-2 the total drilling days was 85 days to drilled 4730 ftMD or 1441 mMD with number days for the stuck pipe event and sidetracking about 13.3 days, whilst in DRJ S-6 the total drilling days was 58 days to drilled 6273 ftMD or 1911 mMD with number days for the stuck pipe event and sidetracking about 5 days. Based on an interview with one of project team who were involved in Darajat slim-hole core, the after-action review and individual well lookback were two key activities performed to lower the learning curve and improve the performance.

Figure 3: Indonesia slim-core hole historical.

Recent geothermal exploration in Indonesia has experienced major problems that diverge completely from expected advantages. In the decade, about six (6) exploration drilling using slim-core hole have resulted in excessive cost overruns, significant project time delays and other problem such as unpaid invoices, labor strikes due to delayed salary payments and contract fulfillment failure.

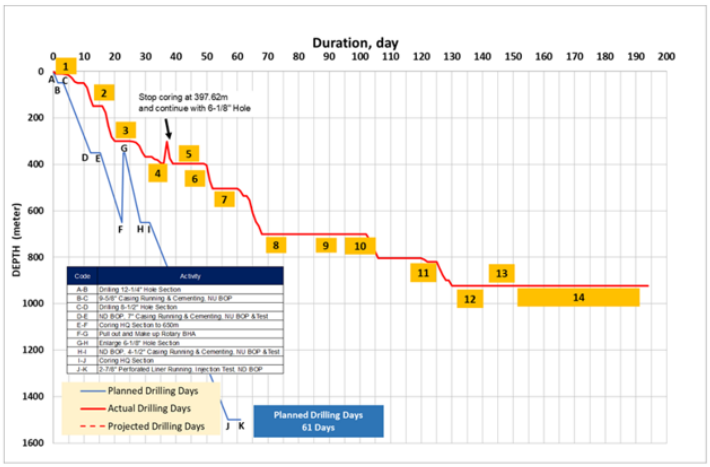
Start with Ijen exploration that was executed in 2016 until the last slim-core hole in 2022 at Klabat wineru, the drilling days to complete one well extremely longer than the target day, with the target days less than 60 days, the execution end up with delays up to close to four times of the target. With the excessive delays, the well cost became exceeded the budgets and the project spending became overruns because of the direct and in direct cost were ramping up a long with the additional days. however, with the delays and overruns, the target depth range to be drilled were able to achieve and this is an important note that's informing the planned target depth still within the design limit of slim – core hole rig equipment.

In the following time performance of the last two slim – core hole drilling, clearly non-related drilling was the major contribution to the total time performance. In Hu'u drilling in figure 04 obviously the drilling progress were stopped because of equipment problems and non-technical issues, from 193 days of spud to rig release, the planned days only 26.9 % or 51.9 days. even though the performance was not satisfied, but if we normalized the total time without NPT and unplanned event, the performance to drill 922m days with 51.9 days is still aligned with the historical performance at Darajat.

In klabat Wineru drilling as illustrate in figure 05 that's the starting drilling about the same with Hu'u. from 204.7 days of spud to released, the planned days only 28 % or 52 days. Same with Hu'u, the drilling performance were very slow progress with a lot of stopped that caused by equipment problems. With all the obstacles, the well can be drilled to 985 mMD of 1000 mMD the target depth, which if the time performance normalized without the NPT, the team performance also aligned with the historical of darajat's performance.

An interesting fact of recent slim – core hole drilling is that from six of slim-core hole drillings, Three (3) of them were drilled by same rig contractor which are Nage, Hu'u and Klabat Wineru, and for Ijen, even though it was drilled with different rig company, the majority of the management were the same as the rig contractor in nage, Hu'u and Klabat Wineru. In Ijen, they wasn't used a brand new rig, but in Nage, Hu'u and Klabat Wineru, they brough three (3) a brand new rigs, which the equipment problems shouldn't be an issue, however in reality all of

those operation have a same problem of the equipment reliability. Some reason behind the equipment problems were lack of engineering design on rig auxiliary equipment selection that's lead to in compatible equipment and un operable the equipment, procuring of an used and nonstandard equipment, none of preventive maintenance plan combined with not ready with the spare parts, and bad contractual with the rig manufacture for after sales support. Unpreparedness and a lack of experience have significantly impacted drilling operations, even though the rig contractor has already hired experienced professional crews to mitigate operation problems, but without a good system, financial and non-financial support, those are not working.



No.	Depth	Duration	Problem

Figure 5: Klabat Wineru slim-core hole performance drilling.

Although the drilling performance did not meet the target time, there were numerous lessons learned and best practices identified that can be used to improve the likelihood of the success next slim-core hole drilling. The understanding of difference between rotary drilling and coring operation is one of fundamental learnings, because most of drilling professional and practicians are very well known with rotary drilling operation, however for slim-core hole updated knowledges almost none because of the time gap between the last slim-core hole drillings back in 1998 until recently drillings and the slim-core hole drilling only use in the initial exploration. In the additional exploration and development state, slim-core hole is no longer used, the slim hole until big hole drilling design are used. Normally the coring is operated a lot in mining, and the interaction between geothermal drilling and mining also almost none, so it's also lead for the coring drilling has no information about slim-core hole drilling for Geothermal exploration. The following is summary of differentiate between rotary drilling and coring operation.

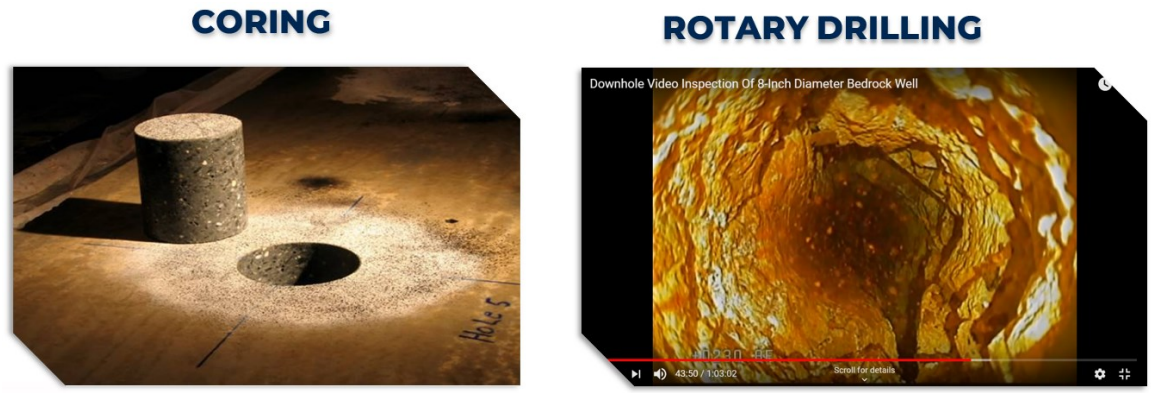

Figure 6: The core hole shape vs rotary drilling shape.

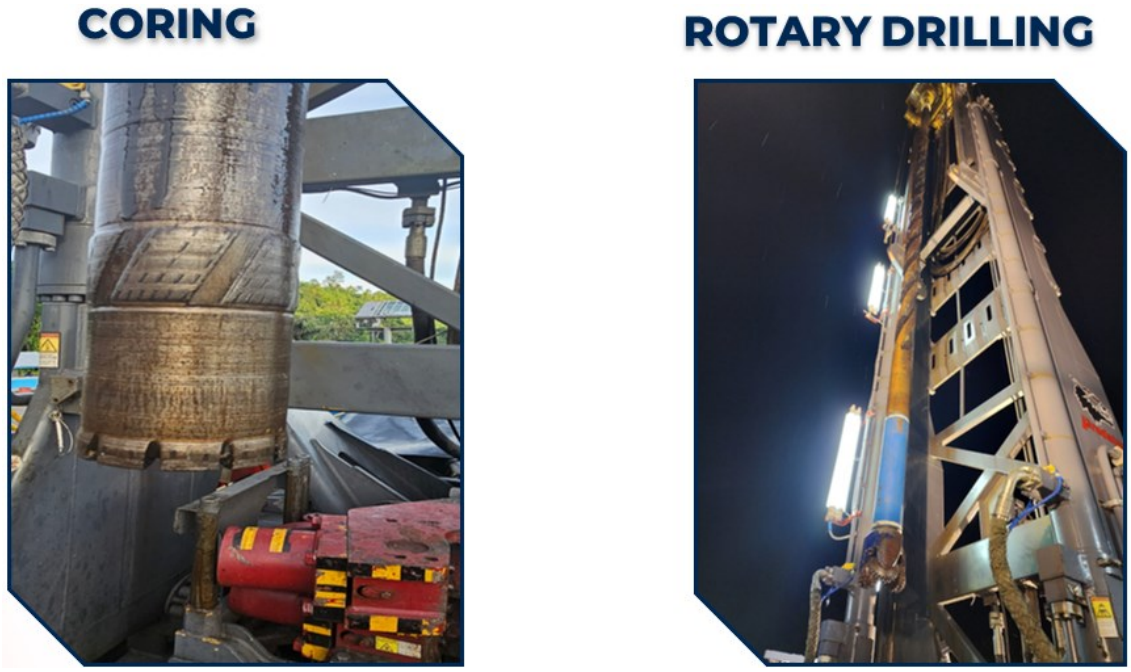

Figure 7: the core hole BHA vs rotary drilling BHA.

2. ROTARY DRILLING VERSUS CORE DRILLING

The following Figures 6 is to compare the shape of core hole versus rotary drilling, and it's very clear the different shape between those, the core hole has smooth rounded shape and in gauge while rotary drilling hole more to rough shape and more to over gauge. The explanation why it being a different shape because of different mechanism as can see in the Table 1.

The coring making a hole using a core head which the size almost the same the pipe that's usually called rod, the coring BHA has slick and straight configuration while rotary drilling BHA making hole using drill bit with the size bigger than the drill pipe, the rotary drilling BHA has size down from the bit to BHA component such as stabilizer, drill collar, and to the drill pipe sizes as can see in figure.07 of coring BHA and rotary drilling BHA.

Table 1: Differentiating Coring and Rotary Drilling mechanisms.

	CORING	ROTARY DRILLING
Formation cut	Polishing	Crushing and shearing
Dominant force	More to the rotation	More to Weight, assisted by rotation
Torque	Low	High
Vibration	Less	More vibrate
Weight on bit	Very low WOB	Higher WOB
Cutting size	Very fine	Rough and bigger
Hole shape	In gauge	Slightly over gauge
Bit	Core head	Drill bit
BHA Geometry	Slick and straight	Size down from bit to the pipe
Circulation	High pressure and low flow rate	High flow rate and relatively low pressure

Table 2: Differentiating Coring and Rotary drilling stuck pipe recovery.

	ROTARY DRILLING	CORING
Stuck pipe mechanism	Pack off/Bridge off, Differential Sticking, Wellbore Geometry	
Stuck pipe recovery	• Pipe severing • Fishing out or side tracking	• Continue drilling with a smaller core size • Cleaning out the annulus with a slightly larger core size • Side tracking
Stuck pipe severing	Explosive (Common) Mechanical cutter Both are using wireline	Mechanical cutter run with smaller rod

To cut the formation, the coring assembly polishing the rock using rotation as dominant force with the weight only to maintain the contact with formation while rotary drilling crushing and shearing the rock using weight with the assist of the rotation. The polishing is resulted in in gauge and smooth hole shape with produced very fine cutting while rotary drilling has slightly over gauge and rough hole with the cutting size roughly and bigger. The coring parameter is low torque and less vibration if compared with rotary drilling. The circulation of coring has high pressure with low flowrate is because of small annulus clearance and very fine cutting while rotary drilling circulation usually high flow rate with the pressure relatively low because of bigger annulus clearance that's required more volume to fill it.

The slim-core hole drilling operation includes rotary drilling and continuous coring, the conductor, surface or intermediate, and production holes are drill with rotary drilling, after the production casing is set and cemented, and permanent wellhead and master valve installed, continuous coring is using to drill the well to the target depth.

Another key learning is the stuck pipe recovery practices for the core hole. The stuck pipe mechanism for both rotary drilling and coring are the same, but stuck pipe recovery and stuck pipe severing in coring has differentiate with rotary drilling as can see in Table 2. There is an option to clean out the pack off annulus with a slightly larger core size but most of the time if the attempt to free the rod is failed, the rod is cut with mechanical cutter that's run with the smaller rod. After the rod is cut, which normally right below the wellhead to maintain small clearance in the anulus to keep the rod stable to core smaller hole.

In addition to the understanding of coring basic concept and stuck pipe recovery practice, another key learning in slim-core hole drilling as follow.

3. SLIM-CORE HOLE DRILLING KEY LEARNING

3.1 Well objective – scale of priority

Well-defined drilling objectives are crucial for good planning, efficient resource allocation, and proper risk mitigation to deliver the project safely and successfully. Adding too many objectives can increase complexity and drag down the project. To meet increasing complexity, mitigation should be increased, and most of the time, the project team was unaware that the invisible project cost had risen dramatically. The most important aspect of determining exploration drilling objectives is setting reserve confirmation objectives, which frequently trap the project team with overly ambitious goals, resulting in higher risk due to high uncertainty conditions and exceeding the design technical limit.

The following table 03 is an example of additional objective during defining well objective of the initial exploration, without the additional objective, the option can be varied, and the slim-core hole is one of the preferred option, however after the additional objective added, the slim-core may have design limit issue, and if still continue with this option, additional mitigation is required, which most of the time the project team did not realized such mitigations had burdened the project cost before the project performed with the consequence of the risk also rose. Most of the time, the project team is too focused on the success scenario and forgets that exploration has a flip of unsuccess risk, with the additional mitigation costs and increasing the complexity. The cost consequence is also automatically high if the exploration result is unfavorable and must be halted, and it becomes a sunk cost that affects the financing of the future project and makes the economics of geothermal project unattractive.

Table 3: An example of additional objective during defining well objective of the initial exploration.

Category	Definition	Additional Objective
PSPE Objectives	Determine Probable Reserve (ref SNI 6009-2017)	• Confirming Probable Reserve Calculation can be used as reference to develop first 20 MW without doing more exploration • Confirming field development strategy • After IPB awarded, Company is able directly to drill 40 kg/s steam production well and 1 brine injector well with capacity of 120 MW and 1 condensate well with capacity of
	▪ Obtaining geological, geochemistry, and geophysics survey data	
	▪ Drill 1 (one) exploration well	
	▪ Able to prove geothermal conceptual model	
	▪ Able to estimate reservoir dimension	
	▪ Able to determine reservoir rock characteristic	
	▪ Able to determine reservoir fluid characteristic	

3.2 Well control – a realistic risk assumption and mitigation

The key risk of an exploration drilling well control which has huge uncertainty and being a big challenge for the project team to do a precise projection of anticipate pressure and temperature with the absence of the offset well and sub surface information. Most of the time, to address this uncertainty the project team come up with very conservative estimation that's lead to excessive mitigations to mitigate all possible conditions, which this is the safest way, but there is a consequence to drilling cost, the economics of project and the technical design limits. The additional mitigations affect not only the mitigation cost, but also to the complexity of well design, drilling equipment set up and the execution time. During the operation, more time will be required to ensure that all the mitigations are in place.

In recently slim-core hole drilling, to mitigate all potential predicted pressure and temperature, a larger and bigger BOP and wellhead stack were required, and to accommodate the installation of wellhead and BOP stacks, the sub structure was modified become a taller and wider. The modification was not just stopped at the substructure, but the other rig equipment was needed to adjust to fit with a modified substructure, such as pipe rack adjustment to be leveled with the new platform elevation, high pressure and low-pressure circulation line adjustment for re-alignment, electrical line re-set up, and so on, and those modifications were not only increased the preparation cost but also the dimension of equipment that's affected to the complexity of handling and mobilization.

To address this challenge, the project team should be innovative to keep the economics of project and ensure the well always secured. The well control risk of anticipate pressure and temperature need to be assessed with realistic number instead of very conservative approach. To prevent the very low likelihood and highest severe well control risk consequences, in addition to the maximum mitigations within the design limit, project team can innovate with decision point mitigation by setting minimum acceptance criteria for reservoir drilling instead of just focusing to the total depth, especially for the first well drilled. When minimum acceptances are fulfilled, the drilling can put

on hold for observation while drilling for the next well and then resumed for deepening if necessary. With the updated sub surface data from the first well drilling, the uncertainty of well control risk will be reduced, risk mitigation can be reassessed to more effective and efficient, well depth can be revisited and adjusted accordingly, and drilling practices can be improved to be more optimized. This initiative ensures all the hazards are always within the design limit of mitigation, and that mitigation costs are kept low due to the rig's compact size for mobility.

3.3 A reliable project drilling team with extensive role and responsibilities

With Preliminary Survey and Exploration License (PSPE) scheme legislation for recent geothermal exploration, there is increased pressure to deliver the exploration project cost-effectively and on schedule because all spending is done by the license holder. Having a dependable exploration team is one of the most crucial components in the success of geothermal exploration drilling operations. Because exploratory projects are typically short in duration, have a wide range of work scopes, and are cost sensitive, the project drilling team must be small, multitasking, problem solver, fast learning, collaborative, and have extended roles and responsibilities.

Slim-core hole drilling as the initial exploration, which combines rotary and coring drilling, requires a project drilling team with a combination of rotary and coring drilling knowledge, as well as multi-project type, roles, and exploration experience, to face all possible challenges during the exploration drilling process.

3.4 Well design – Design limit Optimization

In most circumstances, too many and complex objectives also had impacted on well design, and most of the time, the project team was trapped in this situation where they pushed the limit instead of optimizing the design limit. Given that slim-core hole drilling is an initial exploratory step, and the basic rig equipment design is for continuous coring, the project team must understand the design limit of the equipment in order optimize the coring capability to reach the target depth slim-core hole. What happened recently of the failure of slim-core hole can be caused by the practices of the project team and rig contractor to push the design limit coring rig by modifying rig equipment, with the assumption it could be extended the hole depth and increased the hole size of the rotary drilling for conductor until production hole and reduce the interval depth the coring because of most of the team perception of the continuous coring will take longer time and high risk of stuck pipe if compare than rotary drilling. however, in recently actual slim-core hole performance, with reliable equipment and experience personnel, coring performance can match with rotary drilling and less stuck pipe events.

3.5 Rig and equipment selection – standard equipment optimization and minimize the modification

The modification of rig equipment in slim-core hole drilling projects, when not properly engineered and lacking professional and experienced personnel involvement, could be led to significant risks. These include the potential for incompatible and inoperable equipment, as has been observed in many recent projects. Combined with issues such as inadequate preventive maintenance and poor availability of critical spare parts, these problems often lead to stopped drilling progress. To mitigate these risks, it's essential for project team and rig contractor to focus on proper equipment use and maintenance, optimize design limits rather than modifying equipment.

3.6 Rig contractor selection – proven experience and track record

The key lesson learned of recent slim-core hole is that the incompetence of rig contractors has significantly impacted the success of exploration projects. An underperforming rig contractor can cause delays in drilling progress, which is a critical activity in exploration. Once drilling fails, the entire project is at risk of failure. To mitigate these risks, it's essential to ensure the competence and reliability of rig contractors.

Given that most of the top ten rig coring companies operate in Indonesia as shown in figure 08, it should theoretically not be difficult to find competent and professional rig contractor for geothermal exploration using slim-core hole drilling. What the project team should do is meet with top coring companies to discuss project goals and expectations, and then select a preferred contractor by selecting organizations that offer the best combination of competence, dependability, and cost-effectiveness.

4. SLIM-CORE HOLE COST PROJECTION

If all the lessons learned are addressed and the best practices are followed, which is not a rocket science, slim-core hole drilling will likely be less expensive that other initial exploration options. According to white et all, deep slim-core hole for geothermal exploration, GRC transaction, 2010 , the actual drilling performance for a 1500 m deep continuously cored and subsequently hole opened slim hole is typically 60 – 65 days, which is nearly twice of that standard geothermal production well of the same depth, and cost US$ 1.3-1.8, whereas a standard diameter geothermal production well this deep might cost 3-4 times as much at about US$5-6 million or more.

Assuming the mitigation strategy is already in place, we can determine whether white et al's anticipated time and cost are still applicable in the current Indonesian market. Using core rig capacity of 300 – 450 HP and a daily rig

cost US$ 23 per house power as referred to SK APMI 2017 Tarif harian operasi drilling (THO) onshore, the daily spread cost will be approximately US$ 20,7 K – US$ 31 K, and if the plan for slim-core hole is to drill 1500 meters with the target days is 60 days, the well cost may be US$ 1.24 – 1.86 million, which is consistent with White et all. Estimated.

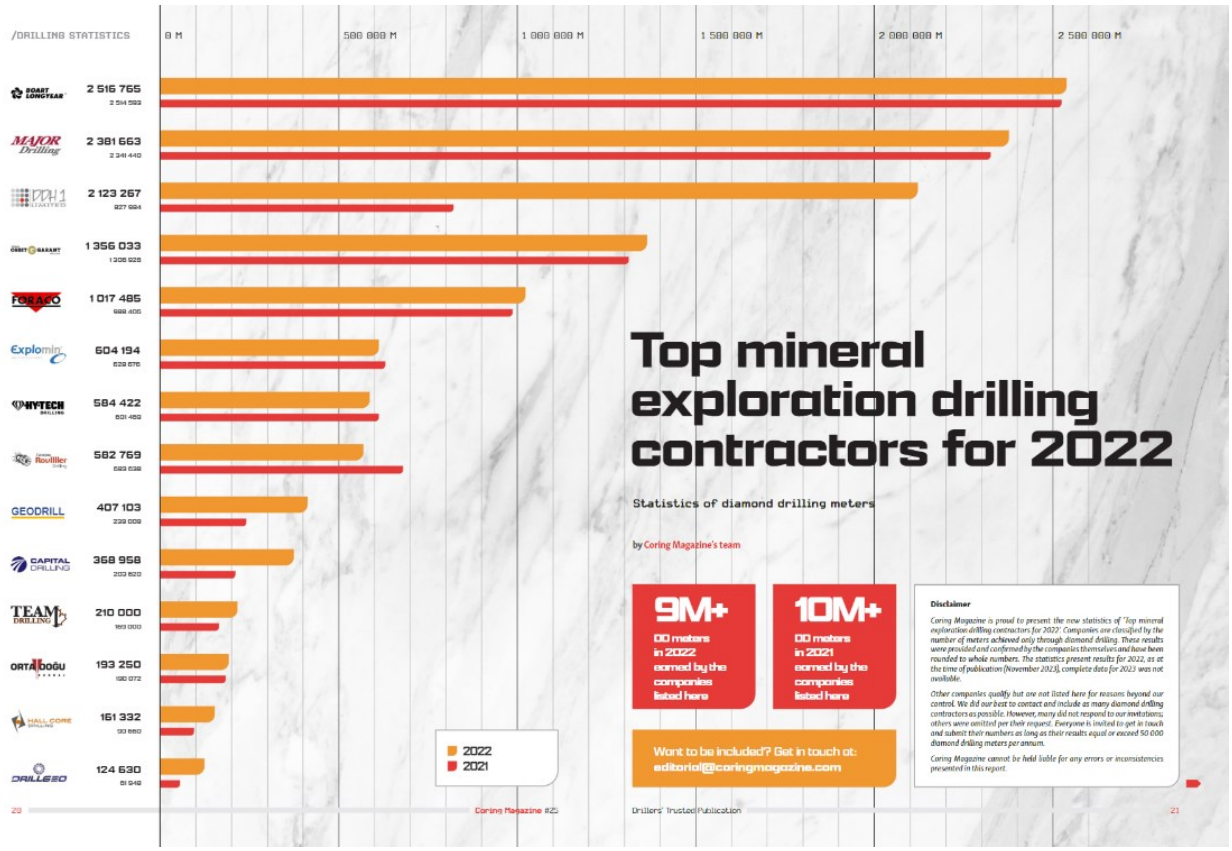

Figure 8: Top ten rig coring companies.

	WELL COST PROJECTION
Rig Capacity	300 HP – 450 HP
Daily Rig cost (* USD 23 /HP)	USD 6,900 – USD 10,350
Daily spread cost	USD 20,700 – USD 31,050
Drilling days	60 Days
Well depth	1500 m
Well cost	USD 1.24 Million – 1.86 Million

* SK APMI 2017, Tarif Harian Operasi Drilling (THO) onshore of USD 19 – USD 23 per HP

Figure 9: Well cost projection.

5. CONCLUSION

The slim-core hole was effectively conducted in the early stages of Indonesia geothermal exploration, yielding positive results in terms of performance and reserve confirmation, confirming the slim-core hole as the best alternative for performing effective and efficient initial exploration. By leveraging historical successes, understanding the critical differences between drilling operations, prioritizing well objectives, assembling a reliable exploration team, optimizing well design, selecting the right equipment and contractors, and implementing best practices and mitigation strategies, the goal of efficient and cost-effective slim-core hole drilling in geothermal exploration high likelihood to be achieved, and the aim of slim-core hole drilling to 1500 m within 60 days at a cost of around US$1.2 million remains realistic. The successful of slim-core hole execution will be

advantageous to enhance number of reserve confirmation of long list geothermal prospects, which can accelerate Indonesia geothermal growth.

Keywords: rock muffler, design, geothermal power plant

ABSTRACT

The approach for designing a rock muffler of a typical 55 MW capacity geothermal power plant in Indonesia is elaborated in this paper. The rock muffler runs as the facility for venting steam in the event of the power plant shut down or emergency cases. Based on historical production data of existing 60 MW gross capacity power plant, the rock muffler may accommodate approximately 400 tons per hour of steam. The objective of this paper is to give the approach of the rock muffler design that needs to meet the requirements for typical 55 MW net power plant in Indonesia. The noise level limit allowed in the residential area is 55 dB during day time and 45 dB during night time. With the site-specific approach, the findings are the dimension of the rock muffler recommended using 6.5 m height of the structure with 5.5 m height of scoria rocks filling. On the other side, the recommended length and width of rock muffler is 18 m x 8 m. In this dimension approach, the highest noise modeling results in approx. 41 dB at the receptor with approx. 700 m straight line. Furthermore, the paper gives the examples and approach of calculations for sizing of a rock muffler in geothermal power plant.

1. INTRODUCTION

Indonesia has enormous geothermal potential as per data published by the Government of Indonesia. One of the development phases of a geothermal power plant is designing the equipment using an engineering approach to get the dimension of equipment. In geothermal power plants and steam above ground systems (SAGS), rock mufflers serve as critical safety and operational components. Their primary function is to safely vent steam during planned shutdowns, unplanned outages, and emergency scenarios. The design of a rock muffler necessitates rigorous calculations that take into account the site ambience conditions, geothermal fluid characteristic, related regulation, and applicable standards. The objective of this paper is to give the approach of the rock muffler design that needs to meet the requirements for typical 55 MW net or 60 MW gross power plant in Indonesia. . The pipeline and diffuser are sizing and design based on mass flow rate for 55-69 MWgross generation of Geothermal power plant.

2. CODES AND STANDARDS

To meet the requirements for a typical 55 MW net power plant in Indonesia, the design of the rock muffler shall consider applicable codes and standards, including but not limited to those specified in Table 1 Applicable Codes and Standards.

Table 1: Applicable Codes and Standards.

No	Code and Standard	Description
1	API 5L	Specification for Line Pipe
2	ASME B31.1	Power Piping
3	ASME B16.5	Pipe Flange and Flanged Fittings
4	ASME B15.47 Series-A	For Large Diameter Flanges
5	ASME B36.10	Welded and Seamless Wrought Steel Pipe
6	API 598	Valve Testing
7	API RP 521	Pressure Relieving and Depressuring Systems
8	API 600 Series	Valve
9	SNI 2847-2019	Structural Concrete Requirements for Buildings
10	SNI 1727-2018	Minimum Loads for Designing Buildings and Other Structures
11	SNI 1726-2019	Earthquake Resistance Design for Buildings and Non-Buildings
12	SNI 8460-2017	Geotechnical Design Requirements

Both for National or Local Government to maintain production facilities and local environment from defects and pollution (air, water, sound, etc.), the designer shall follow applicable regulations from Indonesia Government, including but not limited to those specified in Table 2.

Table 2: Applicable Government Regulations.

No	Regulations	Description

3. ASSUMPTION AND CALCULATIONS

3.1 Assumption Data

The assumptions used in this hydraulic analysis are homogenous rock dimensions with shape assumed nearly to perfect sphere. In designing the rock muffler, there are some criteria with engineering and environmental aspects that need to be considered as follows:

- Design lifetime for 30 years.
- Design shall provide accessibility for operator and engineer to operate and maintenance activities.
- Design shall follow the latest standard that still apply and shall have flexibility and reliability.

Proper material selection for long term operation, minimum maintenance due to corrosion and erosion effect, noise emission and proximity to inhabited area, noise limitation should not exceed 55 dB and 45 dB at 100 meters distance. There are several data for environmental, fluids, and scoria rock that will be used for calculation of the rock muffler design as shown in Table 3 with all units in Metric system.

3.2 Calculations

The calculation will consist of discharge flowrates, sonic velocity, hole sizing, drag force, and noise prediction.

- Environmental: Upstream pressure, atmospheric pressure
- Assumption: Mass flow rate for 60 MW gross (SSC = 7.2 ton/ MWh), Steam fraction (Inlet scrubber)
- Steam properties: Density, Specific volume, Molecular mass, compressibility factor (Z), heat capacity constant volume (CV), heat capacity constant pressure (CP), Universal gas constant (R)

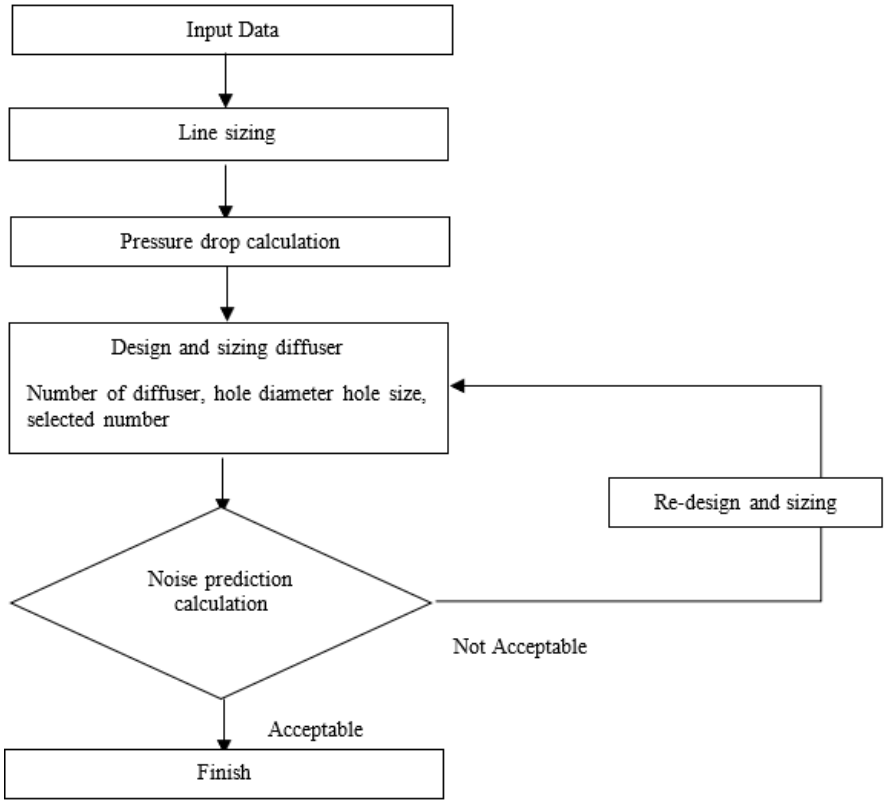

Figure 1: Flowchart.

The compressible fluid flow through the nozzle and orifice can be calculated based on Verma and Pruess (1976)] (equation 2-24), with the following formula:

$$q = YCA\sqrt{\frac{2\Delta p}{\rho}} \quad (1)$$

where

q = Flow rate (kg/hr),

Y = expansion factor,

C = flow coefficient for orifice and nozzle

Δp = pressure differentiation between upstream and downstream (bar),

A = hole area (m^2)

ρ = fluid density (kg/m^3)

Steam sonic velocity can be calculated based on Crane Co [4] (equation 3-8), with the following formula.

$$v_s = 316.2\sqrt{\gamma\, P\, V} \quad (2)$$

where

υ_s = Steam sonic velocity,

γ = Specific *heat ratio* (Cp/Cv),

P = Pressure (bar.a)

V = Specific voulme (m^3/kg)

Hole sizing can be calculated based on discharge flowrate calculation divided by the number of holes. To reduce noise steam sonic velocity limitation should not exceed 0.3 mach based on IEC 60534-8-3 [7]. The drag force value are needed to determine the drag resistance of rock, Drag force can be calculated based on Perry's handbook [5] (equation 6-227) with the following formula (3).

$$F_D = \frac{C_D\, Ap\, \rho\, u^2}{2} \tag{3}$$

where

F_D = drag force

C_D = drag coefficient

C = flow coefficient for orifice and nozzle

A_p = particle cross section area (m^2)

ρ = fluid density (kg/m^3)

elative velocity between particles. Then the noise prediction can be calculated based on silencer Application [5] with the following formula (4).

$$L_W = 17\, W + 50\, log\ T\ - 85\, dB \tag{4}$$

where

L_w = noise level outlet diffuser (dB)

W = steam mass flow outlet

P = diffuser holes (lb/h)

T = upstream temperature (deg R).

Pressure drop calculated using prediction of steam flow pressure drop which is through packed beds of rock layer can be calculated by using Ergun's Equation [10] as follow formula (5)

$$\frac{\Delta P}{L} = \frac{150(1-\varepsilon)^2 \mu U}{\varepsilon^3 {D_p}^2} + \frac{7(1-\varepsilon)\rho U^2}{\varepsilon^3 D_p} \tag{5}$$

Where

$\frac{\Delta P}{L}$ = pressure drop per length (bar/m),

ε = rock porosity

μ = dynamic viscosity of the fluid

U = Superficial bed velocity (m/s),

D_p, = diameter of Particle (m),

ρ = Density of the fluid (kg/m^3).

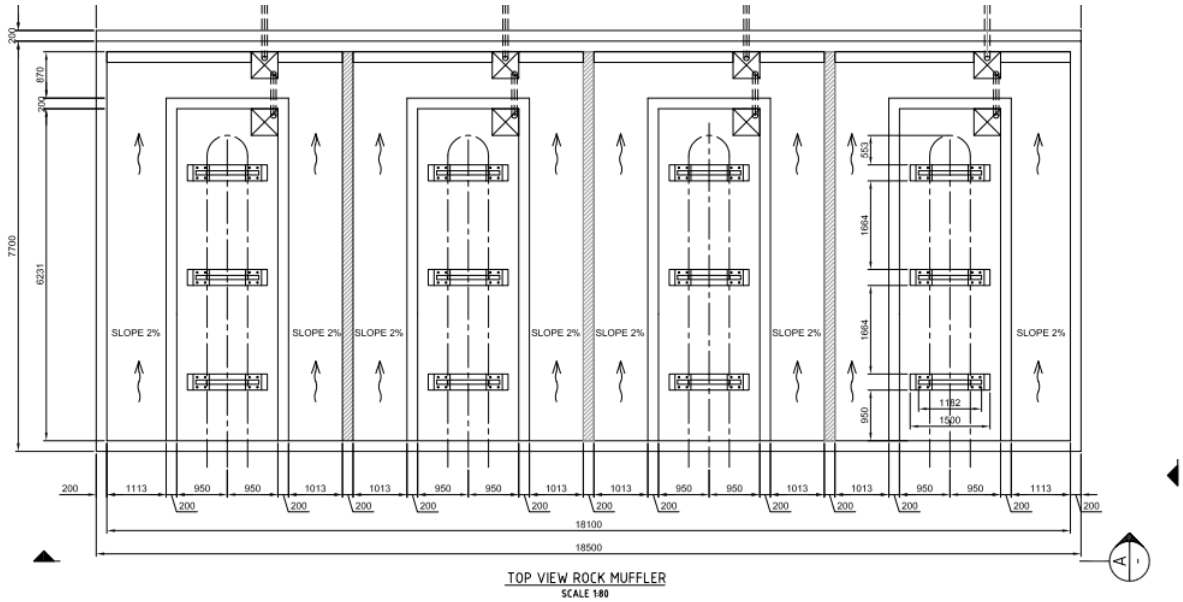
4. RESULTS AND DISCUSSION

The results section will include the calculated values for discharge flowrates, sonic velocity, hole sizing, drag force, noise prediction, and pressure drop as Table 4.

The material for use with maximum operating temperature (MOT) shall be established greater than or equal to the operating temperature. The design temperature at least 10° C above the MOT. The design temperature shall be rounded up to nearest 5°C increment. In designing the rock muffler unit for geothermal applications considered various specifications and materials to ensure optimal performance and durability. The noise levels were a critical consideration, with the design ensuring a noise level of 85 dB at the outlet diffuser and 35 dB at the outlet of the rock muffler. It is acceptable noise level as mentioned in the regulation, the noise in receptor or nearest community is 45 in night time. This comprehensive design ensures that the rock muffler unit will perform effectively under the specified conditions, with careful consideration given to material selection especially for rocks, noise reduction, and structural integrity. The selection of materials, and dimension will lead to the noise level approach as stated in the previous section. It is recommended to lead this desain to noise modeling if required to ensure the noise data is acceptable by the requirements and regulations. Following Figure 2: The proposed drawing of rock muffler can describe about the rock muffler proposed design using the approach.

Table 4: Results.

No	Description	Results
1	Material used for diffuser pipe	API 5L Grade B
2	Pipe size for diffuser pipe	24 in
3	Pipe wall thickness	12.7 mm
4	Schedule	XS
5	Length of diffuser	10,000 mm
6	Amount of holes	704
7	Diameter of holes	40 mm
8	Structure	6.5 m height of the structure with 5.5 m height of scoria rocks filling
9	Dimension of rock muffler	18 m x 8 m
10	The noise levels	85 dB at the outlet diffuser and 35 dB at the outlet of the rock muffler
11	The total weight for the rock muffler unit	estimated around is 265,500.3 kg



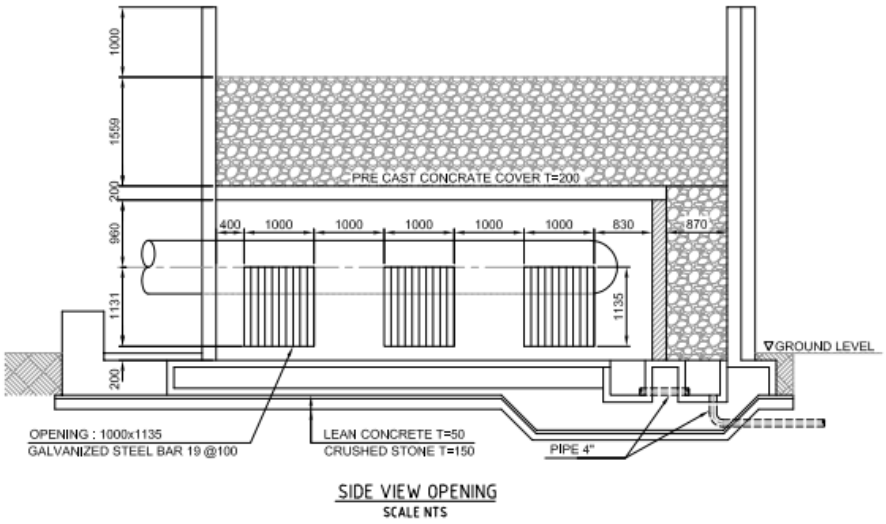


Figure 2: The proposed drawing of rock muffler.

5. CONCLUSION AND RECOMMENDATION

The rock muffler equipment is one of the significant parts of geothermal utilization for emergencies to ensure the flow of steam for emergencies to the air meets regulations in terms of noise level and safety concerns. The approach of a typical 55 MW net or 60 MW gross capacity production geothermal power plant is elaborated in this paper. The rock muffler runs as the facility for venting steam in the event of the power plant shut down. Based on historical production data capacity of the rock muffler may accommodate approximately 400 tons per hour of steam. The objective of this paper is to give the approach of how to design the rock muffler that needs to meet the requirement of regulation, in this case, the Government of Indonesia. The noise level limit allowed in the residential area is 55 dB. In this case, noise modeling may be required to ensure compliance. Current calculation findings are the dimension of the rock muffler recommended using 6.5 m height of the structure with 5.5 m height of scoria rocks filling. On the other side, the recommended length and width of rock muffler is 18 m x 8 m. In this dimension approach, the highest noise modeling results in approx 41 dB at the receptor with a distance of approx 700 m straight line.

Keywords: Learning curve, Geothermal exploration, Geothermal drilling

ABSTRACT

Every new drilling campaign has a learning curve that affects performance, even if it is a development drilling and numerous drilling campaigns have been completed. The learning curve of probabilistic exploration will be longer due to a lack of subsurface hazard knowledge and no offset well data use as a reference, which will increase the risk assumption. The learning curve will also be influenced by the presence of new parties in each drilling campaign, such as new contractor, equipment, or personnel. The ability to shorten the learning curve will automatically improve time and cost efficiency.

This paper will discuss daily drilling continuous improvement and immediate corrective action methodologies that have successfully lowered the learning curve of drilling exploration, resulting in increasing time and cost efficiency. In addition to efficiency, best practices and lessons learned were documented and could be utilized in the next well drilling, and an improvement plan initiative were identified to ensure the continuity of efficiency.

1. INTRODUCTION

Even though geothermal drilling Indonesia has been performed for many years, there was a pause in between drilling campaigns, which can be only a couple of years but can also be more than ten years. The reason for the pause was that the target well to be drilled has already been achieved to supply the steam as per the target, but there was also observation time required before moving to development stage from the exploration. A vacuum situation between drilling campaign causes the learning curve break, the learning curve begins over the campaign is resumed, lengthier vacuum drilling results in longer learning curves.

The learning curve in exploration drilling should be longer than the development drilling because of in absence of sub surface information and offset well, which will increase the risk profile and require additional safeguard to be identified and mitigation plan to be established. The learning curve delays were also contributed by the first time set up and the introduction of new parties such as new contractor, new equipment, new crews, all of which need more time for familiarity and effective coordination and communication.

The learning curve has impact to the performance and economics of project, the ability to shorten the learning curve is one critical aspect in delivering successful projects. The sensitivity and urgency of the learning curve increase with the size of drilling project. For smaller and shorter drilling projects which a restricted time and budget, reducing the learning curve is essential, and most geothermal exploration projects are small and short. Even while the learning curve in the development drilling project is not as sensitive as that in exploration drilling, it is still critical to maintain the project improving over the time. The development drilling learning curve can be shorter than the exploration because of the best practices and lessons learned from the preceding project already there.

2. GEOTHERMAL DRILLING PROJECT PREPARATION TO EXECUTION

Geothermal drilling campaign project will begin with the collaborative work by multidisciplinary project team to prepare comprehensive project plan, with the detailed drilling plan as the key deliverable. Once the plan is included in the budget approved by management, the project team will handover drilling program to drilling team for the execution, and once handed over, the drilling time and learning curves are begins. The drilling team will be responsible for carrying out the drilling according to the drilling program and within the budget. Because exploratory drilling is the ultimate activity in the exploration projects, with assigned budget exceeding 80% of the total project budget, effective drilling execution time and cost expenditure within the budget will increase the exploration project's chance of success. One of the most difficult aspects of drilling execution is reducing the learning curve while maintaining safety and standards. The ability to manage the learning curve efficiently has a significant impact on time and expense budgets. With 24 hours and 7 days of drilling operation, the learning curve should be reduced continually, at the activity level, and with immediate corrective action.

3. LEARNING CURVE CONTINUOUS IMPROVEMENT AND IMMEDIATE CORRECTIVE ACTION

Drilling execution consist of numerous series and concurrent activities that be grouped into preparation, execution, and evaluation. To reduce the learning curve as quickly as feasible, a learning curve plan must be developed prior to drilling execution preparation, a learning initiatives implementation strategy must be established during execution, and the identified learning initiatives must be documented for evaluation. Figure 1 depicts the learning curve continuous improvement and immediate corrective action were designed and implemented by the authors and drilling team, which successfully lowered the learning curve for exploration drilling execution.

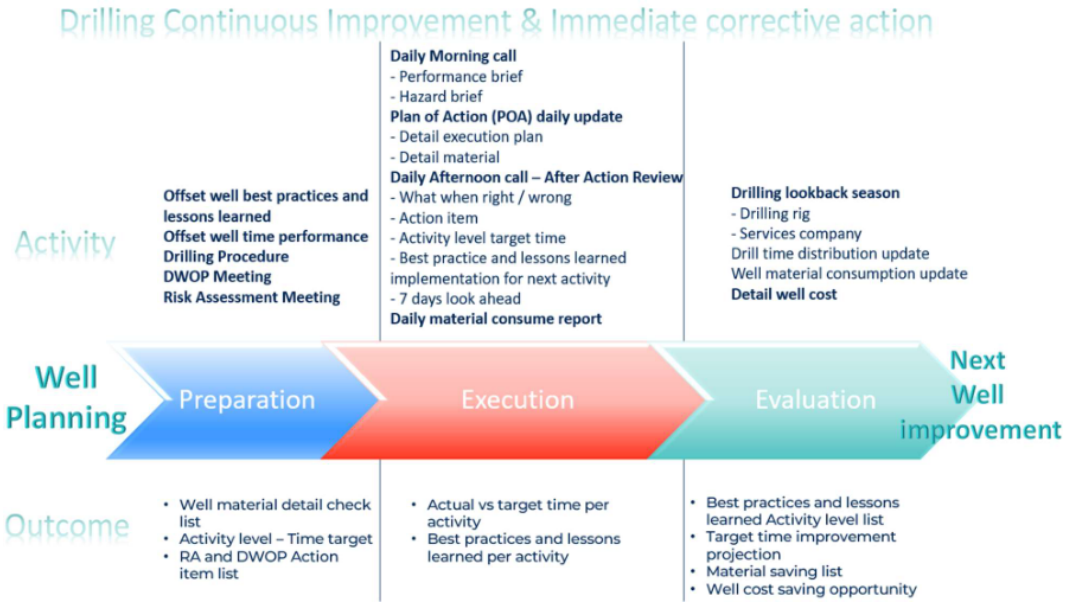

Figure 1: The learning curve continuous improvement and immediate corrective action.

3.1 Drilling Execution Preparation

Drilling execution preparation was optimized to prepare a good learning improvement plan. Through offset well review, all the best practices and lessons learned initiatives were identified and listed to be embedded in the drilling procedure, and the base line time performance of each activity were identified to be set as the execution detail time target. The identified best practices and lessons learned were also used to mitigate all identified risks, as detailed in the risk assessment document.

In the absence of an offset well in the first well of the exploration drilling, the analog well for best practices and lessons learned was selected from Indonesia geothermal well drilling practices, while the base line time performance to calculate the drilling time target was taken from the recent wells drilled by selected drilling rig and services.

In the Risk Assessment (RA) meeting, the mitigation of all identified risks were shared and assessed by all groups involved in the execution to verify all mitigation are practicable and can be implemented prior to the execution at the activity level. While in Drilling Well On Paper (DWOP), the detail drilling procedure includes best practices, the lessons learn mitigation, the detail well material, and the execution detail time targets was reviewed in length and collaboratively with big group to ensure that it is adequate, realistic, and understandable.

All the action items from risk assessment and DWOP meeting were listed, along with the person in charge and target time, and will be carried out as part of the drilling detail execution plan.

3.2 Drilling Execution After Action Review

In drilling execution, well material detail checklist was revisited regularly on daily basis, both before and after the job execution, the detail target time was monitored and reviewed per activity level, and the action item list from RA and DWOP was checked on regular basis before the activity was performed to ensure that all the action items were completed prior to the job.

During drilling execution, in daily morning call that was usually attended by a large group of project drilling team and all involved party representatives, in addition to daily progress reporting and operation discussion, a performance brief session was conducted to compare the actual performance with the target time and gather the best practices and lessons learned from the big group. The drilling hazard briefing was also conducted to ensure

that all mitigation plans for potential hazards in place, as well as to assess the effectiveness of the job's mitigation strategy.

The Plan Of Action (POA) was updated on a daily basis by drilling supervisor in collaboration with the onsite team, and it comprises specific material, services, and support for each activity to ensure that the drilling execution plan is followed accurately and that no human error occurs. The POA was discussed in a daily afternoon call between the drilling engineering team and the drilling operation team as part of After-action review. During this conference, it was examined what when right or wrong in last 12 hours, as well as best practices, lessons learned, and action items for the next 24 hour's work. The activity level target time was ran through to update the 7 days look ahead time. The list of best practices and lessons is constantly updated based on what identified in that day's discussion, and it will be carried over to the drilling evaluation.

3.3 Drilling Execution Evaluation

With the action item review in daily basis during execution, almost none further evaluation was required after the first well was drilled, the team only needed to double check the completeness of the documentation of best practices and lessons learned from the daily drilling execution through drilling lookback season.

During the lookback season, which was attended by all parties involved in the drilling execution, the drilling engineering team shared the drilling performance, including best practices, lessons learned, and sensitivity analysis of the perfect well target, while the rig contractor and each segment of the services company prepared and presented their individual lookbacks. The drilling lookback should be performed before finalizing the next well drilling program to ensure that it is updated with the first well's best practices and lessons learned, target time improvement projection, material saving list and well cost savings opportunity list.

4. DRILLING EXPLORATION LEARNING CURVE IMPROVEMENT

With a detailed learning curve continuous improvement plan and the consistency of project drilling team in the plan implementation, the challenge drilling learning curve has been successfully answered as seen in Figure 2. In the first well, the project team has successfully completed the drilling of the big hole in less than average for the first geothermal exploration well with the big hole design in Indonesia from 2010 to 2023.

With the second well's improvement plan updated with best practices and lessons learned, target time improvement projection, material saving list and well cost savings opportunity list from the first well, the project drilling team successfully completed the drilling two (2) times faster and 31% less cost than the first well and still exceeding the average time of the second geothermal exploration well in Indonesia.

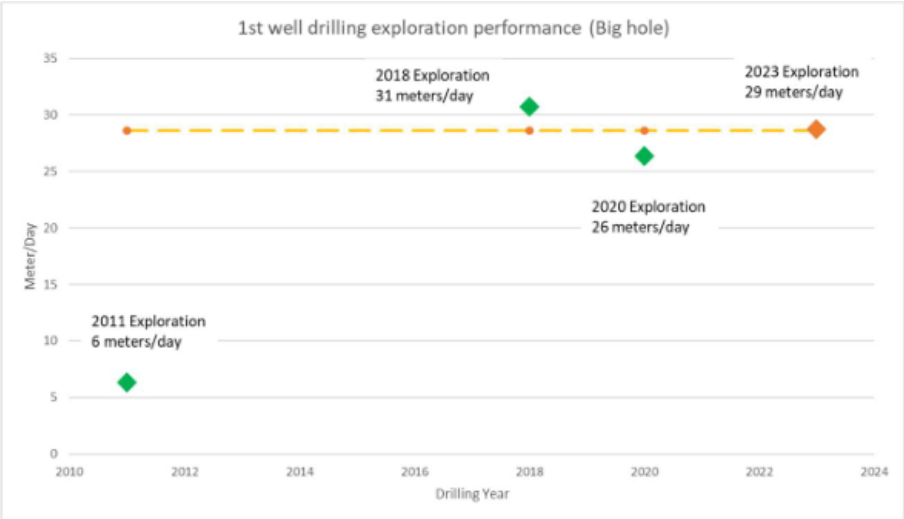

Figure 2: 1st Well drilling exploration.

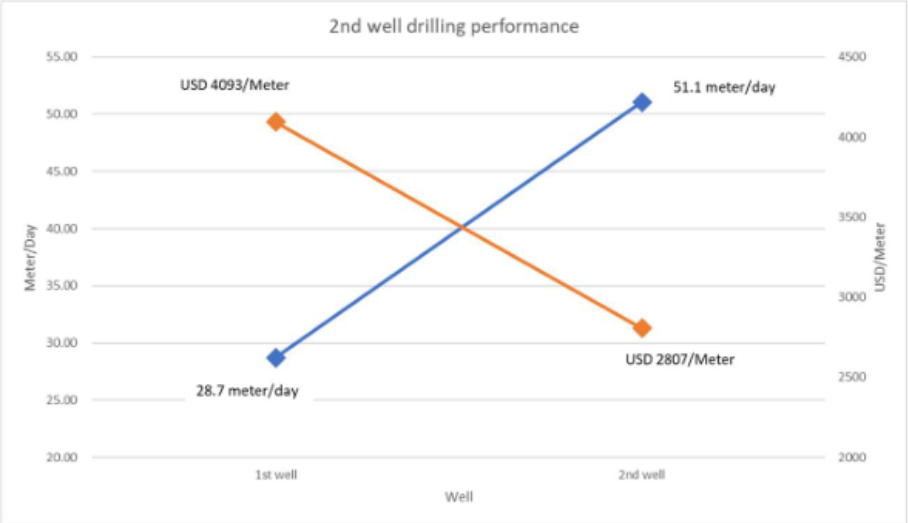

Figure 3: 2nd Well drilling performance.

5. CONCLUSIONS

Drilling learning curves challenges is always there, and they have become more challenging in the exploration well because of the absence of the information as offset, paired with the first operation set up of equipment and organization. With a good detail plan is crucial to the success, the consistency of plan implementation will increase the likelihood of success, close monitoring with immediate corrective action will keeps focus on the center of the target, and team collaboration and coordination increases efficiency have successfully reduced the learning curve of drilling exploration.

Keywords: Brine, CaO, Dieng Geothermal Plant, Silica

ABSTRACT

Indonesia is located in a strategic location with volcanoes which makes the country the world's largest geothermal storage. One of the geothermal sources in Indonesia is Dieng. The Dieng geothermal field has a high silica content from the brine around 1065-1400 mg/L SiO2/kg geothermal brine, but the presence of silica is one of the most significant problems in geothermal power plants. Recovery of supersaturated silica in brines is a good method to eliminate scale precipitation. The use of CaO has a practical advantage in removing dissolved silica from the brines. This research focuses on removing dissolved silica using CaO from the brine's Dieng Geothermal Plant. CaO was added as a flocculant with concentrations of 0.5, 1, 5, and 10 g/L. The retention time varied as 0, 15, 30, and 60 minutes. In the case of CaO addition, silica recovery rates increased with the amount of CaO added. These results indicate that addition of CaO can be used for silica recovery from geothermal brine at the Dieng Geothermal.

1. INTRODUCTION

Indonesia is one of the countries that has a lot of benefits from finding alternative energy to replace fossil fuel energy. Compared with all countries in the world, Indonesia has the greatest potential to further develop geothermal energy because Indonesia has the largest geothermal resources in the world. In other words, Indonesia has 40% of the world's geothermal resource potential but only 4% has been utilized (Ministry of Energy and Mineral Resources, 2023). Geothermal energy can develop in Indonesia because Indonesia's geography is dominated by volcanoes. This volcano was formed due to the subduction zone between the Eurasian Plate and the Indo-Australian Plate. The Dieng geothermal field has become a Geothermal Working Area which has an area of around 63 km2 and has a type of system in a two-phase reservoir which is dominated by the liquid phase with a temperature of around 240 °C – 333 °C (Prasetio et al., 2010). According to Boedihardi, et al (1991), the type of Dieng geothermal reservoir system was two-phase, dominated by the liquid phase, and provided information regarding the existence of three prospect areas in the geothermal field in Dieng, namely Sileri, Sikidang-Merdada, and Pakuwaja (Figure 1).

In the liquid phase characteristics, the Dieng geothermal field has a high silica content from the brine (Pambudi, N.A., 2015). The presence of silica is one of the most significant problems in geothermal power plants (Al Radi et al., 2022). The concentration of silica in geothermal fluids is controlled by the solubility and precipitation of different silica minerals. Silica occurs in various forms or polymorphs such as quartz, chalcedony, cristobalite, opal, and amorphous silica, each of which shows variations in solubility (Nicholson, 1993). In the Dieng geothermal field, there is a type of amorphous silica found in the silica scaling process of 90-98% (Jenie et al., 2018). Because silica has reactive properties, it dissolves easily with water, so the higher the temperature, the greater the solubility concentration. The solubility of various scales in geothermal systems has been reported in a specific order: amorphous silica has the highest solubility, followed by aluminum scale, and then ferric silicate scale (Juhri, et al., 2023). This ranking indicates that amorphous silica dissolves more readily in geothermal brine compared to the other types of scales. Understanding this solubility hierarchy is crucial for developing effective strategies for scale management and prevention in geothermal plants. By targeting the most soluble scales, such as amorphous silica, with appropriate chemical treatments or operational adjustments, it is possible to mitigate scaling issues more efficiently and maintain optimal performance in geothermal energy extraction processes.

Juhri, et al., (2023) showns the mineralogical composition of samples labeled OC-S, BR-S, and TP-S, with specific attention to amorphous silica (AS) content using X-ray diffraction (XRD) in Figure 2. The broad humps observed in the regions marked "AS" indicate the presence of amorphous silica in all three samples, as amorphous materials lack the distinct, sharp peaks typical of crystalline structures. The patterns also show peaks corresponding to various other minerals such as sphalerite, galena, pyrite, magnetite, and halite, identified by different symbols. These peaks suggest that, in addition to amorphous silica, the samples contain crystalline phases of these minerals.

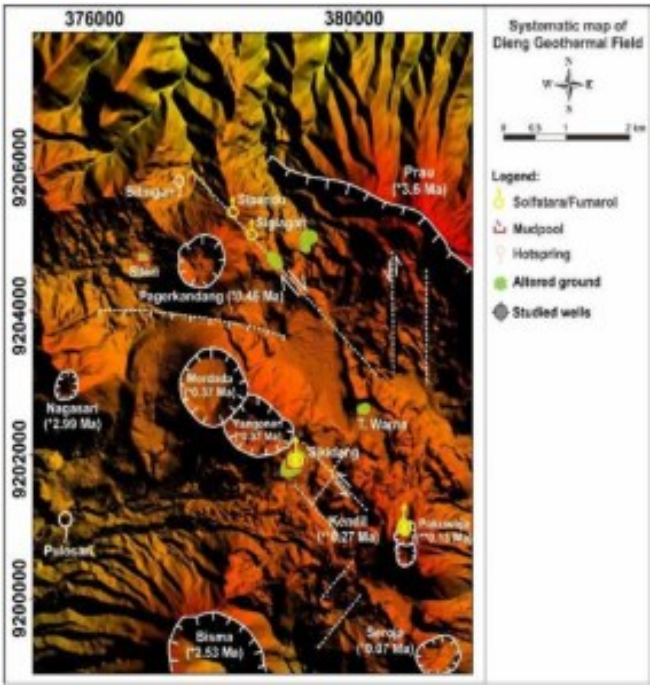

Figure 1: Dieng plateau volcanic area (Shalihin et al., 2020).

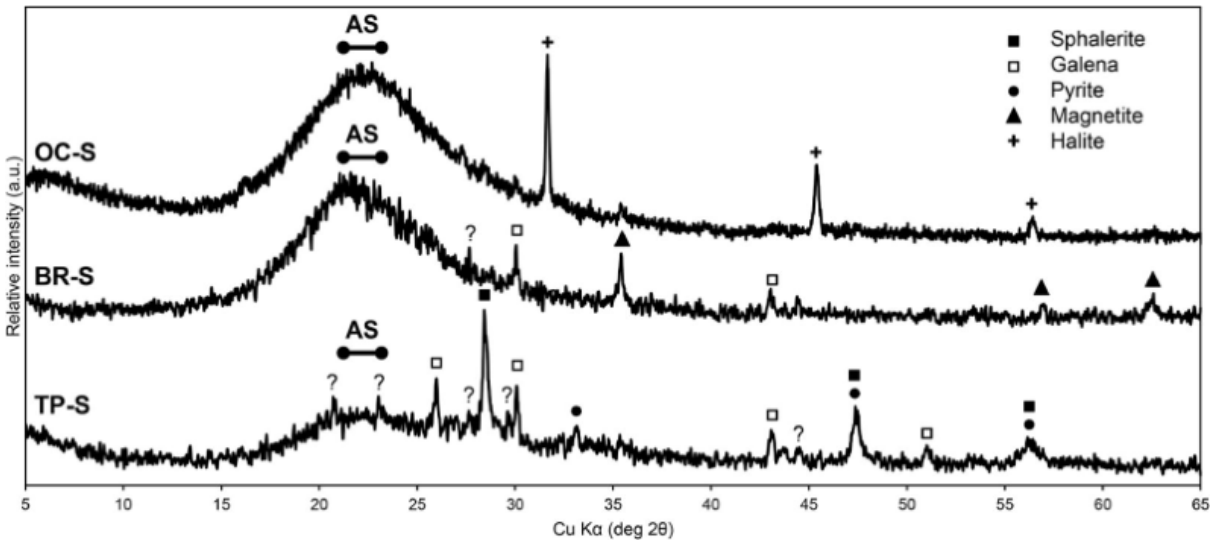

Figure 2. XRD patterns of the scale samples of the Dieng geothermal power plant (Juhri, et al., 2023).

Large concentrations of silica cause scaling in geothermal steam production well pipes and brine injection line pipes. Scaling occurs because of the presence of silica, which originates from salt mineral deposits dissolved in the water. As the concentration of silica increases, it can form a crust that obstructs the fluid flow process within the pipes. This blockage can significantly impair the efficiency and functionality of the geothermal system, leading to increased maintenance costs and operational challenges. The presence of crust and brine from the separation process represents a potential waste product that can be reused, thereby enhancing its utility value. For instance, silica from geothermal brine can be repurposed as adsorbents, used in the field of building materials, the synthetic materials industry, or further processed into nanomaterial-based products. This approach not only addresses the issue of scaling but also aligns with sustainable waste management practices, contributing to the overall efficiency and environmental friendliness of geothermal energy production (Asadi & Norouzbeigi, 2018; Syabani et al., 2020). To be able to utilize silica (SiO2), it is necessary to have a recovery process or recover pure silica from solidified geothermal waste. The recovery results can be further processed into downstream products. Silica downstream products are widely used in various sectors such as civil and construction, cleaning products, pharmaceuticals, and cosmetics. Silica is also the main precursor for various types of inorganic and organometallic materials (Terzioglu et al. 2013).

Recovery of supersaturated silica in brines is a good method to eliminate scale precipitation. The use of CaO has a practical advantage, for it is inexpensive and effective in removing dissolved silica from the brines. This research focuses on removing dissolved silica using CaO from the brine's Dieng Geothermal Plant.

2. METHODS

In this study, brine samples were obtained from the Dieng Geothermal Plant. The chemical reagents to recover supersaturated silica were quicklime (CaO). A total of 850 mL brine was collected in a teflon beaker and kept at 90 ◦C in a water bath. After keeping the brine at 90 ◦C for a given retention time 15, 30, and 60 min, CaO was added as a flocculant and stirred. The concentration of CaO was 0.5, 1, and 5 g/L. After adding the chemicals, the sample water was collected and filtered through a 0.2-µm membrane filter, then filtrate followed by chemical analysis of total silicic acids using a spectrophotometer (Ueda., et.al., 2022). Table 1 shown the data collection matrix for this research.

Table 1: Data Collection Matrix.

Fe	1.35
Al	0.01

3. RESULT AND DISCUSSION

The general chemical characteristics of brine, such as chemical elements, their concentrations, and total dissolved solids, are key for understanding how brines form and their economic values. According to the Mineral Resources Handbook, for water bodies, a salinity value (total dissolved solids) (TDS) of less than 1 g/L is classified as fresh water, 1–3 g/L as brackish water, 3–10 g/L as salt water, 10 ‑ 50 g/L as saline water, and a salinity value of ⩾50 g/L as brine. The average salinity of seawater is 35 g/L (saline water) (Liu et al., 2023). As brine salinity increases, the contents of some components increase or decrease. For example, in the brine of the Kunteyi salt lake in the Qaidam Basin, the potassium and magnesium contents increase with increasing salinity, but the sodium and chloride contents decrease rapidly after the salinity reaches 340 g/L, as a result of sodium chloride crystallization. In addition, the calcium concentration decreases with increasing salinity, due to gypsum precipitation. The contents of some minor and trace elements, such as lithium and boron, generally increase with increasing salinity (Liu et al., 2023).

The formation of silica scaling in the brine injection pipeline is controlled by the chemical and thermodynamic properties of amorphous silica (Pambudi, et al., 2015). During the brine injection process, heat transfer occurs as the brine flows through the injection pipe. This process is exothermic, meaning the system releases heat to the surroundings because the brine's temperature is higher than that of the environment. The heat transfer process causes a distribution of brine temperature as it flows along the injection pipeline. The chemical attribute of amorphous silica that significantly impacts scaling formation is its saturation solubility in relation to temperature. The variation in brine temperature during the injection process leads to a decrease in the saturation solubility of amorphous silica along the injection route. Brine contains cations such as K^+, Ca^{2+} , Na^+, Mg^{2+}, Li^+, B^{3+}, Rb^{2+} , and Cs^{2+}, as well as anions such as SO_4^{2-} , Cl^-, HCO_3^-, CO_3^{2-}, NO_3^-, Br^-, and I^-, which are valuable elements (Liu

et al., 2023). Chemical analysis of anions and cations in brine at the Dieng geothermal power plant shown in Table 1 (Juhri, et al., 2019 and Pambudi, et al., 2015).

Table 2 presents the chemical composition of the brine from the Dieng geothermal power plant. The concentration of each element is measured in parts per million (ppm). Silicon dioxide (SiO2) ranges from 1065 to 1400 ppm. Silica is commonly found in geothermal brine and can lead to scaling in equipment if concentrations are high. Chloride (Cl) is found in high concentrations, ranging from 21200 to 28400 ppm, indicating the high salinity of the brine. Sulfate (SO4) has a concentration of 74.4 ppm, an important component though present in lower amounts compared to chloride. Lithium (Li) concentrations range from 40 to 60 ppm, valuable for its use in battery production. Sodium (Na) is another major cation in the brine, with concentrations between 8340 and 11460 ppm. Potassium (K) ranges from 2520 to 3340 ppm, another significant cation. Magnesium (Mg) is found in very low concentrations at 0.5 ppm. Calcium (Ca) ranges from 440 to 860 ppm and can contribute to scaling when reacting with carbonates or sulfates. Bicarbonate (HCO3) has a concentration of 25.0 ppm, indicating dissolved carbonates which can also lead to scaling. Iron (Fe) is present at 1.35 ppm and can cause corrosion issues in equipment if found in higher concentrations. Finally, aluminum (Al) is found in very low concentrations at 0.01 ppm.

3.1. Behavior of silicic acid in brine

Silicic acid (H_4SiO_4) in geothermal brine exhibits complex behavior influenced by several factors such as temperature, pH, concentration, and the presence of other ions. Silicic acid has limited solubility in water and remains in its monomeric form at lower concentrations. However, as the concentration increases, particularly in geothermal brine, it tends to polymerize into larger molecules like dimers, trimers, and colloidal silica particles, leading to the formation of silica deposits or scaling. The temperature in geothermal environments significantly affects this process; higher temperatures accelerate the polymerization of silicic acid, resulting in faster silica scale formation on surfaces like pipes, turbines, and heat exchangers. The pH of the brine also plays a crucial role in determining the speciation of silicic acid. At neutral to slightly acidic pH, it remains mostly monomeric, whereas in more alkaline conditions, it deprotonates to form silicate anions, which are less likely to polymerize. Additionally, the ionic strength of the brine, influenced bythe presence of ions such as sodium, calcium, and magnesium, can either inhibit or promote polymerization depending on their concentrations and interactions with silicic acid. Silica scaling poses a significant operational challenge in geothermal power plants by reducing efficiency, increasing maintenance costs, and causing downtime. Various strategies are employed to mitigate silica scaling, including pH adjustment, the use of chemical inhibitors, regular mechanical removal of deposits, and gradual cooling of the brine to prevent rapid polymerization. Understanding the behavior of silicic acid in brine is essential for efficient geothermal power plant operation, enabling the management of factors that influence silicic acid behavior to minimize the negative impact of silica scaling and maintain optimal system performance.

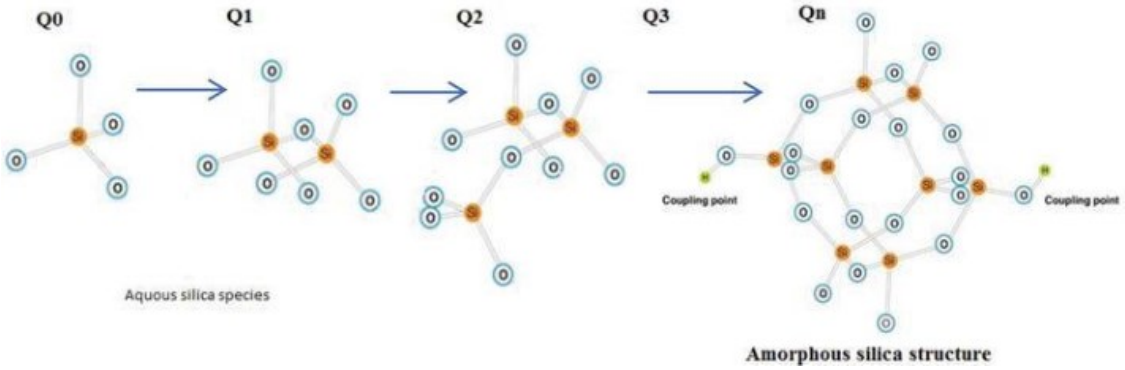

Figure 3: Mechanism of dissolved silica species (Q0 < Q1 < Q2 < Q3 aggregation) polymerisation into amorphous silica structure (Luvenich, 2020).

Dissolved silica species polymerisation path or aqueous silica solubility showns in Figure 3. The process begins with monomeric silica species (Q0), which are individual silicon atoms bonded to hydroxyl groups. These monomers can polymerize to form dimers (Q1), trimers, and eventually larger oligomers (Q2), as the silicon atoms bond together through siloxane bonds (Si-O-Si). As the polymerization continues, the oligomers grow into larger structures (Q3) through further condensation reactions. Finally, these increasingly complex structures aggregate to form amorphous silica (Qn), a non-crystalline, random network of silica. This process involves coupling points where the individual silica species join, leading to the formation of the extensive, interconnected network characteristic of amorphous silica.

3.2. CaO addition to brine

The addition of calcium oxide (CaO) plays a crucial role in enhancing silica recovery. When CaO is introduced into the brine, it reacts with dissolved silica species to form calcium silicate compounds. This reaction promotes

the precipitation of silica, converting it from its dissolved state into a solid form that can be more easily removed from the solution. During the entire retention time, the total concentration of silicic acid in the brine decreased immediately after the addition of CaO. The concentration of silicic acid decreased by around 34% upon addition of 5g CaO at a retention time of 60 min. The total concentration of silicic acid at the Dieng Geothermal Plant was reduced to less than 350 mg/L by adding 5 g/L CaO at a retention time of 60 min. The target silicic acid concentration in the treated brine is about 380 mg/L, which is the solubility of amorphous silica (Fournier, 1977). So in this study the recovery of silicic acid was in accordance with the solubility limit of amorphous silica.

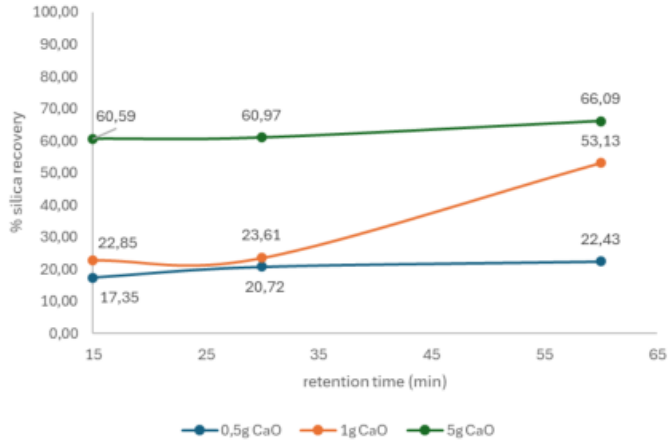

Figure 4: Percentage of silica recovery at various residence times.

The Figure 4 illustrates the effect of CaO addition on silica recovery at three different CaO concentrations (0.5g, 1g, and 5g) over retention times of 15, 30, and 60 minutes. The recovery of silica increases slightly from 17.35% to 22.43% at 0.5g CaO, more significantly from 20.72% to 53.13% at 1g CaO, and from 60.97% to 66.09% at 5g CaO. This trend suggests that higher concentrations of CaO and longer retention times both contribute to increased silica recovery. The underlying reason for this behavior lies in the chemical interactions between CaO and silica. Calcium oxide (CaO) can react with dissolved silica in the brine to form calcium silicate compounds, which precipitate out of the solution. Higher concentrations of CaO provide more reactant available to interact with silica, leading to a greater amount of silica being precipitated and thus recovered. Additionally, longer retention times allow more time for these chemical reactions to occur and for the precipitated silica to settle out, further enhancing recovery. Therefore, both the amount of CaO and the retention time are crucial factors in maximizing silica recovery from geothermal brine.

The addition of CaO increases the pH of the brine, further driving the polymerization and precipitation processes. When 5 g/L CaO is added, the pH increases to about 10. This indicates that returning the treated brine through the reinjection well requires adjusting the pH to neutral or slightly alkaline by adding acid to suppress the reaction between the treated brine and surrounding rocks in the reservoir. As the pH rises, silicic acid deprotonates and forms silicate anions, which readily combine with calcium ions (Ca^{2+}) provided by the CaO. This reaction leads to the formation of calcium silicate hydrates, which precipitate out of the solution. In the neutral pH regions, $SiO_2aq/H_3SiO_4^-$ (or $SiO_2aq/Si(OH)_3O^-$) mol ratios are approximately 1/1000, decrease with increasing pH and are almost unity at pH >10 ($H_3SiO_4^-$ is the dominant species). For Ca species, Ca^{2+} ions are always the dominant ones (Ca^{2+} /$CaCl^+$ mol ratios are always~1.2), and Ca^{2+}/ $H_3SiO_4^-$ and $CaCl^+$/ $H_3SiO_4^-$ mol ratios become 10.5 (Ueda et al., 2003). These results demonstrate that Ca reacts with SiO_2 and $H_3SiO_4^-$ and that the surface of the silica deposits is covered by the dominant species in the brines, i.e. $H_3SiO_4^-$ at pH <10.5, and Ca^{2+} and/or $CaCl^+$ at pH >10.5.

At a pH of 6.77 in these brines, it was observed that the amount of silica extracted from geothermal brines increased. Thomas (1992) noted that raising the pH by adding NaOH to Hawaiian geothermal brines with SiO2 and Ca concentrations of 700 and 500 mg/l, respectively, led to a reduction in total silica levels. Significant silica deposition in the brines occurred at pH levels exceeding 10 (Kato et al., 2003). Table 3 presents findings from the addition of quicklime without pH adjustment. Increasing the reagent concentration resulted in a decrease in the total silica concentration of the brines, with pH levels rising from 6.71 to 11.74 due to the generation of OH- ions through the addition of quicklime ranging from 0.5 to 5 g/l, respectively. Similar outcomes were observed at the Mokai geothermal plant in New Zealand, where most silica could be removed from the brines at pH levels exceeding 11 (Ueda et al., 2003).

The recovery of silica through the addition of CaO is a strategic approach that addresses both operational efficiency and maintenance concerns in geothermal power plants. By facilitating the precipitation of silica, CaO effectively reduces the concentration of dissolved silica in the brine, thereby mitigating the risk of silica scaling. This scaling can otherwise lead to significant performance degradation of the plant's equipment, such as heat

exchangers, turbines, and pipes, due to the accumulation of amorphous silica deposits. The precipitated calcium silicate can be easily separated from the brine through filtration or sedimentation processes, ensuring that the brine entering the geothermal system is much cleaner and less likely to cause scaling.

Table 3: Effect of adding quicklime (CaO) on pH.

Code	pH
Sample 1	6.71
Sample 2	7.57
Sample 3	8.17
Sample 4	7.77
Sample 5	8.11
Sample 6	9.34
Sample 7	9.37
Sample 8	10.74
Sample 9	11.74

Moreover, this method of silica recovery preserves the integrity of the geothermal infrastructure. By continuously removing silica from the brine, the lifespan of the equipment is extended, and the frequency of maintenance shutdowns is reduced. This results in more consistent energy production and lower operational costs. Additionally, the recovered silica, in the form of calcium silicate, has potential applications in various industries, such as construction and materials science, providing an opportunity for resource recycling and value addition.

4. CONCLUSION

In conclusion, adding CaO for silica recovery is an effective method to prevent scaling and maintain the efficiency of geothermal power plants. Silica recovery shows a slight increase from 17.35% to 22.43% with 0.5g of CaO, a more significant rise from 20.72% to 53.13% with 1g of CaO, and from 60.97% to 66.09% with 5g of CaO. This pattern indicates that higher CaO concentrations and longer retention times enhance silica recovery. By exploiting the chemical interactions between CaO and dissolved silica, geothermal plants can improve performance, reduce maintenance costs, and potentially generate valuable by-products. For future research, it is recommended to conduct silica recovery using a series of test circulations or a closed-loop system to better simulate the actual process in a geothermal power plant.

Keywords: Organic Rankine Cyle, Silica Deposition, Cleaning

ABSTRACT

The development of ORC (Organic Rankine Cycle) technology at Sorik Merapi Geothermal Field represents a significant advance in the utilization of geothermal energy. The ORC technology from Kaishan Group can extract more energy from brine. However, the ORC operations are challenged by rapidly changing operational conditions, particularly fluctuations regarding temperature and pressure. These changes can lead to technical issues, including the formation of silica scale deposits within ORC tubing, which adversely affect the ORC's performance and longevity. Scale deposit may cause lower heat exchange process in the system which have necessitate shutdowns for cleaning the tubing. This also effects on efficiency and reliability of the ORC.

To overcome this challenge, chemical methods have been implemented at Sorik Merapi. This method involves dissolving the scale deposits into smaller deposits, even reducing into monomeric silica form. The cleaning procedure includes identifying the suitable chemical and soaking it in the Heat Exchanger tubing before continuing with mechanical cleaning out with water.

The result of this method has been promising. It has effectively restored the heat transfer efficiency and recover the brine flow inside the tubing. The ability to perform cleaning efficiently and with minimal operation disruption ensures that the ORC system can maintain high performance and reliability.

1. INTRODUCTION

Sorik Marapi Geothermal Power project is located in Mandailing Natal regency, North Sumatra. Total generation until January 2024 is 160 MWe. The utilization of Brine ORC (Organic Rankine Cycle) namely ORC-XV begins in June 2021 during unit 2 commissioning. Dengan installed brine ORC-XV from Kaishan Group adds generation 2.5 MW with flow rate 380-400 M3/hr. The brine ORC transfers the heat from the brine to the secondary fluid medium which cause the brine temperature to reduce from 143°C to 75°C. With this energy extraction, reduction in temperature, and the chemistry in the brine, the silica saturation index will increase from 1.11 to 2.41 which indicates that silica scaling and deposition potential will increase during the extraction process, as amorphous silica has prograde solubility with regards to temperature (Fournier and Rowe, 1977).

In extracting geothermal energy, particularly in brine ORC system, silica has long been a critical factor that limits the energy extraction from geothermal fluid. Silica deposition forms a highly insulative that reduce the heat transfer. At severe condition, the silica deposition can hinder the fluid flow to the brine ORC system and reduce injectivity in the reinjection well. The layer that formed, apart from being insulative, it also very tenacious and difficult to remove.

The silica deposition is the result of multiple coexisting chemical reactions and processes in the geothermal fluid: direct deposition of monomeric silica, co-precipitation with other minerals and ions (mostly metals), and monomeric silica polymerization (Gill and Jacobs, 2018). Many chemical and physical parameters, such as the concentration of silica and other minerals, temperature (Fournier et al., 1983), Setiawan et al., 2019), binary unit design (Grassiani, 2000), acidity (Addison, et al., 2015), and others, influence these reactions and processes. To stop silica deposition, every reaction, process, and variable needs to be managed at the same time.

It cannot be denied that even though silica inhibitors are used, the silica scale will still be formed, therefore clean-out is carried out using combination of chemical and mechanical methods to remove scaling in the heat exchanger tubing if generation lower than 80% compared to original performance.

2. METHODOLOGY

Silica (SiO_2) exists in a number of different forms. Quartz (crystalline silica) is one of the most abundant minerals in the Earth's crust and exists as such in the geothermal reservoir, while it is normally precipitated in surface

equipment as amorphous (non-amorphous) silica. As is the case for most minerals, amorphous silica has prograde solubility with regards to temperature (Fournier and Rowe, 1977) as shown in the equation: *log C = -731/T + 4.52,* where C and T are silica concentration and temperature, respectively. Because of this, amorphous silica is one of the most ubiquitous minerals found in geothermal heat exchangers (Zarrouk, 2019). The difference in the solubility of quartz and amorphous silica (see Figure 1) allows the operationality of geothermal power development, otherwise any temperature decrease will lead to silica scaling immediately (Brown, 2011).

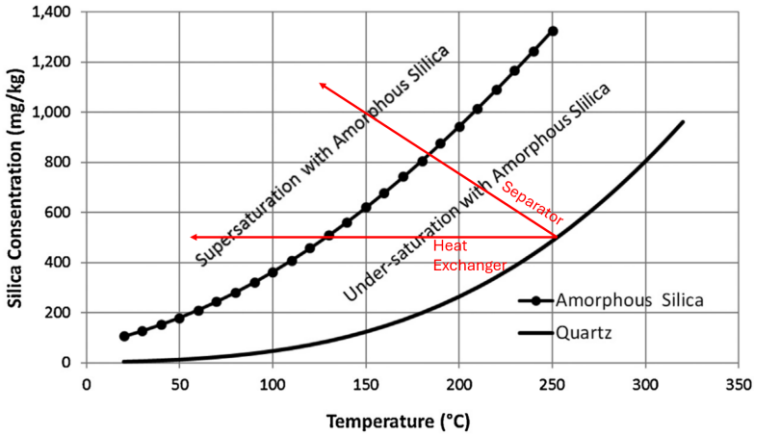

Figure 1: Solubility of quartz and amorphous silica with temperature (Modified from Zarrouk et al., 2014).

One of the most widely used method to prevent silica scale deposition is pH-modification (reduction) which retards the precipitation and deposition of amorphous silica in surface facilities (Gallup, 2011). It is considered a cost-effective approach in dealing with silica scaling. Another scale control method is by using of polymeric silica inhibitors which has the advantage of lower corrosion rates compared to the former. Silica inhibitors can be considered at brines where high silica concentration drives scale formation (Finster et al, 2015). Several tests in the laboratory and in the field were done by geothermal industry experts in the past (Mejorada et al., 2000; Baltazar et al., 2014; Gill and Jacobs, 2018). These studies showed field testing is one of the keys to determine and effectively implement a working and economical method to minimize silica scaling.

Despite efforts to mitigate silica deposition, clean-out of geothermal pipelines and heat exchangers are still needed periodically. Silica deposition leads to deterioration of heat transfer and reduction in power generation of ORC units. Candido and Zarrouk (2017) studied different cleaning methods accounting for both technical and economic aspects to be applied in a binary plant in the Philippines. The methods involved water blasting, mechanical cleaning, chemical cleaning (using HCl, HF acid and inhibitor) or a combination of these.

Caustic solution can also dissolve silica scales and calcite scales in the presence of a chelating agent was shown by some studies (Xu et al., 2009; Rose et al, 2010) in laboratory experiments and in simulation software. This is also in line with the experiments conducted by Lichti et al. (2000) in Ohaaki that silica scaling can be prevented by increasing the pH of the brine using alkali solution. Caustic soda was also shown to be able to disilicate geothermal brine in the experiment by Gallup (2003). This is because solubility of silica increases at higher pH, where the weak silicic acid (H_4SiO4) dissociates to H^+ and H_2SiO4^- ion at very high pH (Brown, 2011). The solubility of amorphous silica as a function of pH is illustrated in the graph below:

The graph in Figure 2 shows that the solubility of amorphous silica sharply increases as the pH increases. The abovementioned studies show that combination of caustic chemicals and thermally stable chelating agents can be effective approach to mineral dissolution or chemical cleanout in geothermal. In this paper, chemical clean-out was also implemented using NaOH and chelating agent to dissolve the silica deposits in the ORC. The method is done by injecting chemicals inside the heat exchangers, soaking, disposing it, then repeating the process until the clean-out is complete. The main equipment and tools used are chemical dosing pump, chemical tank, hose, and NaOH IBC tank. The key parameters monitored are pH, temperature, pressure, silica concentration and conductivity.

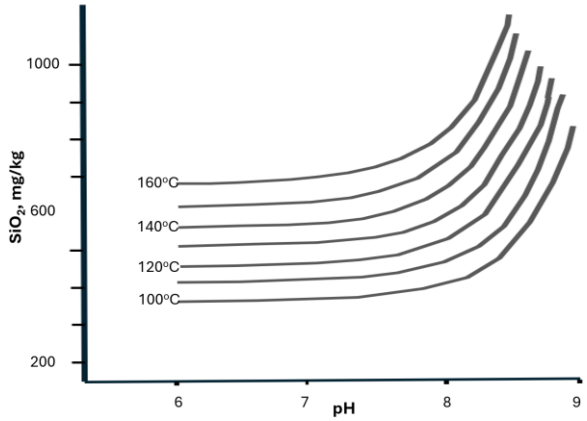

Figure 2: Solubility of amorphous silica with pH (Modified from Brown et al., 2011).

The cleaning process was started by filling the system with hot brine, followed up by turning on the heater and circulation pump. It is critical to keep the temperature within 70-80°C to reduce risk of coagulation of particles. NaOH was then injected until pH reached and stabilized at 12-13, followed by chemical dosing. Soaking of the heat exchangers was done for about six hours before flushing as certain silica concentration and conductivity thresholds were reached. This process was repeated until silica concentration in the solution dropped to the original concentration in the brine. The whole chemical cleanout was run for 36 to 48 hours per ORC. More details in the method are discussed in the Clean Out Program section in this paper.

3. PLANT OPERATING CONDITION

The Brine ORC-XV plant captures the energy from the geothermal brine that collected from two production wells. The plan diagram can be seen Figure 1. The chemistry and thermodynamic properties from each production well can be seen in Table 1.

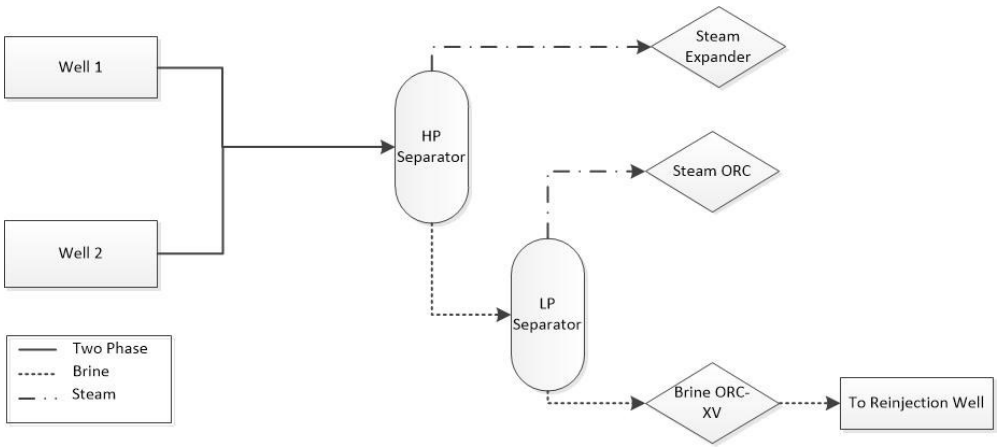

Figure 3: Sorik Marapi Geothermal Field Unit-2 ORC Plant Diagram.

Table 1: Sorik Marapi Geothermal Field Unit-2 ORC Plant Production Well Properties.

Parameter	Well 1	Well 2
Enthalpy (kJ/kg)	1044	1122
Flow Rate (ton/hour)	270	226
Sampling Temperature (0C)	167	167
pH at 250C	8.4	8.5
Silica (ppm)	555	610
Aluminum (ppm)	0.79	0.86

As can be seen in Figure 1, there are three High Pressure separators and one Low Pressure separator. The steam from all HP separators will be combined and sent to Steam Screw Expander. The brine from HP separator combine with two phase fluid from Well 1 and 2 separated once more in LP separator. The brine from LP Separator sent to brine ORC, while the steam go to Screw Expander and the excess team going to Steam ORC. Based on the

operating condition in each separator, the chemical properties and operating condition at the brine ORC inlet can be seen in Table 2.

Table 2: Sorik Marapi Geothermal Field Unit-2 ORC Plant Chemistry & Operating Condition.

Parameter	Brine ORC
Inlet Temperature (^{0}C)	144
Outlet Temperature (^{0}C)	75
Flow Rate (ton/hour)	380-400
Silica (ppm)	~647

Based on the profile temperature in the Brine ORC, we used the formula from Fornier and Rowe, 1977 to simulate the silica saturation index (SSI) based on Amorphous silica solubility, to understand the degree of scaling in the system. The result of simulation can be seen in Figure 4.

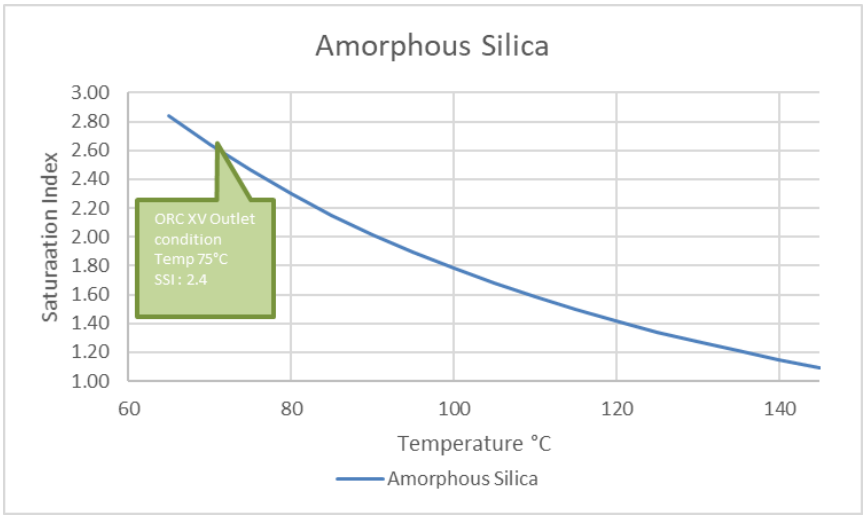

Figure 4: Silica Saturation Index at Brine ORC-XV.

From the Figure 4, it can be seen that the brine at 90^{o}C is in supersaturated condition (SSI 2.09). Therefore, the silica scaling is inevitable and must be mitigated to maintain the heat transfer rate.

4. SILICA INHIBITOR IMPLEMENTATION RESULT

Silica inhibitor has been implemented to prevent silica scale formed in Heat exchanger. The system is closely monitored to determine the effectiveness of this program. The lead parameters that monitored are brine ORC differential pressure, monomeric silica at the inlet and outlet of brine ORC (%polymerization), and the lag parameter is generation.

4.1 Lead Parameter

Monitoring the lead parameter conducted on daily basic. Monomeric silica analysis can be used to determine the silica deposition rate in the system. If well maintained in the monomeric form, the system's deposition rate will be reduced. The monomeric silica analysis can be used to optimize the inhibitor dosage according to requirements because it is done on-site. The inhibitor dosage is deemed sufficient to prevent polymerization if the monomeric silica at the brine ORC outlet is kept at a value of more than 90% of the brine ORC inlet silica concentration (<10% polymerization) as the result,the silica polymerization is able to maintained below 10% with average polymerization is 5.8%.

Delta temperature is obtained from subtracting the inlet temperature from the outlet temperature. The delta temperature will increase as the result of scale, the heat extraction is not in the optimized caused by silica scaling forming in the tubbing. Monitoring delta temperature shows the temperature can be maintained.

Similar with delta temperature, Delta pressure is obtained by subtracting the inlet pressure and outlet pressure. If scaling takes into account the delta pressure, it will increase as the result of blocked tube by scaling silica in the heat exchanger. The Figure 3 suggest that delta pressure is well maintained in a range.

4.2 Lag Parameter

Generation is a lag parameter to determine the success of silica inhibitor treatment. Unlike lead parameter which can be monitored on daily basic and corrective action taken immediately. The generation will be affected if scaling has been formed in Heat exchanger.

Even though the lead parameters show that everything is on target, it cannot be denied that silica scale still forms. However, with management using silica inhibitor chemicals to prevent scale, the generation is able to maintain 80% of its initial capacity. In the case of ORC-XV, modifications were made in October because the source was divided into SMGP U-4 , thus the maximum generation could not return to the condition in February.

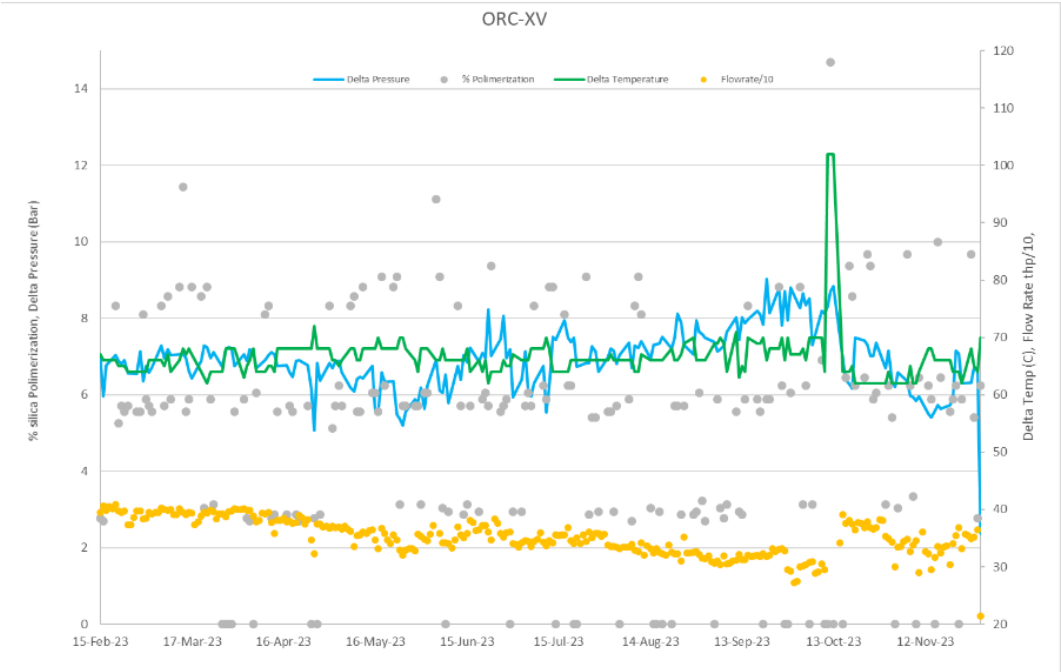

Figure 5: ORC-XV Lead Parameter.

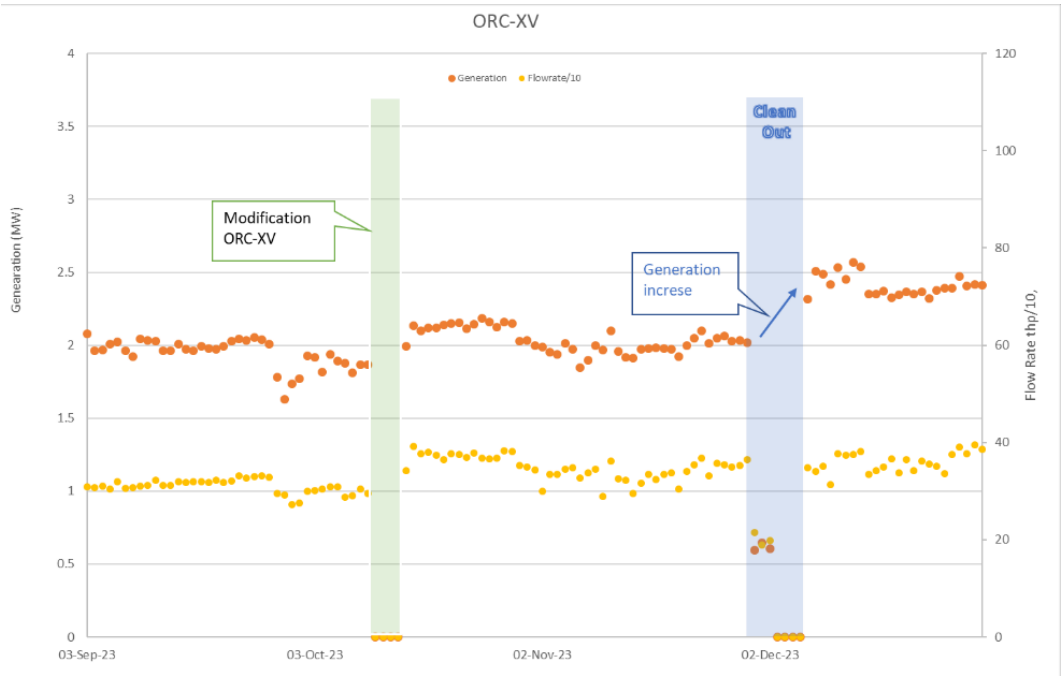

Figure 6: ORC-XV Lag Parameter.

5. CLEAN OUT PROGRAMS

The clean out program carried out is a hybrid using chemical and mechanical. Chemical is carried out first before opening the cover or head of the heat exchanger. The chemical used uses NaOH and cleating agent to dissolve complex silica deposits (T.R McCartney, etc, 2017). The mechanism process is begins with the mixed scale formation in metal surfaces meet with chemical dissolver to become smaller deposit chipping, polymeric silica, monomeric silica, metal silicates and metal ions. It acts as a nucleus for seeding reaction promoting scaling and deposition in the downstream. Increase scaling deposition tendency.

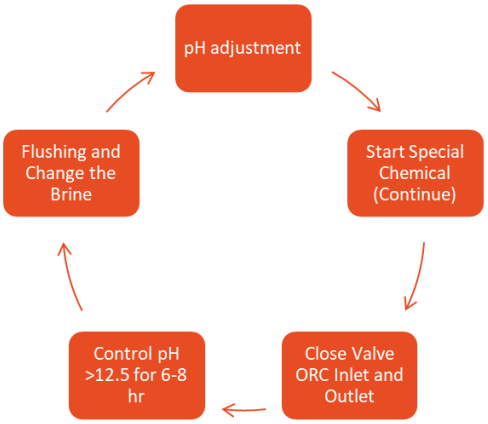

Figure 7: Chemical Clean Out Method.

Chemical clean out is used by the soaking method where NaOH plus cleaning agent chemical is injected into the system and the chemical is routinely replaced when it is saturated (Figure 7). Chemical clean out is carried out for ± 36 hours. During the clean out program, several parameters are monitored, namely pH, electric conductivity (EC) and silica.

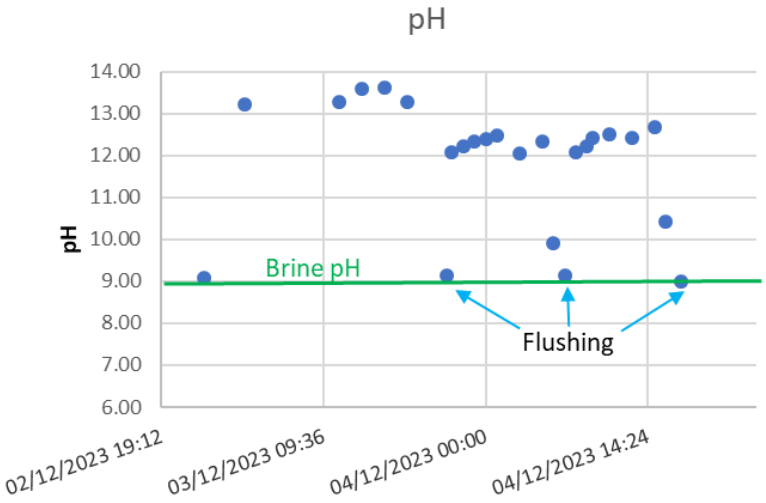

Figure 8: Online Clean out pH monitoring.

The original pH of brine is 8.8, thus during clean out we need to increase the pH to achieve above 12 therefore the cleaning agent, as dissolving chemical is able to dissolve silica. During clean out activity, there were three times to replace chemicals, this is show by the fluid pH being below 10 in the Figure 8. A high EC value indicates that the silica has been dissolved and if the value is stable, it means that the chemical is no longer able to dissolve the silica so it must be replaced, due to limitation of measuring instrument, the maximum EC value is 200,000 ms. Silica concentration monitoring is carried out to ensure that the silica is too high. A high silica value indicates that the chemical clean out has succeeded in dissolving the silica (Figure 9), the silica concentration as baseline is ~660 ppm and during clean out silica increase up to 2,100 ppm.

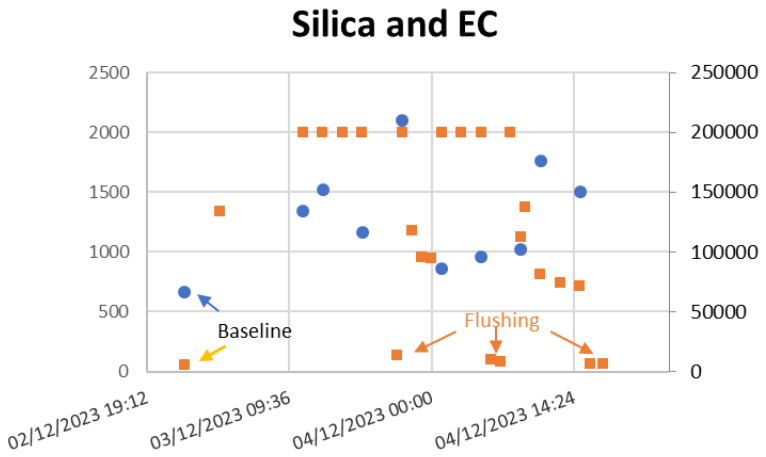

Figure 9: Online Clean out Silica and EC Monitoring.

After the chemical clean out is finished, the mechanical clean out was carried out to remove the silica that has fallen out and clean up the remaining scaling residue. After cleaning out the generation rebounded to the state before the scale occurred, in the case of ORC XV the generation increase was 0.4 MW.

6. CONCLUSION

Managing the silica scale at Sorik Marapi was implemented by using a chemical silica inhibitor to prevent silica, the results show that for approximately a year the generation was able to maintain 80% of the original design at SSI 2.4. A hybrid clean out using offline chemical and mechanical methods is carried out if the scaling has been formed with a lag parameter in generation. The result of clean out the generation is able to rebound to near original design.

ABSTRACT

Realizing the target of 1 GW installed geothermal capacity is the main goal and commitment of PERTAMINA Geothermal Energy Tbk. (PGE) to maximize the potential of renewable energy in Indonesia. This goal inevitably comes with various challenges, both technological and commercial, including drilling activities that play a crucial role in accelerating the realization of this target.

One of the major challenges faced by PGE occurred during the PGE Drilling Campaign at well UBL-M.3, where a downhole problem arose involving the stuck of Running Tools and the drill pipe during the cementing process in the 17.5" Hole Section. This issue was caused by a technical error related to the timing of pulling up the running tool with the thickening time of the cement.

Given that UBL-M.3 is a high-stakes well with significant gigawatt potential, all possible efforts were made to recover the well. These efforts included Working Pipe to release the stuck assembly, Mechanical Back Off to reduce the length of the fish to facilitate the fishing process, Running OEDP Jetting Tools, Rotary Shoe, and Guide Shoe to grind-out the cement around the fish with jetting effects, and eventually, deciding to perform a 20” Casing Sidetrack Open Window.

There were many debates and challenges to overcome in executing the Sidetrack Open Window process, ranging from procurement issues and limited availability of tools, long delivery times for equipment, well integrity issues, high index directional drilling challenges, and most critically, the lack of experience with sidetracking 20” casing in geothermal wells operated in Indonesia.

This paper will discuss the process and long journey of the Success Story of the 20” Casing Sidetrack Open Window in well UBL-M.3, and the lessons learned to prevent similar issues in the future, thereby facilitating smoother drilling operations.

1. INTRODUCTION

The Ulubelu Geothermal Area is located in the Tanggamus Regency of Lampung Province, within the Pulau Panggung District, approximately 100 km west of Bandar Lampung. The area can be accessed by a four-wheeled vehicle via a paved road from Bandar Lampung to the Pulau Panggung District, followed by a roughly 15 km stretch of rocky and partially paved road towards Ulubelu.

Geoscience and reservoir studies have revealed that the reservoir zone in the northern sector, which is close to the upflow zone, contains high-enthalpy fluid (2600 kJ/kg) and high temperature (270 – 280°C), along with high non-condensable gas (NCG) content (1.4-1.7 wt%) but moderate permeability (300-900 lpm/ksc). Nearly all wells in this zone exhibit relatively high production outputs between 18-30 MW with high dryness (50-90%). However, there is a possibility that the reservoir characteristics could align with the wetter cluster I or K due to the location of M in between them. These makeup wells are also intended to replace the loss or decline in production from these wells.

The top of the reservoir in the northern sector is located around sea level. The depth of the feed zones in this sector has been well mapped using PTS injection and production data. Generally, productive feed zones are found at depths ranging from -150 to -750 meters above sea level. The permeability control of the reservoir is influenced by fracture zones-oriented NW-SE and NNW-SSE (Karangrejo Fault trend) and the lateral permeability of the matrix in the Rhyolitic Tuff formation.

UBL-M.3 is one of the well which are drilled in the PGE Ulubelu area. This well is considered a crucial and concluding well of the PGE Drilling Campaign 2023-2024 in the PGE Ulubelu Area. It is a directional makeup well with four hole sections: 36", 26", 17.5", and 12.25". The well has a total depth of 2156 mMD, a kick-off point at 150 mMD, a hole direction of N 49 E, and four targets located at depths of 1315 mMD, 1755 mMD, 1942 mMD, and 2068 mMD.

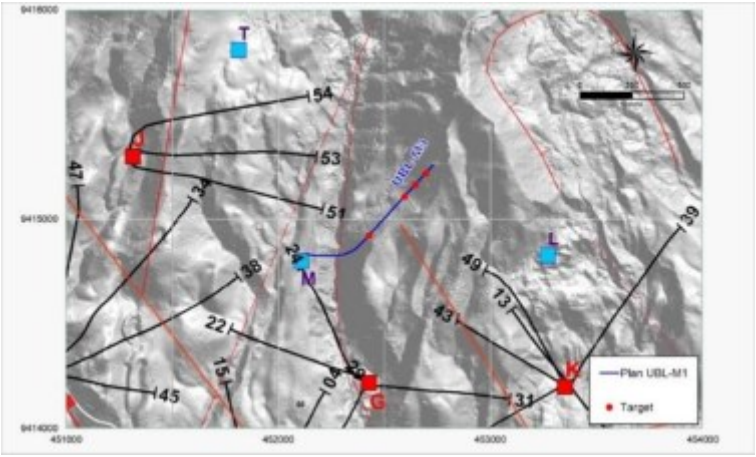

Figure 1: UBL-M.3 Well Targeting Map.

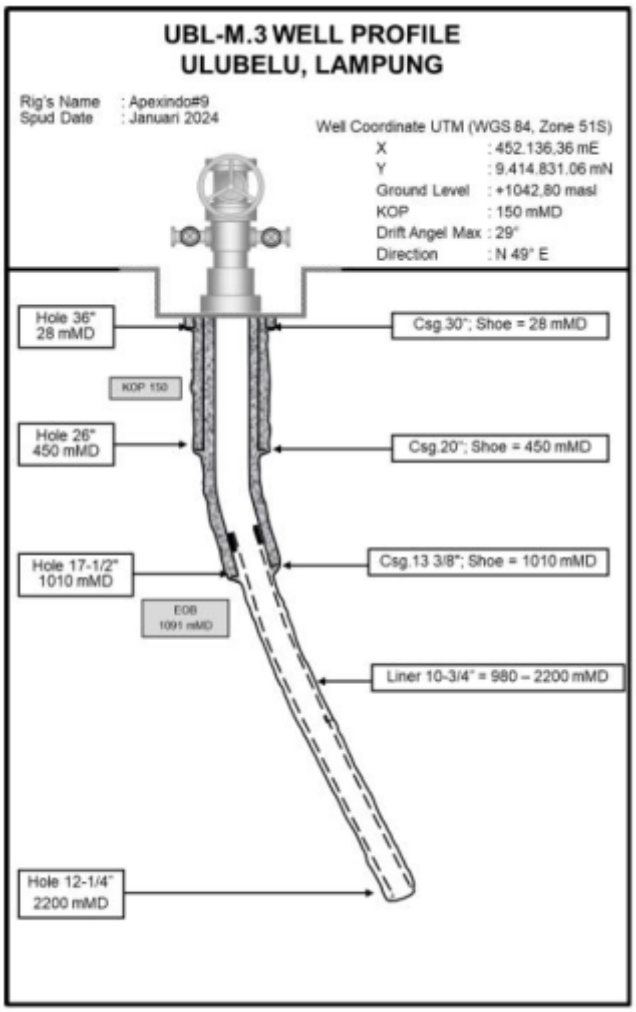

Figure 2: UBL-M.3 Well Profile.

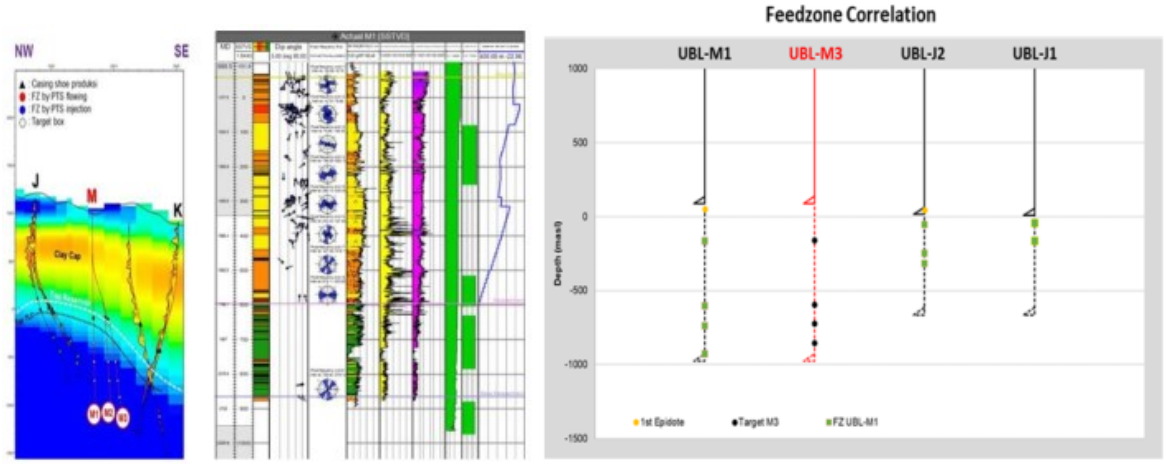
Well UBL-M.3 commenced drilling at 21:30 WIB on January 16, 2024. In actual operations, the drilling proceeded smoothly starting with the 36" Hole Section (0 - 28.5 mMD), which took 39.5 working-hours. This included the formation drilling, reaming, trips (B/O and L/D), circulation and conditioning of the hole, WOC, cutting of the 30" stove pipe, installation of the 29.5" bottom flange and the 30" x 1000 psi diverter, and performing the diverter function test.

Similarly, the 26" Hole Section (28.5 - 449 mMD) also progressed smoothly, taking 123 working-hours. This involved formation drilling, trips, circulation and conditioning of the hole, installation of the 20" casing,

cementing of the 20" casing, WOC, installation and function testing of the 21.25 x 2000 psi BOP, cutting off the casing, and other related activities.



Target	Keterangan	mMD	mKT	X	Y	Z
Target-1	Korelasi feedzone sumur UBL-51	1291	1215	452,459.76	9,414,901.90	-162
Target-2	Korelasi feedzone sumur UBL-51; 53; 54 & Fracture model	1786	1648	452,640.84	9,415,059.31	-595
Target-3	Korelasi feedzone sumur UBL-51, 53, Fault Kr. Rejo & Fracture model	1935	1778	452,695.16	9,415,106.53	-724
Target-4	Korelasi feedzone sumur UBL-43, Fault Kr. Rejo & Fracture model	2083	1908	452,749.48	9,415,153.75	-855

Figure 3: Feedzone Correlation and Distribution for UBL-M.3 Well Targetting.

The issue encountered with Well UBL-M.3, which will be discussed furthermore in the next section of this paper, occurred during cementing operations in the 17.5" Hole Section (449 - 1004 mMD).

2. RELATED WORK

Based on the previous study and experience, cementing, either it was in Geothermal or in Oil and Gas, is one of the most critical steps to done in drilling operation. Cementing is a key and essential part of the wellbore construction process (Lootens, 2004) and the integrity of the well construction depends to its cementing (Ridha et al., 2010), also cementing is the key to ensure the safety of the well and durability (Pourafshary et al., 2009 ; Ershadi et al., 2011)

Cementing techniques invlolve the deployment of cement slurry on the Geothermal Well annulus and casing to provide proper zonal isolation. The target is to completely hinder fluids in the well from Interacting from one part to another, provide an anchor for the casing, prevent corrosion of the Casing, prevent shock loads during drilling, prevent blowouts, plug off vugular zones or fractures, and the last is for Abandonment (Anaele et al., 2020).

Geothermal Cementing is one of the most challenging steps in Geothermal Drilling Operation. Besides of its criticality, the environment in geothermal is classified as High Pressure and High Temperature (HPHT). One of the cementing parameter, Thickening Time is affected by High Temperature. Thickening Time (TT) test was performed using a High-Pressure- High-Temperature (HPHT) Consistometer rated at a pressure of up to 206.8 MPa (30,000 psi) and temperatures of up to 204 deg-C (400 deg-F).

The cement slurry was mixed according to API procedures and then placed in a slurry cup into the consistometer for testing. The testing pressure and temperature were controlled to simulate the conditions the slurry will encounter in the well. The test concluded when the slurry reached a consistency considered unpumpable in the well. The time it takes the cement slurries to reach 40Bc, 70Bc and 100Bc consistency were recorded (Anon,1997 and 2013). The test was done at 80 deg-F, 100 deg-F, 120 deg-F, 140 deg-F and 160 deg F. From this study, it was shown that at constant concentration, increase in temperature leads to decrease in thickening time and leads to the faster setting of the cement slurry. (Anaele et al., 2020).

The issue of UBL-M.3 occurred during cementing operations in the 17.5" Hole Section while pulling the running tools and conducting drill pipe out of the hole after the first step of tieback cementing was completed. The chronology began with the process of pulling them out from 386 – 250 mMD and circulating the displacement

cement with a flow rate of 500 GPM and stand pipe pressure of 0 psi, with the water return obtained from the cementing process. The process of pulling the running tools and conducting drill pipe continue from depth 250 mMD – 241 mMD.

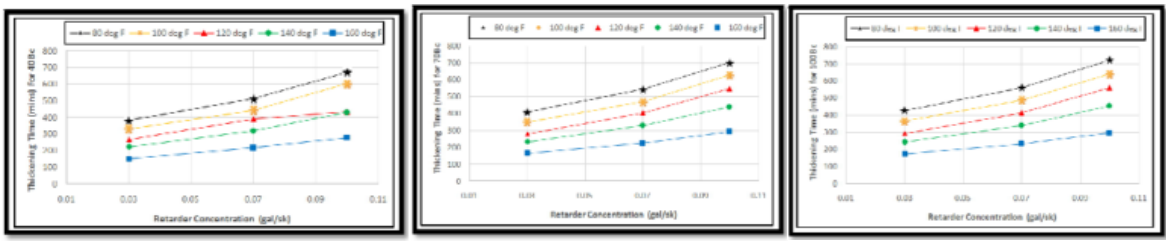


Figure 4: The Effect of Temperature on the Thickening Time at 40 Bc, 70Bc and 100 Bc.

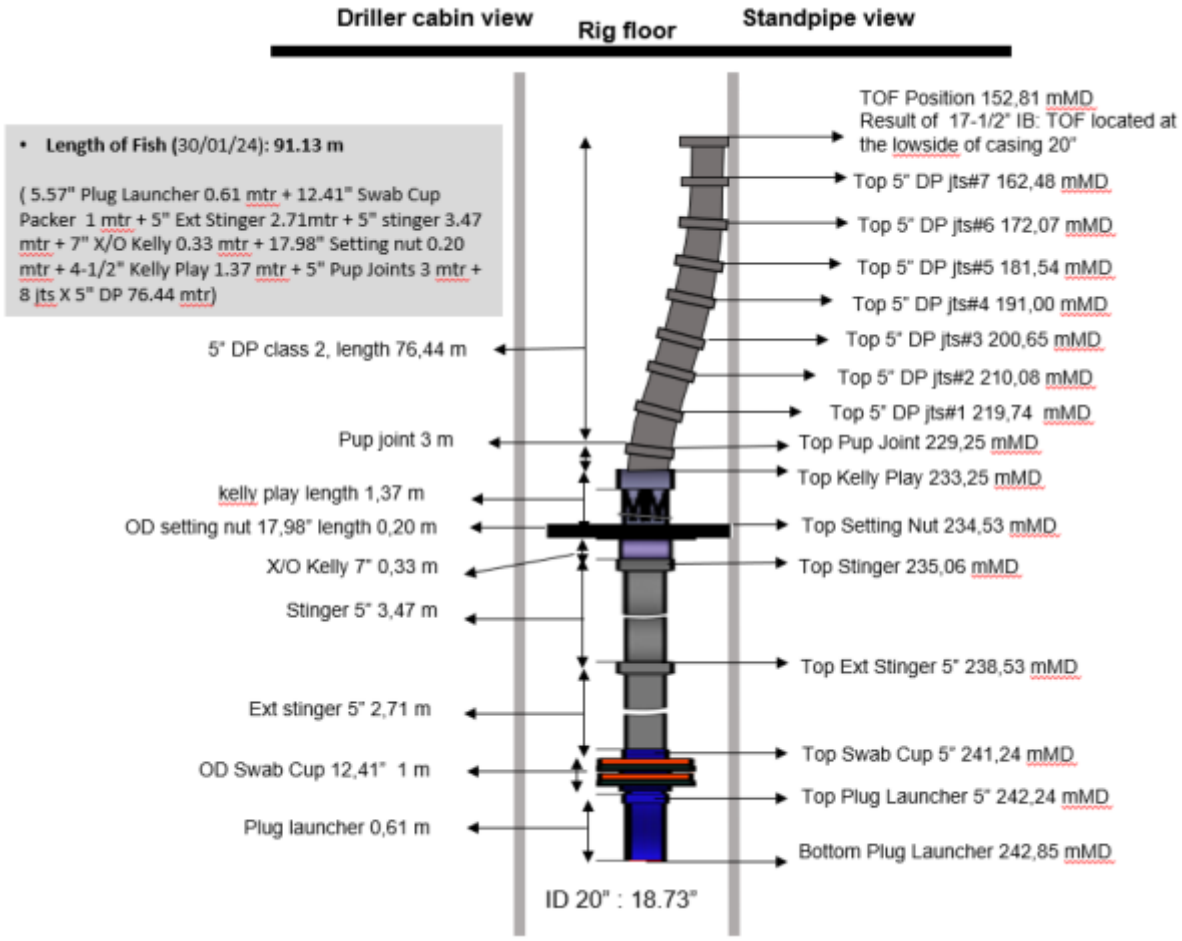

Figure 5: Running Tool Fish Illustration (Initial Condition).

While the pulling process is conducted at 241 mMD, drag overpull was found ranging from 40 – 110 klbs (the normal P/U is 60 klbs). Continued the effort to pull with reciprocating at interval 241-240 mMD, with a pulling force of 330-335 klbs, while pumping with a flow rate of 1210 gpm and stand pipe pressure of 380-415 psi. Tried rotating with a torque limit of 30-32 klbsft, but it was still unsuccessful.

The next plan, the decision to mechanically blind backed off the 5" drill pipe is taken with the string weight positioned at 70 klbs, setting torque to 32 klbsft, RPM 1-2, with two left turns achieving a torque of 28 klbsft. Lifted the assembly, pulling up weight of 50 klbs (indicating the 5" drill pipe had disconnected). Continued pulling the drill pipe assembly to the surface (retrieved 18 joints of 5" drill pipe).

There are several probable causes back then when the stuck of running tools is happened, caused by the early cement set. This early cement set caused by the dynamic condition of the borehole of UBL-M.3, therefore the Thickening Time is set earlier than the program. The combination between the high uncertainty of the subsurface condition (such as anomaly temperature increase, etc), which may lead to the unmatched chemical composition

of cement with its condition, causes the anomaly in the thickening time of the cement. The composition of the cement should have match with the dynamic condition of the well itself.

The other causes is the pumping speed when the cementing operation conducted. Due to the technical difficulties of the pumping speed while cementing, the cementing coverage to annulus isn't ideal enough. The cement that already set at the lowside solidified faster than the upper side while the cementing process hasn't done, and eventually causes the stuck running tools.

Finally, after all those efforts above are done with nothing in result, eventually the team decided to do the contingency plan consists of Fishing and Well Intervention Operations and Sidetrack Drilling.

3. METHODOLOGY

3.1 Fishing and Well Intervention Operations

Fishing and Well Intervention is the first option that the team decided to use to overcome this problem after all the jarring efforts are resulting none. These methods are done by the teamwork of all the parties that responsible and in charge for the Fishing and Well Intervention processes from Pertamina Geothermal Energy itself, PDSI-WIS (Pertamina Drilling Services Indonesia – Wellbore Integrity Solutions) from Fishing Services, and also Apexindo (APX-09) as the Rig Contractor.

The equipment provided by all the parties, whether from the Fishing and Well Intervention Tools, Drilling Bit, Drilling Accessories, and others. The journey of the well and geological recovery is not easy. There are so many trials and errors that done, using the combination between the equipment provided by PGE, PDSI-WIS and Apexindo itself, that summarized into the flowchart below until the team decided to do the accidental Sidetrack Drilling to Recover the Geological Prognosis at UBL-M3.

These activities in total spent about 858.5 Hrs of total NPT 1026.5 hours, contributed to the 46.48% of the total NPT percentage 55.58% from the whole drilling operation activity at UBL-M3 well. Therefore, the main contributor of the biggest NPT percentage contribution comes from the 17.5" Hole Section drilling activity due to this stuck running tools.

3.2 Sidetrack Drilling

After all the long journey and trial & errors of the Fishing Operation and Well Intervention activity have no success results, the team eventually decided to do the Sidetrack Drilling. Sidetrack Drilling at UBL-M3 well journey is not an easy thing to do. There are so many considerations, pros and cons and also debates and challenges to overcome in executing the Sidetrack Open Window process such as:

1. Procurement issues and limited availability of tools
2. Long delivery times for equipment
3. Well integrity issues
4. High index directional drilling challenge
5. Lack of experience with Sidetracking 20" Casing in geothermal wells operated in Indonesia.

For the technical of drilling operation itself whenever the decision to do the sidetrack is taken, there are no technical issues that faced by the team. All the sidetrack drilling operation working smoothly and so does the safety a spect.

4. RESULTS

Sidetrack Drilling of the UBL-M.3 Well commenced on March, 9th 2024 at 1:30 a.m. from depth 264 mMD (Hole Section 17.5"). The sidetrack drilling operation applies drilling parameter as the same normal Drilling Operation previously, such as WOB 5-30 klbs, FR 700-800 gpm, SPP 1400 – 1800 psi, etc. The sidetrack operation process are going smoothly, and finally reached the Total Depth of 2152 mMD at March, 29th 2024 at 19:00 a.m. The total amount of days needed to successfully conduct the Sidetrack Drilling from the depth where the running tools stuck until 2152 mMD is 20.72 days or approximately 497.5 hours of operation.

For the procurement isues and limited availability of tools, it contributed to a minor amount of NPT approximately 4-5 days due to the special requirements of tool to do the sidetrack activity. For Well Integrity issues, all the works are done safely whether is it from the Drilling aspect or the Geological aspect. There are no significant difference of formation lithology between the initial prognosis and the actual sidetrack operation. The geologist perform a real time analysis from the actual cutting that came out from the shale shaker, and found no difference prior to the previous prognosis. High index directional drilling challenge also can be overcomed safely without any issues.

Figure 6: Fishing and Well Intervention Operations Summary Flowchart.

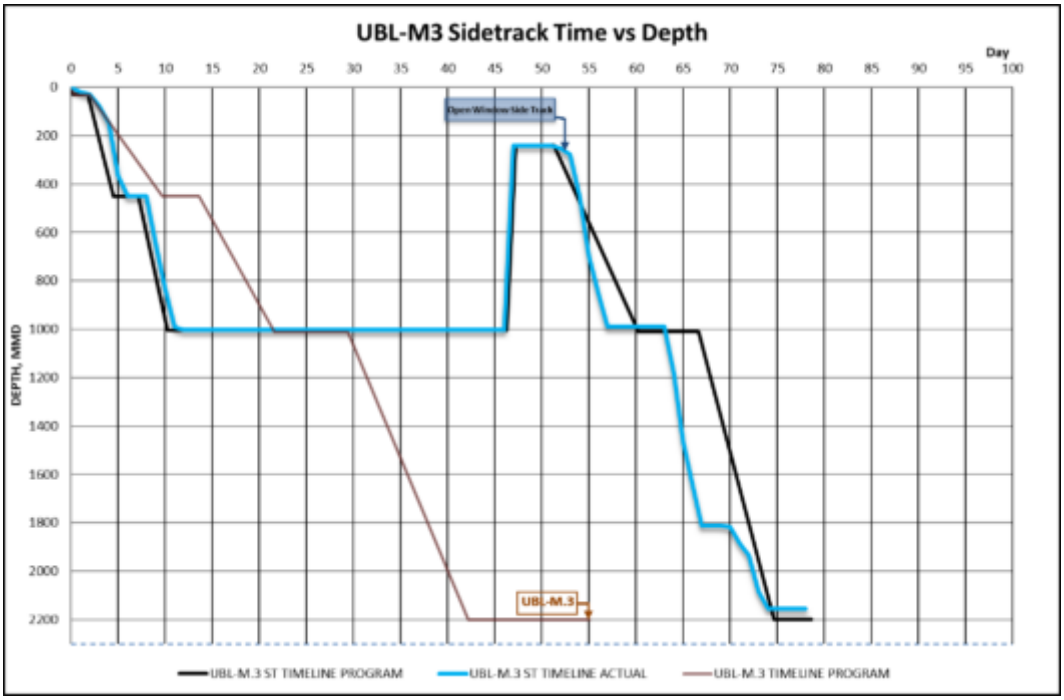

Figure 7: Time vs Depth UBL-M3 ST Graph.

5. DISCUSSION

Sidetrack Drilling of the UBL-M.3 Well all done in total amount of days needed to successfully is 20.72 days or approximately 497.5 hours of operation. The total amount of the UBL-M.3 days already included with the other NPT while the sidetrack operation is ongoing. The NPT breakdown besides the Fishing Operation are:

a. Well Control Operation (68.5 hours)
b. Other Services Problem (22.5 hours)

c. Circulating System Reparation (19 hours)
d. Directional Services Problem (9.5 hours)
e. Repair Power System (3.5 hours)
f. Wireline Services Problem (3.5 hours)
g. Aerated Drilling Services Problem (1.5 hours)
h. Location Problem (2 hours)

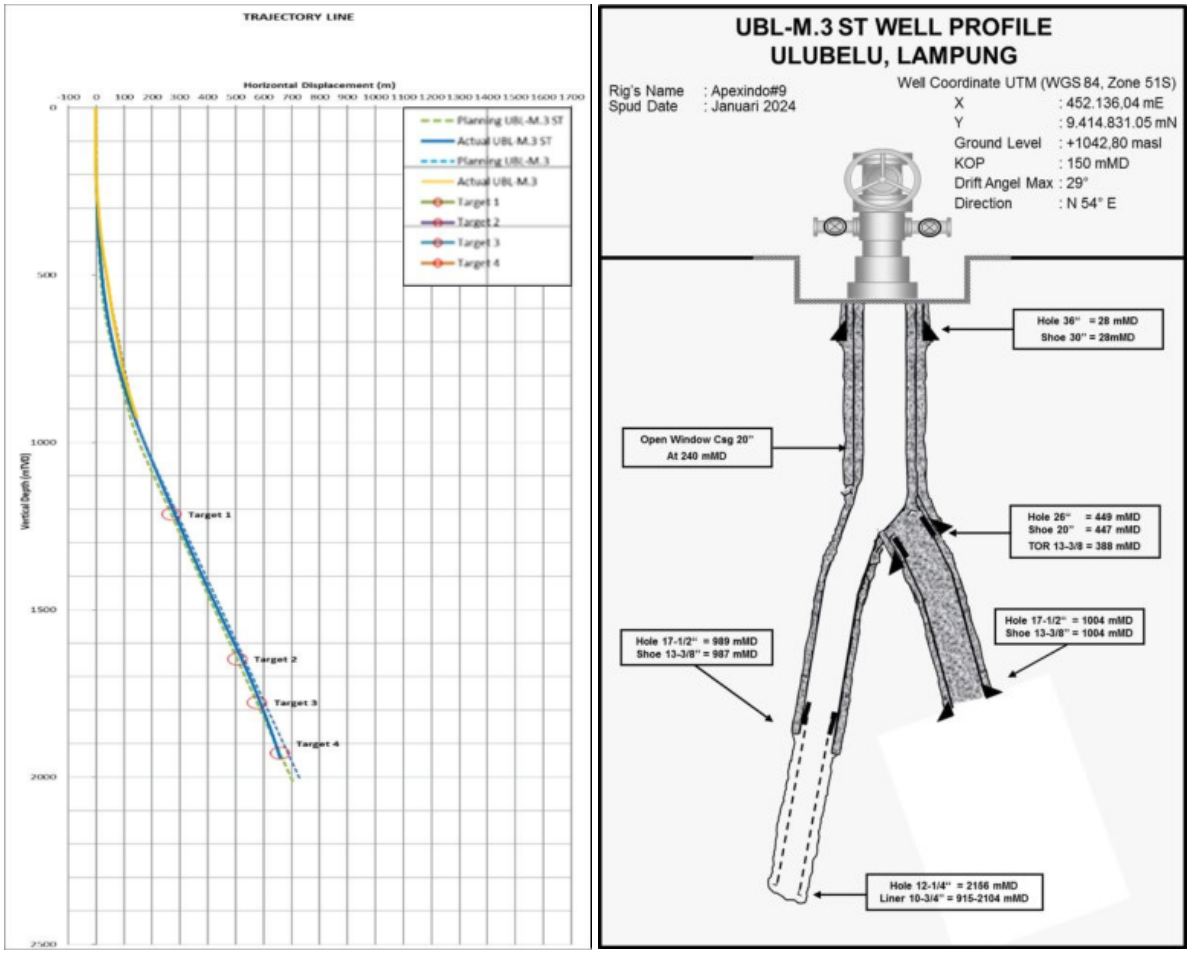

Figure 8: Well Trajectory Path & Well Schematic of UBL-M.3 Sidetrack.

Based on this data, while the sidetrack operation is ongoing, there are no major issues that related to the sidetrack operation itself. The Well Control Operation problem happened due to a steam kick while the drilling formation process is going through. This problem can be done by increasing the water volume pumping to annulus, the usage of aerated drilling and other well control efforts that usually done while there is a steam kick happened at a geothermal well. The other NPT whether from the Rig System or from the services company are just a minor technical difficulties that can be solved within under 24 hours.

6. CONCLUSION

As already mentioned previous earlier for the cons of this operation, Sidetrack is a massive and critical decision that should be considered by any Geothermal Company especially when the drilling operation are facing the unwanted downhole problems, and in this paper is the cementing process. It is known that major technical difficulties or any other unwanted accident are inevitable, especially when it comes to the dynamic condition of the subsurface, that cannot be precisely preedicted.

The biggest consideration of Pertamina Geothermal Energy to do this operation is the lack of sidetracking 20" Casing experience in geothermal wells operated in Indonesia, because this could be a do-or-die process due to a lack of experience and can lead to a bigger problem or even abandon the hole itself.

The teamwork and hardwork between Pertamina Geothermal Energy and all the Services Company that contributed to the UBL-M3 drilling operation are two key of success to do this complicated sidetrack 20" Casing experience that rarely done in Indonesia and should be given an enormous appreciation

The lesson that can be learned from this sidetrack operations are:

a. Always be critical and mindful whenever the critical steps in drilling are going to be executed such as Cementing Process and any other steps that considered to be important, critical or even dangerous
b. Reanalyzing the cementing process before the operation is going to be done, whether it was the material aspect such as the chemical addition, the composition of the cement to match it with the downhole condition or subsurface condition based on the drilling program prognosis to minimize the uncertainty of downhole condition, or the cementing operation process such as the pumping rate of the cement so that the coverage of the cement in the annulus will be perfect.
c. Reanalyzing the drilling operation process whenever the cementing process is going through such as the circulation process or pulling the drill string out of hole while waiting the Thickening Time process of the cement itself, and other activity.

ACKNOWLEDGEMENT

We would like to extend our deepest gratitude to the individuals and teams who have made significant contributions to the success of this project. First and foremost, we thank Mr. Tesha, Vice President of Drilling and Services, for his visionary leadership and unwavering support. We are immensely grateful to Mr. Radianto Ritamawan, Manager of Drilling Operation & WO/WI, whose expertise and guidance have been invaluable throughout the drilling process. We also express our sincere appreciation to Mr. Wahyu Sutresno, Manager of Drilling Planning & Support, for his meticulous planning and strategic insights. Special thanks to Mr. Fery Malau, the Assistant Manager of Drilling Operation, for his dedicated efforts and operational oversight. Our heartfelt thanks to Mr. Umar Sidiq, Drilling Engineer, for his technical acumen and problem-solving skills. We also acknowledge the entire Pertamina Geothermal Energy Drilling Team for their hard work and collaboration. We are grateful to the Pertamina Geothermal Energy Area Ulubelu team for their on-site support and operational assistance. Special recognition goes to the UBL-M3 Drilling Team for their perseverance and commitment in overcoming the challenges faced during this project. Lastly, we thank the UBL-M3 Rig Contractor and Services Company Team for their professionalism and expertise, which were crucial in achieving the project milestones. This project would not have been possible without the collective efforts and dedication of all these individuals and teams.

Achievement of Drilling Incident Free Operation by Implementing of Safety Behavior Method

Fachrul Subarkah, Budi Santoso, and Mangojak Siagian

Star Energy Geothermal, Wisma Barito Pacific II, 17th – 21st Floor,
Jl. Letjen S. Parman Kav. 60, Jakarta Barat 11410, Indonesia

fsub@starenergy.co.id

Keywords: drilling, safety behavior, safety culture, risk management, incident free operation

ABSTRACT

Successful safety behavior must take place in several well-controlled stages, beginning with capturing an individual's attention to the fact that a change of safety behavior attitude is needed; and by convincing that individual that his currently held attitude is wrong or inappropriate to the situation.

Star Energy Geothermal Drilling Team took a proactive approach to manage anticipated and emerging safety behavior issues. A good example of this approach is the adaptation of the Incident Free Operation (IFO) method through the implementing of Drilling IFO concept, fostering Safety Culture and applying Behavior-Based Safety (BBS) observation at drilling operation site. Utilizing data from daily BBS observation, safety concerns are prioritized using daily and weekly priority scales to improve the safety culture, focusing on both safe person and safe condition strategies, which directly correlate with workplace behavior. 'Safe person' strategies, in particular address individuals' risk perceptions and should be considered in the risk assessment process. Similar to BBS cards, applying the COACH Cards method by Parker Wellbore Indonesia as Drilling Contractor aids in analyzing safety behavior challenges, such as, unsafe act, behavior and deviation from Standard Operating Procedures (SOP's). To address these challenges, an extensive IFO program and integration of new safety culture findings, facilitates the refinement of safety concept in the field. Key updates also include increased understanding of Coach Cards terms and their application. These insights and the updated conceptual understanding of the BBS Coach Cards have provided a credible identifying of the performance trend to have the necessary confidence to improve safety culture performance.

The Drilling Team Leadership need to place greater emphasis on human behavior at work and would benefit greatly from training in areas of behavior which can contribute to unsafe situations, unsafe conditions, and accidents. Both Drilling Team Leadership Management and Employee attitudes vary dramatically with respect to safety and risk management. The effective development and promotion of health and safety by Leadership is an important feature of the health and safety culture of any organization.

1. INTRODUCTION

Behavior is translated from English "behavior" and is often used in everyday language, but the notion of behavior is often interpreted differently from one person to another. In general, behavior is all actions or actions carried out by living things (Notoatmojdo, 1985). Behavior is also often interpreted as an action or activity displayed by a person concerning others and the surrounding environment (Syaaf, 2007).

Behavior is an actual activity observed directly or indirectly through attitudes and actions. However, it does not mean that behavior can only be seen from the perspective or actions (Notoatmodjo, 1985). According to Notoatmojdo (1985), behavior is a person's psychic reaction to his environment in the form of active or real action and passive state or unreal action. The American Encyclopedia of Introduction to Health Behavioral Science defines behavior as an organism's reaction to its environment. New behavior will occur when something is needed to cause a response, called a stimulus. Thus, a particular stimulus will produce a specific behavior as well.

Understanding behavior that is very diverse and plural requires an understanding that is always related and cannot be separated from its contextuality. Because the behavior displayed by a person can occur at different times but in the same situation, or appear in other cases, relatively not too much additional time (Notoatmodjo, 1985).

Habits, values, and use of resources in a society or group will produce a pattern of life (way of life) which is generally called culture. In the book, Notoatmodjo (2007) says behavior is one aspect of culture, and then culture profoundly influences this behavior. Human behavior is a balance between the driving forces and the restraining forces. Furthermore, the behavior can change if there is an imbalance between the two parties within a person so that there is a possibility of behavioral changes in a person, namely the increase of the driving force, the restraining points decrease, or the driving force decreases and the restraining force increases (Lewin, 1970).

Borman and Motowidlo (1993) distinguish **Safety Behavior** at the individual level into two categories, namely safety compliance and safety participation. **Safety Compliance** is defined as the main activity that individuals must perform to maintain safety in the workplace, including compliance with work procedures and the use of personal protective equipment (PPE). On the other hand, **Safety Participation** is defined as behavior that does not directly contribute to safety activities but will help the work environment to remain safe. Some examples of safety participation are attending safety meetings and helping co-workers solve work safety problems. It can say that behavior is the result of a person's efforts achieved with abilities and actions in certain situations, so that behavior is the result of a link between safety behavior efforts and the ability to carry out their duties. Therefore, behavior is essential to know about the employee's performance. A leader will use the job description as a benchmark by carrying out such an assessment. If the execution of the work matches or exceeds the job description, it means that the job is carried out successfully. Therefore, behavior is the essential thing used to know about the employee's performance.

Safety Behavior applies task behavior in the workplace (Griffin and Neal, 2000). Safety Behavior is task behavior and contextual behavior, Borman and Motowidlo, (1993) in (Griffin and Neal, (2000) namely individual compliance and participation in safety maintenance activities in the workplace. As feedback, employees should be aware of the importance of safety for themselves and for the company he works for.

Safety Behavior in work safety, which is directly related to employee behavior in working for individual safety, is closely related to the safety culture and safety knowledge because the company's current safety culture can affect employee health. With high work safety knowledge, employees can understand the meaning of work safety well. And the most crucial component in maintaining the safety of life and safety of work equipment is knowledge of the use of safety equipment for employees where the impact that can fill from safety behavior for the company is work productivity (Wardani, 2013).

Safety behavior is related to Safety in the workplace to minimize workplace accidents. Sahab (1997) says that failure in carrying out Safety Missions is due to a lack of motivation to work safely. He also noted that Safety Communication is needed to encourage behavior change to motivate them to work safely. One of the factors that can relate to Occupational Safety and Health (OSH) is the Predisposing Factor. The predisposing factors in this analysis include five sub-variables: knowledge, training, attitudes, motivation, and communication.

Behavior-Based Safety (BBS) provides robust positive results when applied in organizations seeking to reduce employee injuries due to at-risk / unsafe behaviors. Primary techniques in BBS include peer observation and feedback, training and education sessions, behavior-based incentives, prompts, and goal setting (Geller, 2001; Krause, Robin, and Knipling, 1999). Almost all prior BBS research has been applied in work settings where employees can systematically observe the safe versus at-risk / unsafe behavior of their co-workers. BBS programs are advantageous because they are easy to implement, are easy to teach, and can be implemented in the setting where the problem occurs (Daniels, 1999; Geller, 2001). BBS programs have been successfully used to increase safety related work behaviors in a variety of organizational settings, including drilling operation.

While BBS focuses on workers' safety-related behaviors, this focus does not imply a one-dimensional (i.e., behavioral) view towards safety. In fact, Geller (2001) and Krause (1997) believe safety interventions that focus exclusively on reducing at-risk safety-related work behaviors without acknowledging the system in which they occur will have modest long-term success. Comprehensive BBS programs focus on three interdependent factors (person, behavior, and environment) in an organization's safety system.

2. JOURNEY TO APPLY BBS – COACH CARDS OBSERVATION

Star Energy Geothermal Drilling Team took a proactive approach to manage anticipated and emerging Safety Behavior issues. A good example of this approach is the adaptation of the Incident Free Operation (IFO) method through the implementing of Drilling IFO concept, fostering Safety Culture and applying Behavior-Based Safety (BBS) observation at drilling operation site. Utilizing data from daily BBS observation, safety concerns are prioritized using daily and weekly priority scales to improve the Safety Culture, focusing on both safe person and safe condition strategies, which directly correlate with workplace behavior. 'Safe person' strategies, in particular address individuals' risk perceptions and should be considered in the risk assessment process. Similar to BBS cards, applying the **COACH Cards** observation method aids in analyzing Safety Behavior challenges, such as, unsafe act, unsafe behavior and including deviation from Standard Operating Procedures (SOP's).

The development of a proper safety management system requires continual attention to three domains, namely the environment (equipment, tools, and housekeeping), the person, (knowledge, skills, abilities, intelligence, and personality) and behavior (Geller, 1998a and 1998b). The behavioral safety approach which introduces a planned schedule of events that combine to create an overall continuous improvement intervention (Krause, 1995).

A behavior-based program targets specific are unsafe behaviors. The focus of the program is on that small proportion of unsafe behavior that is responsible for most of the accidents. The unsafe behavior identified in the process is written onto a checklist in a system where employees observe each other. Behavior-Based Safety is based on observational data collection which is applied using COACH Card method. The higher the number of observations, the more reliable the data. According to the Heisenberg Uncertainty Principle, the very act of observing and measuring people's safety behavior alters the behavior of those being observed (Cooper, 2000). This analysis is aimed at assessing for implementation of a Behavior-Based Safety Coach Card intervention plan amongst drilling operation workers in the Star Energy Geothermal drilling site.

3. DATA COLLECTION PROCEDURE

The instrument employed for data collection was the BBS Coach Card checklists, requiring the workers to either tick box “safe‟, or “unsafe‟ for each condition and behavior type item listed. Baseline data were established with respect to respondents’ behavioral safety trend. This was to track their level of safe behavior or unsafe behavior over time during 24/7 operations.

3.1 Participants

The drilling operation workers at Star Energy Geothermal comprising of Company Man (Drilling Site Manager), Rig Superintendent, Drilling Technicians, HSE Reps, Toolpusher, Drillers, Derrickman, Floorman, Cementing Supervisor & Team, Mud Engineer, Crane Operator, Drivers, Welder, Material Man, Warehouse Man, Paramedic, Directional Drillers, Casing Crew, H2S Engineer, and etc. at project sites, were included in the analysis and not only one or some portions (sections). The following activities were carried out by these workers: Mobilization, Rig-Up/Down, Drilling, Mud Mixing, Running Casing, Cementing, Well Completion and etc. at drilling site.

3.2 Coach Card Checklist

The checklist administered with respect to these observations were behavioral based. It consists of seven (7) segments and has a completion time of approximately 5-10 minutes for each card. The segments include Workplace Exposures, PPE, Tools & Equipment, Environmental, Policies & Procedures, and Personal State of Mind – in COACH Cards terminology The checklists were of simple design, requiring the workers to either tick box “safe‟, or “unsafe‟ for each condition and behavior type item listed then following by describe observation. Those completing the peer-observation checklist on other workers‟ actions were advised to ask for the reason the unsafe act had occurred, direct coach or reinforce if safe. Drilling HSE Reps team members at the end of the daily workday (Day and Night Shift) collected completed these COACH Cards checklists and descriptions. These checklists were either placed into election type boxes scattered around the site, or handed back directly to the Drilling HSE Reps, or often via work group team leaders.

4. DATA ANALYSIS

The observation data analysis was used for collecting responses from the subject selected from the daily observation cards. It assessed different employees' perceptions and opinions regarding how strongly they believe them and others within the organization support safety, measures employee perceptions of many formal safety management systems and those instances of behavior which directly or indirectly impact on the safety of others. It was designed in a multiple thick box format upfront side card and describe the observation on the backside card. The Step 1 and 2 choose thick box that apply had statements in the 7 segment and following by summary notes of describe the observation.

The data analysis is to identify the major significant intervention observations among the respondents in terms of improvement in behavioral safety was to develop a simple chart that fits the collected data defining the relationship between respondents’ perception of unsafe behavior and percentage safe behavioral practices at the workplace.

The purpose of this analysis was to explore workers, supervisors, and all team member perceptions of safety behavior at work in Star Energy Geothermal drilling operation and identify the factors that discourage safe behaviors. Using quantitative and qualitative approach based on COACH Cards data and conventional content analysis to interpret the data, this analysis found the most cited the contributory factors to exhibit unsafe behaviors were:

- inadequate direct supervision,
- unsafe workplace conditions,
- workers’ perceptions, skills, and training,
- broader organizational factors.
- unsafe behavior and human error are important contributors to dangerous incidents and occupational injuries.

2,413,829 Man-Hours Free LTI (= 3,6 Years)	**1,713,878** Safe Km Driven
26,561 Permit To Work	**28,136** Job Safety Analysis
82,851 BBS Observation Cards	**3,855** SHE Inspections

5. RESULTS

On the chart Figure 1 a, b and c, Unsafe Behavior based on the Workplace Exposure factor analysis within 3 years collected COACH Card data present the symmetric plots of the observed Workplace Exposure parameters against responses from respondents Coach Cards by drilling workers, respectively. This figure presents the Workplace Exposure observation reflecting the resultant factors trend of Top Three factors of Unsafe Behaviors. Furthermore, this Figures also present plots of percentage risk of workers based on observations card and checklist describe analysis.

Star Energy Geothermal Drilling Team took a proactive approach to manage anticipated and emerging safety behavior issues. A good example of this approach is the adaptation of the Incident Free Operation (IFO) method through the implementing of Drilling IFO concept. Table 1 and 2 above stated the SHE Performance was achieved accumulative **2,413,878 Man-hours Free LTI or 3.6 years Free LTI**. And the COACH Cards observation accumulative were **82,851 cards** as record of Safety Behaviors during SEG Drilling Make Up Well Program in 2018 – 2022.

This achievement was consisting of both Drilling Team Leadership Management and Employee (workers on drilling site) attitudes vary dramatically with respect to safety, risk management and IFO concept. The effective development and promotion of health, environment and safety improvement by Leadership is an important feature of the Safety Culture and Performance of organization which was confirmed that SEG Drilling Team on the 4th Stage position in the Bradley Curve in Figure 2 below:

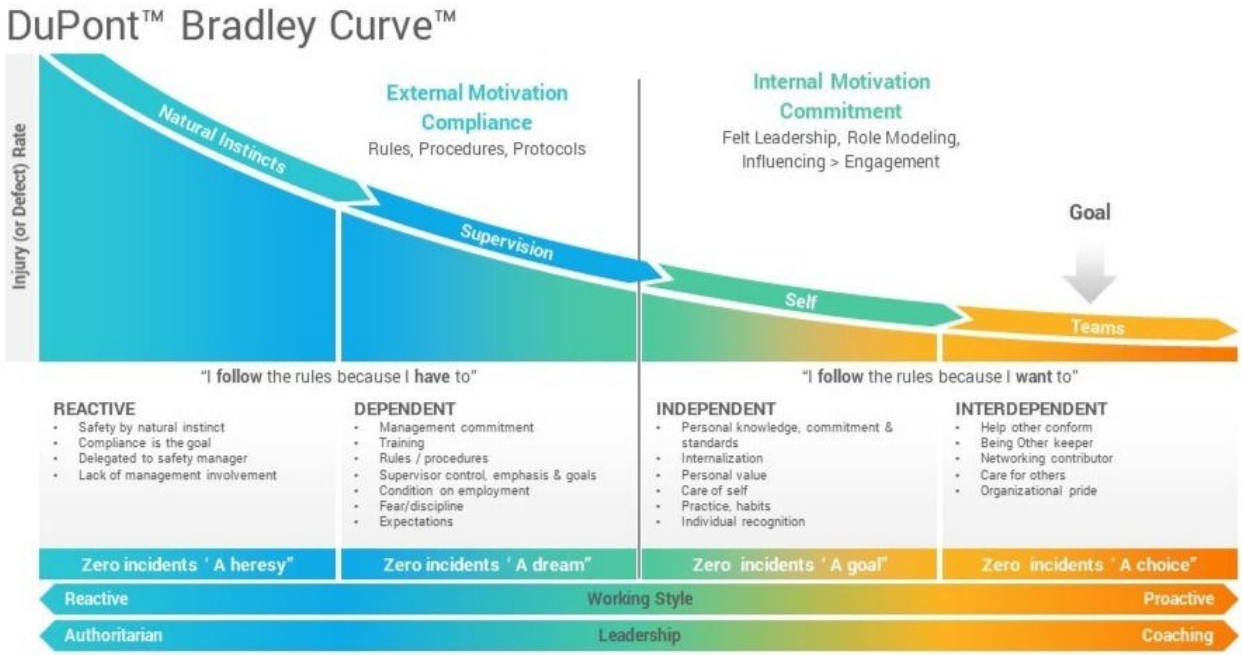

Figure 2: The DuPont Bradley Curve.The Bradley Curve was created by DuPont in 1995 to try and benchmark notions of culture and performance in relationship to safety. The DuPont Bradley Curve depicts four stages of safety culture. A company's culture can be attributed to any one of these stages and then developed to reach others. Companies with frequent accidents are in the First Stage. At the other end of the spectrum, in the Fourth Stage, are companies where accidents are rare or do not occur at all. Two interim stages lie between the first and the fourth stage. Each stage is characterized by a behavioral basis in relation to occupational safety. This is based on a key question: What is the foundation to prevent accidents - natural instincts, rules and supervision, responsibility, or shared responsibility.

The way Star Energy Geothermal Drilling Team organizations act out their safety management systems and how systems operate in drilling operations were includes safety culture, safety leadership and safety behavior fit modification which was categorized in **4th Stage** position on the DuPont Bradley Curve as the Goal achievement:

- Internal Motivation Commitment
- I follow the rules because I want to
- Interdependent Stage
- Zero Incidents A Choice, Proactive Working Style, and Leadership Coaching

5. CONCLUSION AND RECOMMENDATION

5.1 Conclusion

Based on the results of this analysis, the following conclusion can be drawn:

1) The findings of this analysis suggest the implementation of the behavior-based safety program lowered the number of recordable safety incidents in the drilling site.

2) Behavior-based feedback increased percentage safe scores from baseline to intervention, and these improvements were maintained for the various groups of drilling workers at the various team involved.

3) The Behavioral Based Safety process using Coach Cards observation at SEG Drilling Operational site, showed Top Three a baseline data of "unsafe behavior" of Workplace Exposures during data quantitative in **2020 – 2022** Drilling MUW observation cards record, to be significantly high in Figure 1 a, b and c:

- Housekeeping factors (399, 1064, 209 cases),
- Struck by/against factors (329, 395, 60 cases)
- Slip/trip/fall factors (105, 236, 61 cases).

5.2 Recommendation

1) For a more proactive safety culture, a behavioral based safety program can be maintained; by peer-to-peer observation of workers safe and unsafe behavior; direct coaching and giving feedback, thereby gaining trust, and improving on the safety behavior, safety culture and performance.

2) Hand and fingers Injury Prevention program should be established periodically, as Workplace Exposure for Struck by/against statistics at work were contributed as the Second of Top Three Unsafe Behaviors record.

3) Allocation of resources (operational cost, additional times consume and method), as regards finding of observation factors data for Workplace Exposure Slip/trip/fall and Housekeeping on drilling site are mandatory to improve the best selective solutions. If these were not applied, it will be leading to the high contributed factor of Unsafe Behavior recorded on sites.

4) The drilling operation workers feel that skills in Safety Culture are not shown, so drilling rig contractor and service company must provide more things that support improving or strengthening Safety Behavior. Therefore, the drilling rig contractor and service company must maximize the applicable rules to improve Safety Behavior.

Keywords: H_2S abatement system, flow test, production test, zeolite, caustic soda, NaOH

ABSTRACT

Geothermal power offers a significant advantage over traditional fossil fuel plants by producing lower emissions. However, geothermal fluids can still contain dissolved non-condensable gases (NCG) like H_2S, which poses environmental and safety concerns. Effective abatement systems are crucial to address these challenges and ensure the responsible development of geothermal resources.

Star Energy prioritizes safety, health, environment, community protection, and efficient geothermal operations. In line with this commitment, we have developed and successfully tested a H_2S abatement system, complying with Ministry of Energy and Mineral Resources regulations on pre-requisite for newly drilled wells production test.

This system utilizes a compact tower scrubber with a two-stage treatment process. H_2S Scrubbing with diluted Sodium Hydroxide (NaOH): A dilution of 48% NaOH solution is sprayed countercurrent to the H_2S flow, effectively neutralizing the gas through a chemical reaction. A circulating system replenishes the NaOH solution, and a mist eliminator minimizes caustic carryover, preventing potential skin irritation. Small size – high cation exchange capacity zeolite (Aluminum Silicate with CEC > 100 meq. /100g) is packed within the tower to further capture H_2S through a physical adsorption process. The zeolite's small size optimizes contact surface area for efficient adsorption.

The system's effectiveness was demonstrated during function test and a bleed trial on well DRJ-41. Initial H_2S concentrations of 200 ppm were reduced to zero within minutes, showcasing the system's ability to both adsorb and neutralize H_2S. Furthermore, H_2S levels in the surrounding area remained at 0 ppm throughout the bleeding process, confirming the system's success in mitigating potential environmental and health risks.

Star Energy's Darajat H_2S abatement system exemplifies our dedication to responsible geothermal development. This successful implementation paves the way for safe and efficient utilization of geothermal resources while minimizing environmental impact. We commit to advancing technology and best practices for a cleaner and more sustainable future.

1. INTRODUCTION

Aligned with Star Energy Geothermal Darajat objective to support development of geothermal resources, a Make Up Well drilling project was planned and executed during February - July 2022 to maintain steam supply for Darajat powerplant Unit-2 and Unit-3. Upon completion of each well drilling, a well production test is planned as a mean to measure well productivity. During this test, fluids produced from the well are flowed through flow test line to rock muffler. Included in the fluid produced is NCG (Non-Condensable Gas), e.g., CO_2, CH_4, H_2S which accumulated at upper part of wellbore during well heating period (post well drilling completion and prior well flow test). These gases – especially H_2S – brought with it safety concern due to its poisonous nature.

A series of incidents involving H_2S gas release during well drilling/well production tests in geothermal field operated by other developers occurred in January – March 2022 period. These incidents led to investigations which resulted in EBTKE (Directorate General of New, Renewable Energy and Energy Conservation) – a part of GOI Ministry of Energy and Mineral Resources - issuing additional requirement for an H_2S abatement system/procedure in place for a well production test project. The system should be placed to neutralize H_2S gas accumulation flown from well in a way that H_2S gas discharged from well to surroundings is maintained at zero ppm, or at least at acceptable minimum safety level.

This pre-requisite for an H_2S abatement system in a well flow test operation presented a challenge worth taking in return for a safer operation. Darajat team – consists of Asset Management, Power Plant Operation and Facility

Engineering team – were working on literature study on H_2S abatement system, as well as gaining knowledge and sharing lessons learned with personnel at the Kamojang geothermal field, operated by PT Pertamina Geothermal Energy, on their H_2S abatement system design for well flow test operation.

The design process continued with main idea of utilizing 48% NaOH solution (as learned from Kamojang geothermal field) combined with zeolite packed inside H_2S scrubbing tower. The H_2S gas flow from well will undergo adsorption by zeolite rock and chemical reaction with 48% NaOH solution inside scrubbing tower. These processes are accommodated inside scrubbing tower, in which the inflow of H_2S gas is controlled/throttled to avoid H_2S gas and NaOH solution carry over – out to surroundings. The process should finish with steam flown out from scrubbing tower mist eliminator as all the H_2S gas accumulation has all been neutralized and then the well is declared safe for flow production test operation.

2. DESIGN

The objective of this phase was to design a system accommodating a circulation of 48% NaOH solution countercurrent to the H_2S flow inside a zeolite-packed tower, in which the flowing H_2S gas will undergo process of adsorption by zeolite rock and chemical reaction with 48% NaOH solution.

2.1 Process Flow Diagram

The process of H_2S gas neutralization by NaOH and adsorption by zeolite is described as follow:

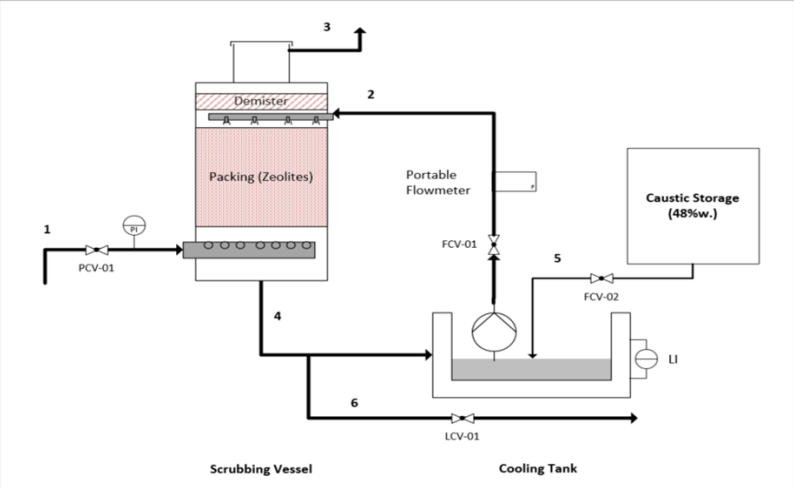

Figure 1: Process flow diagram for H_2S gas neutralization by NaOH and adsorption by zeolite in a scrubbing tower.

The process commences with (1) flowing steam containing H_2S gas from well to scrubbing tower inlet through a throttled 3" line. A valve is installed to control the flow rate. The incoming steam flows upward through zeolite-packed bed where adsorption process occurs. (2) NaOH solution is pumped from cooling tank up to scrubbing tower top, where it is sprayed countercurrent to the steam flow. The NaOH solution neutralizes H_2S gas in the steam flow. (3) The neutralized steam flows out of scrubbing tower through demister. Demister/mist eliminator is installed to minimize NaOH carryover to avoid potential irritation. (4) Reaction residue flows through drain line back to cooling tank. (5) Make-up NaOH is supplied from storage tank to replenish NaOH solution. (6) Once H_2S gas content is neutralized and leaving steam flow coming out of the scrubbing tower, Reaction residues is then drained to nearest sump to be pumped into re-injection well.

2.1.1 H_2S gas neutralization by NaOH

As shown in the process flow diagram above, process no. 2 involves H_2S gas neutralization by countercurrent flow of NaOH solution. The reaction that occurs between NaOH and H_2S is as follow:

$$NaOH + H_2S \rightarrow NaHS + H_2O \quad (1)$$

$$NaHS + NaOH \rightarrow Na_2S + H_2O \quad (2)$$

The amount of NaOH that is readily available in relation to the amount of H_2S that is scraped into the solution determines the extent of reactions 2.1 and 2.2 (Mamrosh et al., 2014). The progression of reaction 2.1 to reaction 2.2 is encouraged when there are higher levels of NaOH present compared to the sulfide that is present. The NCG and H_2S content used as basis of design comes from previous well production test conducted in Darajat geothermal field is as follow:

Table 1: NCG content reference for H_2S abatement system design.

Well Reference	NCG in Total Flow (wt.%)	H_2S in Total Flow (wt.%)	H_2S in Total NCG (wt.%)
DRJ-A	3.6	0.10	2.83
DRJ-B	7	0.09	1.2

The data used as basis of design is from DRJ-B where the well production is categorized as standard or normal in Darajat (at a range of 10 kg/s – 20 kg/s steam flow rate), thus is considered more representative to model the future well production tests condition. The data from well A is considered not representative since the well steam flow rate is low (below 1 kg/s). Mass balance calculation made based on neutralization reaction and reference data shown in table 1 is shown below.

Non-Condensable Gas mass fraction $= 7wt.\%$

Steam (H_2O) mass fraction $= 100\ wt.\% - 7\ wt.\% = 93\ wt.\%$

H_2S mass fraction $= 0.09\ wt.\%$

Assuming total flow through well through 2" scrubbing tower inlet pipe $= 1\ kg/s$

Then,

Steam (H_2O) mass flow rate $= 93\ wt.\% \times 1kg/s = 0.93\ kg/s$

Non-Condensable Gas mass flow rate $= 7\ wt.\% \times 1kg/s = 0.07\ kg/s$

H_2S mass flow rate $= 0.09wt.\% \times 1kg/s = 0.0009\ kg/s$

$= 0.0009\ kg/s \times 34.1kg/kg.mol$

$= 0.0000257\ kg.mol/s$

$= 0.0257\ mol/s$

Assuming selective reaction to H_2S with 50% NaOH excess above stoichiometry requirement:

$2NaOH + H_2S \rightarrow Na_2S + 2H_2O$

NaOH mass flow rate $= 2 \times 0.0257\ mol/s = 0.05\ mol/s$

NaOH with 50% excess $= 0.05\ mol/s \times (1 + 50\%) = 0.077\ mol/s$

$= 0.077\ mol/s \times 39.997kg/kg.mol$

$= 0.003\ kg/s$

Table 2: Mass balance calculation for H_2S reaction with 50% excess NaOH.

Component	2NaOH (aq)	H_2S (g)	Na_2S (aq)	$2H_2O$ (aq)	UoM
Initial	0.0770	0.0257			mol/s
Reaction	-0.0462	-0.0231	0.0231	0.046	mol/s
Residue	0.0308	0.0026	0.0231	0.046	mol/s
Mass Rate	0.0012	0.0001	0.0018	0.001	kg/s

From calculation above, the H_2S gas flow rate is reduced from 0.0009 kg/s down to 0.0001 kg/s, indicating 90% H_2S gas neutralization efficiency.

Calculating NaOH 48 wt.% requirement in 1 liter solution (NaOH density 1.5 kg/l):

NaOH 48 wt.% flow rate $= 0.003\ kg/s \div (48\% \times 1.5\ kg/l) = 0.004\ l/s$

NaOH 48 wt.% mass rate $= 0.00641\ kg/s$

Calculating NaOH 32 wt.% requirement in 1 liter solution (NaOH density 1.3 kg/l):

NaOH 32 wt.% flow rate $= 0.003\ kg/s \div (32\% \times 1.3\ kg/l) = 0.007\ l/s$

NaOH 32 wt.% mass rate $= 0.00962\ kg/s$

From calculation above, the required NaOH 32 wt.% for the H_2S neutralization reaction is 0.00962 kg/s.

Simulation the reaction using DWSIM for wellhead condition at 13 barg (194.4ºC saturation temperature), 2.5 barg scrubbing tower inlet pressure and 1 barg outlet pressure, we get:

Table 3: DWSIM simulation for well DRJ-B H_2S neutralization with 50% excess NaOH.

Stream	UoM	1	2	3	4
		DRJ-B Bleed	NaOH 32 wt.%	Outlet Vapor	Drain
Temperature	ºC	194.4	50.0	100.0	100.0
Pressure	bar	2.5	2.5	1.0	1.0
Mass Flow	kg/s	1.0	0.00962	1.0	0.02359
Volumetric Flow	m^3/d	71,496.0	0.76	141,167.0	2.1
H_2S Concentration	ppm	900.0	-	90.7	0.9

The summary of mass balance calculation for process flow diagram (Figure 1) is shown in Table 4.

The calculation shows that the neutralization process utilizing countercurrent flow of NaOH solution should reduce the H_2S gas concentration from 900 ppm down to 91 ppm, equal to 90% reduction of H_2S gas concentration. Nonetheless, a 91 ppm of H_2S gas concentration is considered poisonous. According to the National Institute for Occupational Safety and Health (NIOSH) Recommended Exposure Limit (REL), the acceptable level of hydrogen sulfide exposure is 10 ppm, while U.S. Occupational Safety and Health Administration (OSHA) Permissible Exposure Limit (PEL) stated that the acceptable level is in between 10 ppm - 50 ppm depends on the activity. Thus, additional compound could be added into the system to neutralize or absorb the remaining 10% of H_2S gas concentration. Team decided to add natural zeolite rock into the system to further increase H_2S gas neutralization.

Table 4: Mass balance calculation summary for process flow diagram.

Stream	UoM	1	2	3	4	5	6
Description		Fluids from well	NaOH to Scrubber	Outlet Vapor	Liquid from scrubber	Make-up NaOH	Liquid Disposal

	ppm	900	0	91	0.91	0	0.91

2.1.2 H_2S gas adsorption by natural zeolite

The tetrahedron is the fundamental building component of the zeolite framework, having a silicon or aluminum atom at its center and four oxygen atoms at its vertices. The negative charge of the framework is defined by the substitution of Si4+ by Al3+, which is compensated by monovalent or divalent cations placed together with water.

The most conserved and stable component is the aluminosilicate framework, which specifies the structural type. Water molecules can exist in voids of huge cavities and be bonded via aqueous bridges between framework ions and exchangeable ions. Water can also act as a bridge between two exchangeable cations.

Zeolites and adsorbates interact strongly. Different diffusion and polarity characteristics of adsorbates interact with the zeolite framework differently and are thus distinguished by certain zeolite kinds (Kamarudin et al., 2007). Because of their open, cage-like structures, high cation exchange capacities, large internal surface areas, variable aggregate sizes, and high permeability features, zeolites have diverse commercial uses such as highly selective adsorbents, ion exchangers, and highly active catalysts (Sand and Mumpton, 1978).

The reaction mechanism that occurs in removing H_2S by using zeolites is as follows (Sigot et al., 2015).

$$H_2S(g) \rightarrow H_2S(ads) \quad (3)$$

Reaction 3 occurs when the hydrogen sulfide is adsorbed at zeolites surface. After that, the hydrogen sulfide experienced dissolution in water contain in zeolites pores as seen in equation 4:

$$H_2S(ads) \rightarrow H_2S(aq) \quad (4)$$

$$H_2S(aq) + H_2O(l) \rightarrow HS(aq)^- + H_3O(aq)^+ \quad (5)$$

$$HS(aq)^- + O(ads) \rightarrow S(ads) + OH(aq)^- \quad (6)$$

$$xS(ads) \rightarrow Sx(ads) \quad (7)$$

Equation 5 indicates the dissociation of hydrogen sulfide in the water film. After that, the HS- undergoes oxidation with adsorbed oxygen as seen in equation 6. Furthermore, in equation 7 occurs the formation of cyclic sulfur polymers.

Zeolites have pores that allow molecules with smaller diameters to be adsorbed, whereas molecules with bigger diameters cannot pass through these pores. This is an appealing adsorptive property for eliminating pollutants from natural gas such as hydrogen sulfide, carbon dioxide, and moisture (Abdirakhimov et al., 2022). Thus, the addition of zeolite into the system to further decrease H_2S gas content – below acceptable exposure safety limit.

2.2 Scrubbing Tower Design

To accommodate the two process – i.e., H_2S gas neutralization by NaOH and H_2S gas adsorption by natural zeolite, a scrubbing tower is designed. The design objective of scrubbing tower is to estimate minimum scrubbing tower diameter and height that would allow for the calculated speeds of load and flood in tower of filling. This way, the H_2S gas flow will have sufficient retention time inside scrubbing tower to react with NaOH and zeolite. As initial guess, the scrubbing tower diameter and height will resemble the dimension of available flash tank in Darajat geothermal field. This is done to optimize material usage and to minimize construction time. In this case, the size of available flash tank is around 1.029 m in diameter and about 3.875 m in height.

2.2.1 Scrubbing Tower Diameter

The minimum required diameter is calculated using packed tower flood correlation to estimate the speed of loading and flooding in scrubbing tower.

Packed bed diameter calculation:

Column inside diameter (ID) $= 40.5\ in = 1.029\ m$

Column surface area (A) $= 0.25\ \times \pi \times (1.029\ m)^2 = 0.831\ m^2$

Referring to Table 3, mass flow rate of steam mixture and NaOH are 1 kg/s and 0.00962 kg/s, respectively. Density of steam mixture and NaOH are 1.21 kg/m^3 and 1,300 kg/m^3 with viscosity of 0.45 cP.

Steam mixture flux (G) $= (1\ kg/s\ \times\ 3600\ s/hr)/(0.831\ m^2\ ) = 4{,}331.5\ kg/m^2.hr$

NaOH mixture flux (L) $= (0.00962\ kg/s\ \times\ 3600\ s/hr)/(0.831\ m^2\ ) = 41.7\ kg/m^2.hr$

Calculating x and y for packed tower flood correlation:

$$x = \frac{L}{G}\sqrt{\left(\frac{\rho_G}{\rho_L}\right)} = \frac{41.7\ kg/m^2.hr}{4{,}331.5\ kg/m^2.hr}\sqrt{\left(\frac{1.21 kg/m^3}{1{,}300 kg/m^3}\right)} = 2.93 \times 10^{-4}$$

Using the calculated x value above and with extrapolation, the y value can be found using correlation below (Joaquin, Gabriel, Jesus, 2016):

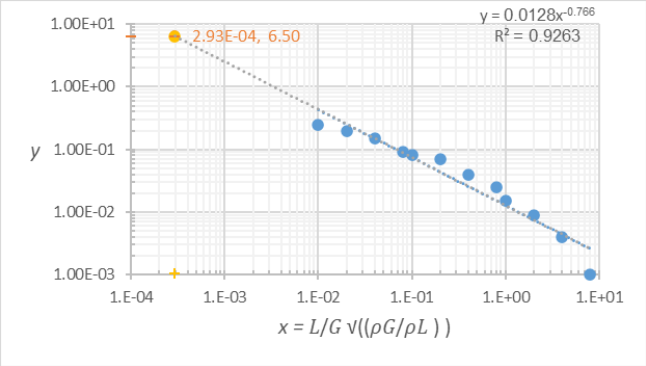

Figure 2: Packed tower flood correlation for *x* and *y*.

From correlation above, the *y* value is used to calculate *G flooding* with assumption:

Zeolite filler bulk density $= 1{,}600\ kg/m^3$

Zeolite filler surface area $= 800{,}000\ m^2/kg$

Zeolite filler porosity $= 0.75$

Surface area of dry filler$= 800{,}000\ m^2/kg \div 1{,}600\ kg/m^3 = 500 m^2/m^3$

With $g = 1.27 \times 10^8 m/hr^2$, then:

$$G_{flooding} = \sqrt{\frac{6.5 \times 1.27 \times 10^8 \times 1.21 \frac{kg}{m^3} \times 1{,}300 \frac{kg}{m^3}}{(0.45\ cp)^{0.2} \times \left(\frac{500 \frac{m^2}{m^3}}{0.75^3}\right)}} = 35{,}857.35\ kg/m^2.hr$$

$$G\ to\ G_{flooding}\ ratio = \frac{G_{steam\ mixture}}{G_{flooding}} = \frac{4{,}331.5\ kg/m^2.hr}{35{,}857.35\ kg/m^2.hr} = 0.12 = 12\%$$

Gas flow assuming 60% flooding $= 60\% \times 35{,}857.35\ kg/m^2.hr = 21{,}514.41\ kg/m^2.hr$

Minimum required scrubber area $= \frac{1 kg/s \times \frac{3{,}600\ s}{1\ hr}}{21{,}514.41\ kg/m^2.hr} = 0.17\ m^2$

Minimum required scrubber diameter $= \sqrt{\frac{0.17 m^2}{0.25\ \pi}} = 0.46\ m$

Adding 30% safety factor for scrubber diameter, then:

Minimum required scrubber diameter $= 0.46\ m \times (1 + 30\%) = 0.6\ m = 24\ in$

From this calculation, available material diameter ($40.5\ in = 1.029\ m$) is above minimum requirement ($24\ in = 0.6\ m$), considered sufficient diameter for the scrubbing tower.

2.2.2 Scrubbing Tower Height

Minimum scrubbing tower height is calculated as follow:

Assuming diffusivity value for H_2S and NaOH:

$D_A = DH_2S = 3.51 \times 10^{-9} m^2/s$

$D_B = DNaOH = 1.4 \times 10^{-9} m^2/s$

Assuming Henry constant for H_2S, $HH_2S = 25\ bar.m^3/kmol$

Assuming mass transfer coefficient for liquid phase and gas phase:

Liquid phase mass transfer coefficient $k_{AL} = 1.2 \times 10^{-4} m/s$

Gas phase mass transfer coefficient $k_{GA} = 2.6 \times 10^{-2} kmol/bar.m^2 s$

Kinetic reaction constant $K = 9.5 \times 10^3 m^3/kmol.s$

Then calculating Liquid to Gas mass flow rate ratio by using mass balance calculation in Table 3:

$$\frac{G}{L} = \frac{0.00962\ kg/s}{1\ kg/s} = 0.01$$

Also from Table 3, calculating NaOH concentration, $C_B = \frac{0.077\ mol/s}{0.004\ l/s} = 18\ mol/l$

Then to check the effects of reaction kinetics we can calculate Hatta Moduli:

$$M_H = \sqrt{\frac{DH_2S \times K \times C_B}{k_{GA} \times HH_2S}} = \sqrt{\frac{3.51 \times 10^{-9} m^2/s \times 9.5 \times 10^3 m^3/kmol.s \times 18\ mol/l}{2.6 \times 10^{-2} kmol/bar.m^2 s \times 25\ bar.m^3/kmol}} = 0.03$$

For very low Hatta Moduli (M_H below 1) is met that $E \approx 1 + \frac{{M_H}^2}{3} \approx 1 + \frac{(0.03)^2}{3} = 1.0003$

The condition of neglecting kinetic is that $E > 5M_H$, which is:

$E > 5M_H$

$\leftrightarrow 1.0003 > 5 \times 0.03$

$\leftrightarrow 1.0003 > 0.15$

Thus, the kinetics do not affect the reaction.

To calculate the scrubbing tower height, first we calculate:

$$\frac{1}{K_{GA}} = \frac{1}{A \times k_{GA}} + \frac{HH_2S}{A \times \sqrt{K \times C_B \times DH_2S}}$$

$$= \frac{1}{500 m^2/m^3 \times 2.6 \times 10^{-2} kmol/bar.m^2 s} + \frac{25\ bar.m^3/kmol}{500 m^2/m^3 \times \sqrt{9.5 \times 10^3 m^3/kmol.s \times 18\ mol/l \times 3.51 \times 10^{-9} m^2/s}}$$

$$= 2.12\ bar.m^4.s/kmol$$

According to Robert E. Treybal, the pressure drop for an absorber should be around 200 N/m^2– 400 N/m^2 (Treybal, 1980), thus we may take $\Delta P = 400\ N/m^2 = 0.004\ bara$

$\Delta P \times Z = Pa$; while $Z = \frac{G_m}{K_{G \times A \times P}} \int_{y2}^{y1} \frac{dy}{y - ye}$. With known parameters below:

Molar gas flow rate per unit cross sectional area: $G_m = \frac{53.2194}{1{,}000 \times 0.831\ m^2} = 0.064\ kmol/s.m^2$

Gas phase mass transfer coefficient: $k_{GA} = 2.6 \times 10^{-2} kmol/bar.m^2 s$

Surface area of dry filler per unit volume: $a = 500 m^2/m^3$

For iteration process, we use Z initial guess = 2.4 m. Then:

$$Pa = \Delta P \times Z = 400 \frac{N}{m^2} \times 2.4\ m \times 10^{-5} = 0.0094\ bara$$

$$H_{0G} = \frac{G_m}{k_{GA}.a.Pa} = \frac{0.064\ kmol/s.m^2}{2.6 \times 10^{-2} kmol/bar.m^2 s \times 500 m^2/m^3 \times 0.0094\ bara} = 0.52m$$

While the scrubber tower height Z, is also defined as:

$Z = H_{0G} \times N_{0G}$, we need to find the values of H_{0G} and N_{0G}.

$$N_{0G} = \frac{1}{1 - \left(\frac{m_{Gm}}{L_m}\right)} \times ln\left[\left(1 - \frac{m_{Gm}}{L_m}\right)\frac{y_1}{y_2} + \frac{m_{Gm}}{L_m}\right]$$

Colburn (Colburn, 1969) suggested that the optimum value of $\frac{m_{Gm}}{L_m}$ is between 0.7 – 0.8. For this case we take:

$$\frac{m_{Gm}}{L_m} = 0.7$$

For ratio of mol fraction of solute in gas phase at bottom and top, from Table 2 data we get: $\frac{y_1}{y_2} = \frac{0.0257}{0.0026} = 10$

Then we can use the following correlation (or N_{0G} formula above) to find N_{0G}:

$$N_{0G} = \frac{1}{1-(0.7)} \times ln[(1-0.7)10 + 0.7] = 4.36$$

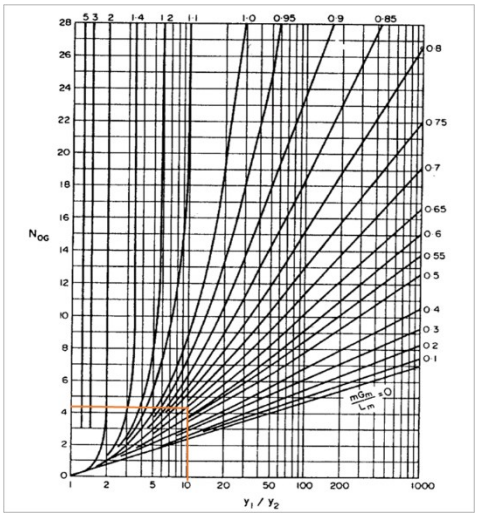

Figure 3: Packed tower flood correlation for $\frac{y_1}{y_2}$, $\frac{m_{Gm}}{L_m}$, and N_{0G}.

Now we can calculate scrubber tower height *Z*:

$$Z = H_{0G} \times N_{0G} = 0.52m \times 4.36 = 2.28m$$

Adding 10% safety factor for scrubber tower height we get $Z = 2.28m \times (1 + 10\%) = 2.5m$

From above calculation we find that the height of available material (3.875 m) is above minimum required height (2.5 m), thus is considered sufficient to accommodate tower flooding. Below is the calculated design for the minimum required diameter and minimum required height for the scrubbing tower:

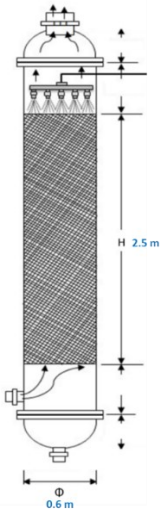

Figure 4: Calculated minimum required diameter and minimum required height for scrubbing tower.

3. IMPLEMENTATION

Construction was commenced with the idea of optimizing available material in Darajat geothermal field while also fulfilling design requirement for technical, environment and safety concern. Several reasons to progress with

this idea included efficiency. By utilizing available materials, we avoided procurement lead time, which could potentially delay the new well production tests and commissioning of the wells. Below is general arrangement drawing for scrubbing tower:

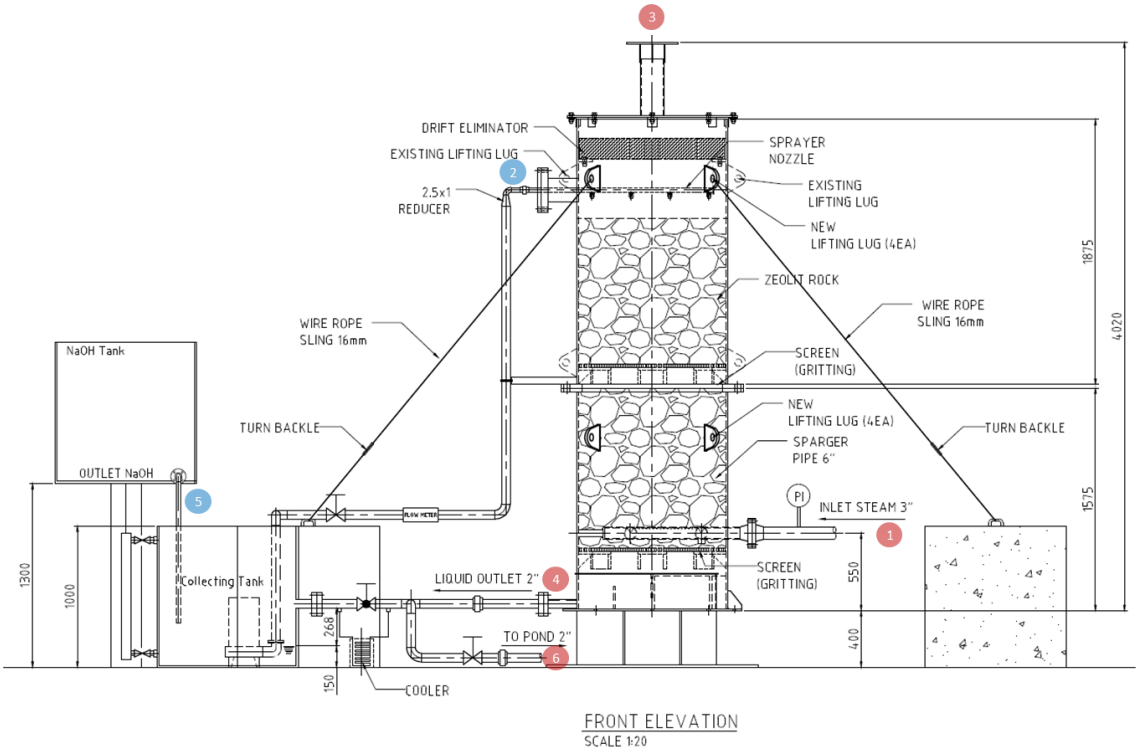

Figure 5: General arrangement drawing for scrubbing tower.

Figure 6: Construction phase.

The construction phase started at the end of March 2022, approximately two weeks after EBTKE issued regulations for an additional H_2S abatement system on March 12, 2022, and about one week after a sharing session with PT. Pertamina Geothermal Energy – Kamojang, a neighboring geothermal field that shares similar field characteristics. The construction was completed in around six weeks in early May 2022 and soon after the completion, a pilot test was conducted on 13 May 2022 on well DRJ-B.

The test was witnessed by EBTKE inspector for well production test and was supported by medical team, FERT (Fire and Emergency Rescue Team) and Security team for environment and safety concern. The test started with water circulation test inside scrubbing tower to ensure pumps were working well. Then, after preparing a solution of NaOH 48wt.% and water (in a volume ratio of 1:2), with 600 liters of NaOH 48wt.% and 1,200 liters of water, the pH was measured at 13.The process continued with re-circulation of NaOH and water solution through scrubbing tower and back to circulating tank. Once the system function test completed, the steam mixture from well DRJ-B was opened through 3" bleed line, 2" scrubbing tower inlet and into packed scrubbing tower. During

the test, operators wore SCBA (Self Contained Breathing Apparatus) and H_2S gas was monitored using portable H_2S gas detector and multi-gas detector.

Figure 7: Pilot test on well DRJ-B.

The accumulated H_2S gas concentration from well DRJ-B prior to the test was measured at 200 ppm. After approximately 30 – 60 minutes, steam came out from scrubbing tower outlet after all H_2S accumulation was adsorbed by zeolite pack and NaOH solution. During the test, the H_2S gas concentration at 0 m – 100 m radius from scrubbing tower was measured at 0 ppm. This shows that the scrubbing tower system was working effectively in binding H_2S.

Post the test, the used NaOH solution was drained through drain line into sump. The sump fluid was then pumped into condensate line and then to injection well. The portable scrubbing tower system was dismantled and moved to next location for another well production test. As shown in Table 5 below, the system was working well during well DRJ-C production test.

Table 5: H_2S scrubbing tower performance during well DRJ-C production test.

Time	H_2S (ppm)	CO (ppm)
09:43	0	181
10:00	0	37
10:31	0	16
10:40	0	0

4. PROCESS OPTIMIZATION

During 2022 make up well drilling campaign, five wells were drilled. All of the wells were treated using an H_2S scrubbing tower system during the initial phase of the well production test to neutralize H_2S gas accumulation. Improvements were made on the H_2S scrubbing tower system through well #1 to well #5 production test to make the system safer and more effective. The improvements made were the change of circulating line from rigid pipe to a flexible hose, improvements on pump electrical panel, NaOH circulation tank top cover, iteration of NaOH 48 wt.% volume used in solution and zeolite rock re-use through washing and boiling. The optimization of NaOH 48 wt.% and zeolite rock are described in below sub-sections.

4.1 NaOH Optimization

The data processing is conducted to determine the optimum concentration of NaOH to absorb non-condensable gas contained in wells. There are 5 concentrations of NaOH, some of them were chosen from literature data and the other were determined by choosing the closest interval. The trial was conducted by using the predetermined NaOH solution to absorb non-condensable gas in gas removal system of Unit-3 in Star Energy Geothermal Darajat II for 72-96 hours. After that, the solutions that have been in contact with non-condensable gas were researched its pH and absorbance to determine the best NaOH concentration. The flowchart of determination of NaOH concentration is presented in Figure 8.

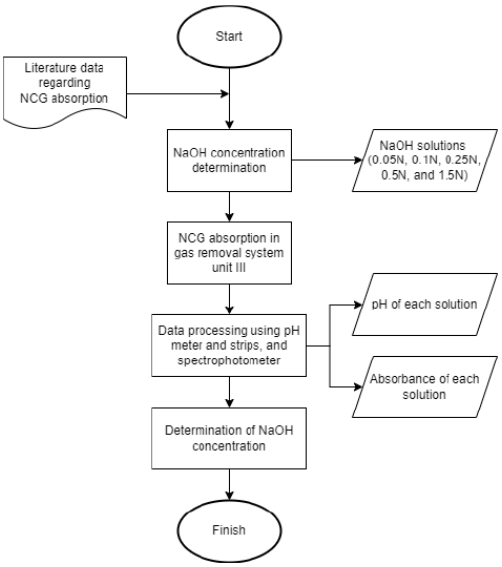

Figure 8: NaOH concentration determination flowchart.

Following the research conducted by Bontozoglou and Karabelas (1993), the selected NaOH concentrations were 0.05N, 0.5N, and 1.5N. The experiment was done by flowing the non-condensable gas from gas removal system unit III into the tube and leaving it to react for 72 hours. From the detector, the value of H2S detected was greater than or equal to 200 ppm with the inlet pressure was 1.173 mbar.

Figure 9: NaOH 0.05N after 72 hours contact.

Figure 10: NaOH 0.5N after 72 hours contact.

Figure 11: NaOH 1.5N after 72 hours contact.

Physically, the NaOH with 0.05N concentration gave cloudy appearance and a little amount of NaS solid was also discovered as it can be seen in Figure 9. On the other hand, the 0.5N NaOH solution gave a significant difference in terms of color. From the Figure 10, the appearance of solid NaS is more visible as it precipitated in the bottom of the tube. The biggest concentration, in this case is 1.5N, gave a stronger yellow color than the 0.5N as well as had more NaS precipitation in the bottom of the tube. From these trials, it can be concluded that the higher the concentration of NaOH will give stronger yellow color and more precipitation will be formed.

Considering the price of NaOH is currently high, the goal is to determine the lowest concentration of NaOH that can achieve satisfactory absorption.. Therefore, trials with 0.1N and 0.25N NaOH were conducted. However, due to a certain condition, the absorption process cannot be done in 72 hours, thus a monitoring was conducted in 24 hours and 96 hours.

As it can be seen from Figure 12 and Figure 14, the 0.1N concentration did not give any significant change in terms of color, however a small amount of precipitation was formed. Contrary to the previous concentration, 0.25N of NaOH offered a slightly yellow color of solution as well as formation of solid Na2S as it can be seen in Figure 13 and Figure 15.

The higher the concentration of NaOH will result in more Na2S precipitation. The pH of each solution was measured using pH meter. The result can be seen in Table 6.

Figure 12: NaOH 0.1N after 24 hours contact.

Figure 13: NaOH 0.25N after 24 hours contact.

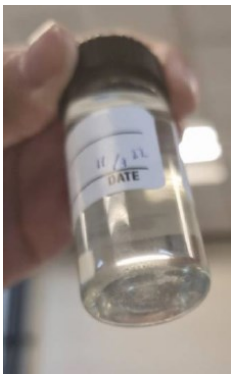

Figure 14: NaOH 0.1N after 96 hours contact.

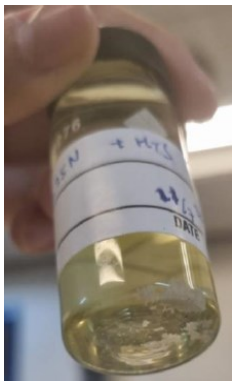

Figure 15: NaOH 0.25N after 96 hours contact.

Table 6: Initial and final pH of various NaOH concentrations.

NaOH Concentration (N)	Initial Theoretical pH	Initial Actual pH	Final Actual pH
0.05	12.70	11.63	8.62
0.1	13.00	13.11	7.84
0.25	13.40	13.54	7.02
0.5	13.70	13.90	8.88
1.5	14.18	13.96	8.26

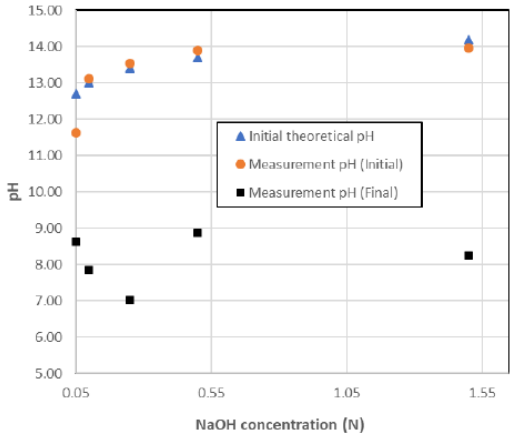

Figure 16: pH of various NaOH concentrations.

It is shown that gas in gas removal system unit III contains with acid gas due to the decrease of pH from more than 11 to in the range of 7 to 8. Compared to the other concentrations, the final pH of 0.05N and 0.5N were bigger; more than 8.5. This might be because the pH measurement was not conducted directly after the samples were taken. This will result in the evaporation of acid gas and thus pH to increase.

On the other hand, the absorbance of each sample was also determined by using spectrophotometer. The obtained data for various concentrations of NaOH is presented in Table 7.

Table 7: Spectrophotometer data of various concentrations of NaOH.

	λ_{440}	λ_{465}	λ_{546}	λ_{590}	Absorbance	%Transmittance
0.05N	0.093	0.085	0.070	0.065	0.313	0.731
0.1N	0.156	0.141	0.106	0.100	0.503	0.605
0.25N	0.783	0.283	0.054	0.053	1.178	0.308
0.5N	0.175	0.072	0.024	0.022	0.293	0.746
1.5N	2.282	0.792	0.106	0.100	3.281	0.038

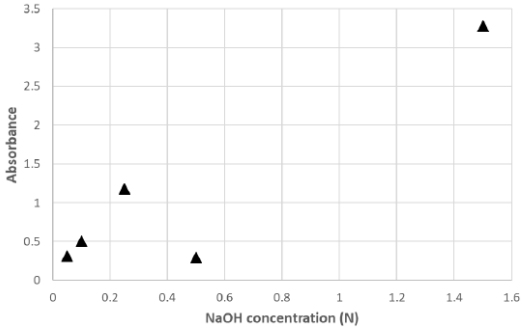

Figure 17: Absorbance of various concentrations of NaOH.

Due to some limitations that occurred in the laboratory, the spectrophotometer can only be used for measuring the absorbance of each concentration by using multiwavelength. Table 7 shows the absorbance of each solution tends to increase when the concentration of NaOH becomes higher. It is proven by the Lambert-Beer law in which the absorbance is linear as it shows in equation below:

$$A = abc = -logT$$

Where A indicates the absorbance, a is the molar absorptivity, b is the path length, and c is the concentration of the sample.

The high value of absorbance indicates that there is absorption in the solution. The higher the concentration of NaOH will result in higher absorbance which leads to more effective absorption. However, the exact chemical compound contained in the sample cannot be determined as it needs to be tested with certain reagents. Since there was a limitation in terms of having all necessary reagents to detect sulfide, the action could not be performed. Therefore, it could only be concluded that something was absorbed by NaOH, but the exact compound was unknown.

There is a depletion in the absorbance of 0.5N of NaOH as seen in Figure 17. This might be because the solution was tested before the other solutions. Thus, resulting in evaporation of absorbed NCG especially H_2S content.

4.2 Zeolite Optimization

The zeolite used in this research were natural zeolite, and zeolite which have been used for well bleeding of well DRJ-C. The zeolite were experienced in 2 treatments, which are with and without boiling.

Figure 18: DRJ-C ex-use zeolite without boiling.

Figure 19: Aquadest of DRJ-C ex-use zeolite with boiling.

Figure 20: Aquadest of natural zeolites with boiling.

Physically, the color of aquadest of DRJ-C ex-use zeolite with boiling was yellowish transparent, while the aquadest of natural zeolite was a little cloudy. The aquadest of DRJ-C ex-use zeolite without boiling had darker color and in certain sides, the dark color of zeolite turned into its original color as seen in Figure 21 below. This phenomenon was also proven that the DRJ-C zeolite were boiled.

The spectrophotoscopy and pH strips data are presented in Table 8.

Figure 21: Original and DRJ-C zeolite after boiling comparison.

Table 8: Spectrophotometer pH data of zeolite.

	λ440	λ465	λ546	λ590	Absorbance	pH
DRJ-D zeolite without boiling	0.181	0.17	0.143	0.133	0.627	6
DRJ-D zeolite with boiling	0.105	0.081	0.041	0.031	0.258	6.5
Natural zeolite with boiling	0.137	0.126	0.1	0.091	0.455	7

Theoretically, the boiled sample has higher absorbance due to the presence of heat will make the reaction occurs faster. The different result to the theory might be due to redeposition. The exact activity in zeolite cannot be seen with naked eyes and specialized instruments are needed. Compounds that previously were adsorbed by the zeolite and then released due to high temperature or being rinsed re-enter the different pores of zeolite. Since the absorbance measurement was conducted by measuring the aquadest, then the particles or compounds that have been re-entered the zeolite as redeposition cannot be measured.

On the field implementation, the boiling of zeolite was provided by exothermic reaction between NaOH solution and H_2S gas. The reaction releases heat that boils zeolite rock inside scrubbing tower. This results in faster reaction/adsorption of H_2S gas by zeolite rocks.

Zeolite fulfill the characteristics of gas adsorption such as the accessibility of the molecules, and pore network system. As zeolite are three-dimensional, thus the pore blockage to the adsorption sites can be prevented (Kamarudin et al., 2007). The high value of cation exchange capacity (CEC) of used zeolites (>100) also led to high number of negative charge and more cations that can be detained (Mengel, 1914). In addition, the natural zeolite have been widely employed as adsorbents in separation and purification procedures due to their excellent cation-exchange ability and molecular sieve capabilities.

Due to their high cation-exchange ability as well as to the molecular sieve properties, natural zeolite have been widely used as adsorbents in separation and purification processes in the past decades (Wang and Peng, 2009).

5. CONCLUSION

The conclusions that can be obtained from the described work on H_2S abatement system are as follows:

1. High concentration of NaOH will result in faster equilibrium state, thus resulting in more Na_2S precipitation.
2. The effective absorption and optimum concentration of NaOH is 0.25N by considering the price and environmental perspective. Smaller NaOH volume is cheaper, and the more neutral the final pH of drained fluid, the more environmentally friendly it is.
3. Presence of zeolite will increase the effectivity of abatement system due to its ability to adsorb H_2S. The presence of zeolite pack provides more retention time for H_2S gas to react with NaOH solution. In the other hand, the exothermic reaction between NaOH solution and H_2S gas provides heat that boils zeolite rock, resulted in faster adsorption of H_2S gas by zeolite rock.
4. The H_2S abatement system is considered effective as H_2S gas absorbents can adsorb H_2S gas from new wells.
5. The design, parameter, and composition of abatement have met the requirement of EBTKE letter no. 2.E/EK.04/DEP.T/2022

Keywords: Geothermal Drilling, Geothermal Cementing, Drilling Fluid, Loss Optimization, Lost Circulation Material

ABSTRACT

In geothermal well drilling, things do not always go smoothly as planned. One of the problems in drilling operations is lost circulation, which is the loss of drilling fluid into the formation, preventing the drilling fluid from circulating back to the surface completely. This issue has the potential to become a significant problem, particularly when it occurs in a 26" section, both operational days and costs. ement plug is a method used to prevent lost circulation by pumping cement to the depth where the lost circulation is occurring. However, it often requires multiple cement plug attempts to address the lost circulation effectively, especially since lost circulation in the 26" section is often found to be due to large fractures or faults.

Several previous attempts have been already done at one of the previous wells at PGE (TPS-P2.1) by using only cement plugs and lost circulation materials, resulting unsatisfactory results. As the time passes by, also with further analysis between drilling engineering, drilling fluids and cementing aspects, an optimal cement design was developed in this case for the lost circulation mitigation method, specifically for the 26" section, by combining high-viscosity drilling mud and cement. This method was applied in well TPS-P2.1 and it needed only one cement plug attempt to address lost circulation in the 26" section, indicating it was more effective compared to the methods used in the previous well.

The success-ratio of this method was analyzed through laboratory testing, which involved mixing high-viscosity drilling mud with cement. The laboratory results showed a rapid physical change in the cement mixture when combined with high-viscosity mud, causing it to thicken quickly and form a solid mixture. This analysis demonstrated that the method is more effective because the rapid physical change of the pumped fluid for the cement plug can seal the lost circulation path, making it a more efficient solution for mitigating lost circulation.

This paper will explore the extensive process and journey behind the successful mitigation of total losses in the 26" section of the TPS-P2.1 well. Moreover, it will highlight the lessons learned to prevent similar issues in future operations, ensuring smoother and more optimized drilling operation processes.

1. INTRODUCTION

The Lahendong PGE Area is one of the areas of Pertamina Geothermal Energy that has generated significant installed capacity to benefit Indonesia, particularly in supplying electricity to the North Sulawesi and Gorontalo regions. Starting from 2001, which marked a milestone in the development of geothermal energy in eastern Indonesia, PGE began operating geothermal power plants commercially in the Lahendong working area, North Sulawesi Province.

Pertamina Geothermal Energy main goal, is to be the World Class Green Energy Company with largest geothermal capacity globally. One of the short term goal is to reach the 1 GW installed capacity all across indonesia. One of he process that has to be done and gone through is drilling and exploration process itself, and Lahendong is becoming one of the biggest potential investor and contributor to make this happen. During the drilling campaign of PGE at 2023-2024 timeframe, Lahendong had one of the most wells drilled compared to other areas during that timeframe such as Kamojang or Ulubelu, and one of the Lahendong wells that drilled that time is TPS-P2.1

TPS-P2.1 is the second of two exploration wells in the Lahendong 7&8 project. Well TPS-P2.1 is a directional big hole exploration well with a final depth of 2919 mMD and a total duration of 45 days. This well will be utilized as a production well to support the development plan of PLTP LHD unit 7&8 in the Tompaso field, Lahendong geothermal area. Below is the well profile of well TPS-P2.1

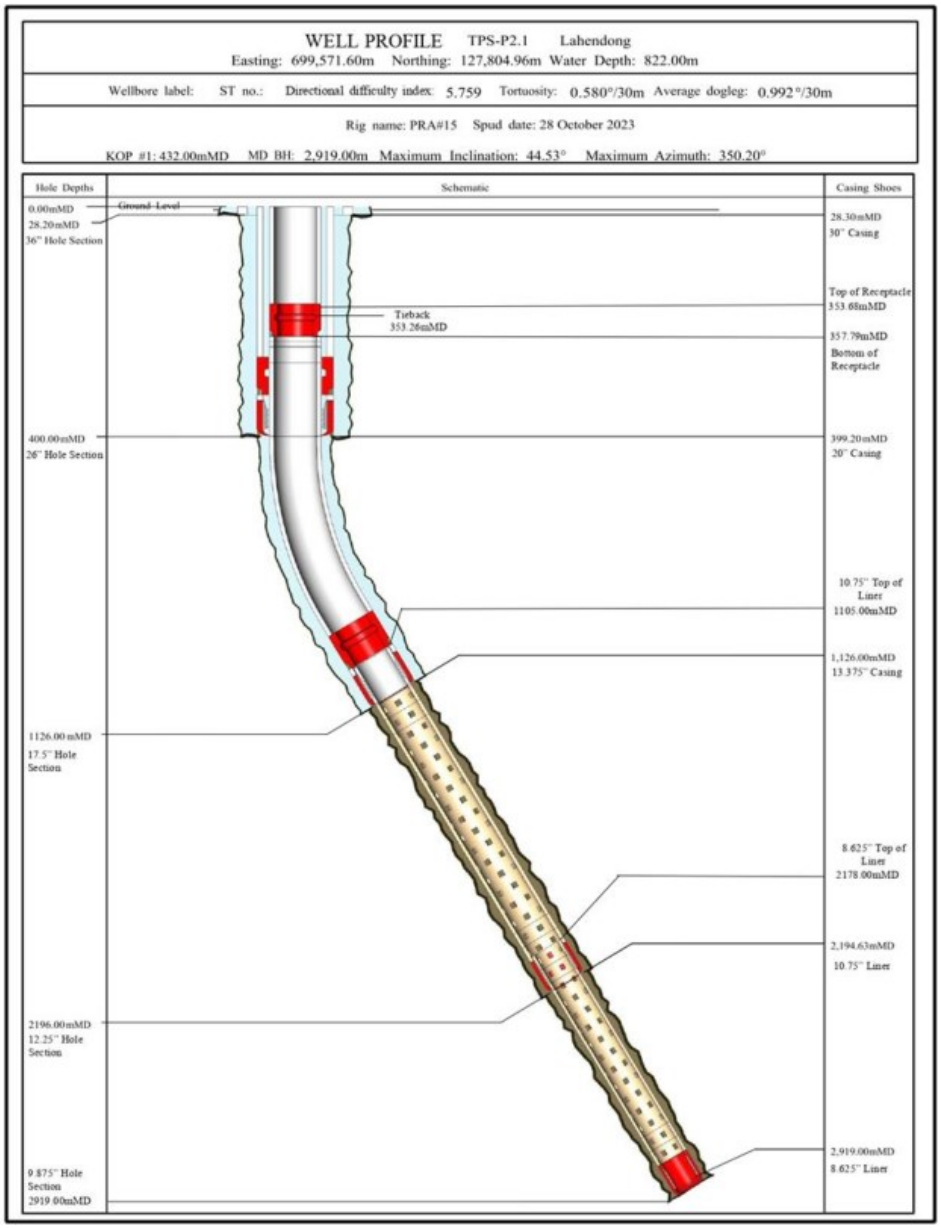

Figure 1: TPS-P2.1 Well Schematic.

2. RELATED WORK

The Concept of drilling in Geothermal and Oil and Gas is slightly different. Drilling, when it was conducted in Oil and Gas whenever loss condition is encountereed during drilling, the process should be done cautiously because the loss condition in oil and gas can lead into kick and even blowout without proper well control action. Therefore, in oil and gas the preparation of kill mud weight should be prepared well while the loss condition or even kick is encountered during the drilling operation.

While in Geothermal, whenever the loss condition is encountered, that means the reservoir is going to be achieved at a certain depth especially whenver we already set at a production depth based on reservoir and geological prognosis. But the danger of kick in geothermal is still can be faced when we encountered the loss condition at the early depth, especially ate early hole section (36" or 26"). The kick that will be happened is the steam kick and one of the most dangerous substances is the Hydrogen Sulfide gas if the steam kick happened, and it also can lead into a blowout such as drilling operation in oil and gas.

During the drilling of well TPS-P2.1 with a 26" trajectory at a depth of 58 mMD, total loss circulation (TLC) was encountered. Previously, in the first exploration well (TPS-A.1), a similar issue occurred where during the drilling of the 26" trajectory at a depth of 39 mMD, TLC was encountered. To mitigate the TLC, a cement plug was

applied using cement and natural LCM a total of 12 times. However, this effort was not successful in mitigating the TLC, so blind drilling was performed until the casing point of the 26" trajectory depth.

Therefore the background of this history will be one of the reason why this paper will explain furthermore about the analysis until the new method to cure the losses at early stage at TPS-P2.1 especially at Hole Section 26" is invented, which is the HighMent, the combination of High-Vis Mud and Cement to combat and cure the losses at the early depth, to achieve a smoother drilling process.

Table 1: Sequence Cure Losses at TPS-A.1 Well.

12	Cement Plug #7	5 Juli 2023	200 bbls	39 mMD	15.8 ppg, UCA 500 (6h : 55m)

In previous drilled wells especially in Tompaso Area, numerous attempts have been done to cure severe losses specifically for the 26" section. Methods by using only cement plugs and lost circulation materials prove to have unsatisfactory result. Due to the severe losses normal conventional lost circulation materials are no use and to overcome this challenge alternative solution is needed.

With further analysis between drilling engineering, drilling fluids and cementing aspects, an optimal cement design was developed in this case for the lost circulation mitigation method, specifically for the 26" section, by combining high-viscosity drilling mud and cement.

3. METHODOLOGY

3.1 High-Viscosity Drilling Mud Design

The hi-vis mud used is optimized to maximize its viscosity while still allowing it to be pumped using a rig pump. The purpose of maximizing the mud's viscosity is to act as a cushion, so when the hi-vis mud is pumped into the well where TLC occurs, it is hoped that it will not immediately enter/disappear into the fractures.

3.2 Cement Design

To combat severe losses due to cavernous formation it was proposed to have cement slurry with high viscosity and rapid gel development properties. Cement with these properties can reduce its fluidity properties once it entered the loss formation and pumping is stopped, hence improving sealing thief zone and mitigate loss formation.

Cement slurry is tested at 30ºC by testing the rheological properties, thickening time, and the compressive strength with an ultrasonic cement analyser. These tests are run to have cement that is mixable and pumpable during cementing job and after cementing job have rapid gel development once it is static, indicated by early strength development during static time.

3.3 High-Viscosity Drilling Mud and Cement Mixture

In lab high-viscosity drilling mud and cement was hand-mixed with 1:1 by volume mixture to observe the fluid profile during intermixing. This mixture has high viscosity that rheological properties can not be tested by rheometer.

Table 2: Design Mud Hi-Vis.

MUD PROPERTIES		SPECIFICATION	Initial Result

Time to Reach 500 psi (hh:mm)	05:23

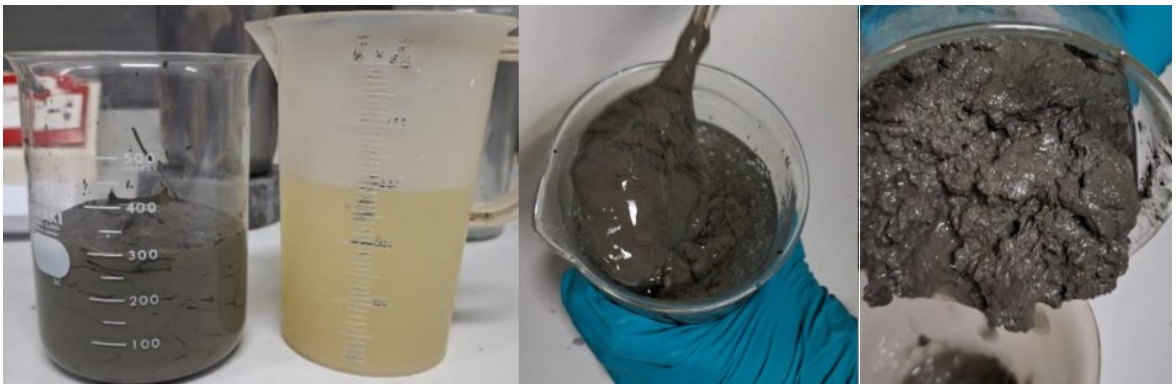

Figure 3: High-Viscosity Drilling Mud and Cement Mixture.

3.4 Cementing Job

Cementing plug job were performed with open-ended DP to reduce friction pressure from viscosity of mud and cement. Open-eneded DP was set around 30" conductor shoe.

During cementing job 200 bbl of high-viscosity drilling mud was pumped ahead of 200 bbls of 15.8 ppg cement slurry. 200 bbl is equal to hole volume with 100% excess. Throughout cementing job no return was observed even with high excess volume.

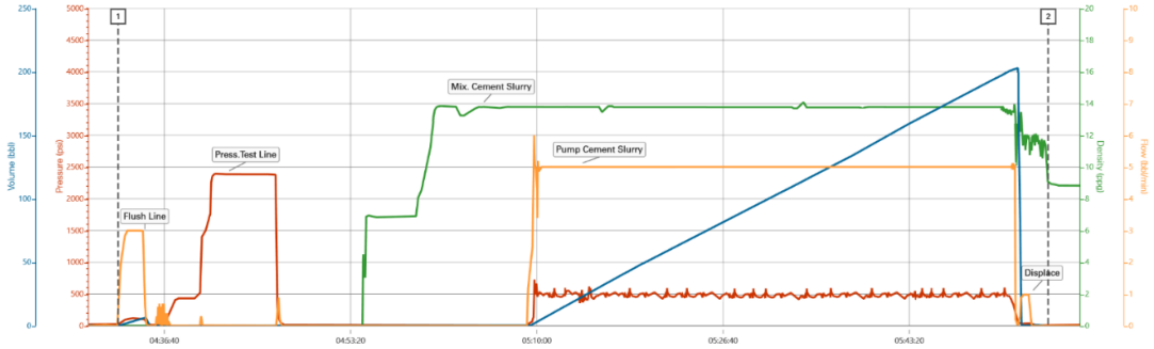

Figure 4: Cementing Plug Job Chart.

4. RESULTS

After WOC for 7.5 hours, cement was tagged at 30m. The cement plug was drilled out, and no losses were observed during and after drilling out the cement, meaning that the job was successfully completed up to the 20" casing point. Additionally, no losses were encountered during the cementing of the 20" casing.

5. DISCUSSION

The Combat Total Loss experiment by using High Vis + Cement at Trajectory 26" is one of the most creative and innovative breakthrough to cure the losses. One of the main advantages of this innovation is there is no need to do a new mixture or create a big amount of trial and error by using new chemical that never used at geothermal drilling operation especially in Pertamina Geothermal Energy.

High Vis and Cement is absolutely available in Pertamina Geothermal Drilling operation because these two materials are a critical and essential materials that used for cementing and drilling mud. The simplicity of the chemical to create a high percentage of effectiveness is truly a genius work to be done.

Based on this data, while the cement plug is performed with open-ended DP to reduce friction pressure with 200 bbl of High Vis Drilling mud pumped ahead of 200 bbls of 15.8 ppg cement slurry (200 bbl is equal to hole volume with 100% excess), there are no major issues that related to the combat loss operation itself, and the loss is cured.

6. CONCLUSION

Geothermal Cementing, until recent days, is still considered as one of the most critical and tricky steps. The prognosis about Loss Condition prediction and fractures prediction about losses at per depth as per analyzed at prognosis always cannot be 100% accurate. The downhole uncertainty is still a major problem to be considered because the nature is so unpredictable, including in geothermal downhole condition.

The biggest consideration of Pertamina Geothermal Energy to do this operation is because the endless and ineffective loss circulation can lead into NPT and increase of massive amount of drilling operation cost, especially in daily rig costs, cement plugs and of course loss circulation material. Therefore, this study needs to be analyzed and applied to every well, because this method is proven to be more effective than usual loss circulation material.

Combining high-viscosity drilling mud and cement has been proven effective in treating loss circulation in the 26-inch outer diameter (OH) surface section, especially in the Tompaso Area. The purpose of using this high-viscosity and cement for the cement plug is to seal off fracture paths/loss zones so that a large volume is not required if total loss circulation (TLC) is encountered, particularly in geothermal wells where TLC is often found in the 26" section. This method can be a new breakthrough to be implemented whenever the loss at early depth will be encountered in any geothermal wells.

The lesson that can be learned from this combat loss operations are:

a. Always be critical and innovative to do an experiment to invent the most innovative and efficient way whenever the combat loss at early section is encountered to reduce and optimized the daily operation costs
b. Reanalyzing the combat loss process before the operation is going to be done, whether it was the material aspect such as the loss circulation material addition, the composition of the LCM to match it with the downhole condition or subsurface condition based on the drilling program prognosis to minimize the uncertainty of downhole condition.
c. Don't only use and repeating the same method to cure the loss that has a big uncertainty, because it will resulting in a waste of time (NPT)

ACKNOWLEDGEMENT

We deeply appreciate the contributions of everyone involved in this project's success. We extend our sincere gratitude to Mr. Tesha, Vice President of Drilling and Services, for his exceptional leadership and unwavering support. Mr. Radianto Ritamawan, Manager of Drilling Operation & WO/WI, has provided invaluable expertise and guidance throughout the drilling process. Special recognition goes to Mr. Wahyu Sutresno, Manager of Drilling Planning & Support, for his meticulous planning and strategic insights, and to Mr. Fery Malau, Assistant Manager of Drilling Operation, for his dedicated efforts and oversight. Our heartfelt thanks go to Mr. Ade Dwi Prasetyo, Drilling Engineer, for his technical proficiency and problem-solving skills, and to the entire Pertamina Geothermal Energy Drilling Team for their hard work and collaboration. We are grateful to the Pertamina Geothermal Energy Area Lahendong team for their on-site support and operational assistance. We commend the TPS-P2.1 Drilling Team for their perseverance and commitment in overcoming project challenges. Lastly, we acknowledge the professionalism and expertise of the TPS-P2.1 Rig Contractor and Services Company Team especially the cementing services, whose contributions were instrumental in achieving project milestones. This project's success is a testament to the collective efforts and dedication of these exceptional individuals and teams.

Steam Turbine Casing Leak Issue and On-site Repair Process

Rasyid, Andrianto, and Hepy

PT Sulzer Indonesia

rasyid.aziz @sulzer.com, andrianto.hapsoro@sulzer.com, hepy.hanipa@sulzer.com

Keywords: Steam leakage, casing on-site repair, Laser Metal Deposition (LMD)

ABSTRACT

This paper details the on-site repair work performed on the high-pressure (HP) casing split line of the 11 MW Steam Turbine casing in East Java. Commissioned to address casing leakage issues, the scope of work included assessing the flatness, gap, and contact of the split line surfaces, performing weld build-up for dimensional restoration using the Laser Metal Deposition (LMD) method, and completing on-site final machining. The repair outcomes demonstrated effective sealing of the steam pathway at the contact surface. High-temperature sealant was applied to optimize surface sealing performance.

1. INTRODUCTION

Sulzer was commissioned to address casing leakage issues on the high-pressure (HP) casing split line of a 11 MW Steam Turbine unit. The issue of leakage along the casing split line has persisted since the previous overhaul of the unit, where it was temporarily addressed using sealant. The turbine casing consists of two parts: the HP casing and the LP casing. Both casings are joined together with bolts, forming the assembled casing, with the joint located in the midsection. Each casing comprises upper and lower halves.

Indications of the leakage issue are marked by the absence of contact between the upper and lower casing surfaces along the split line area. Visible gaps and leaks have been identified at distinct points, as indicated by the blue ink in Figure 1 and Figure 2.

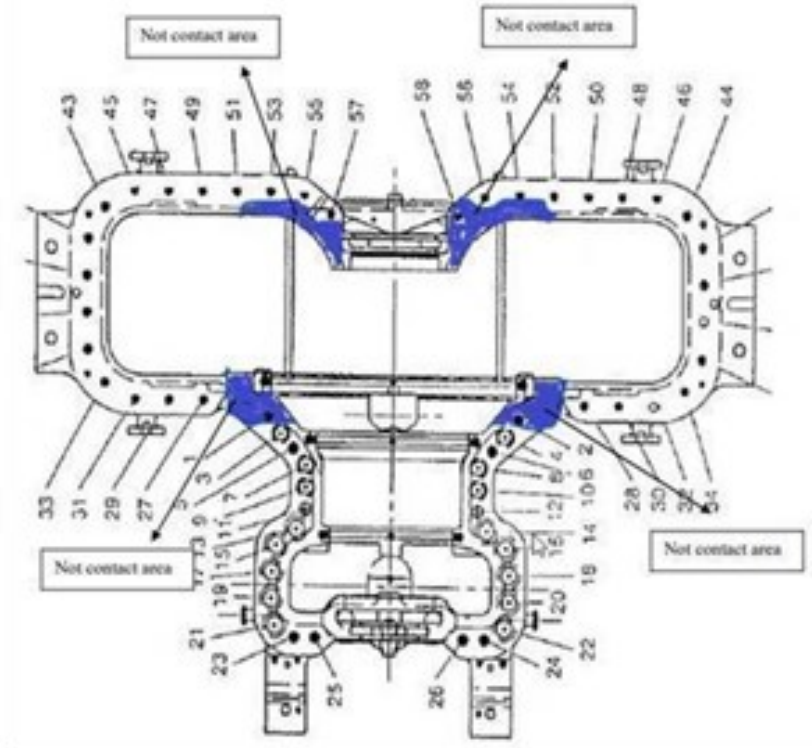

Figure 1: Non-contact area schematic on HP & LP casing split line surface captured during previous overhaul work.

Figure 2: Contact check result indicating non-contact area on lower casing split line.

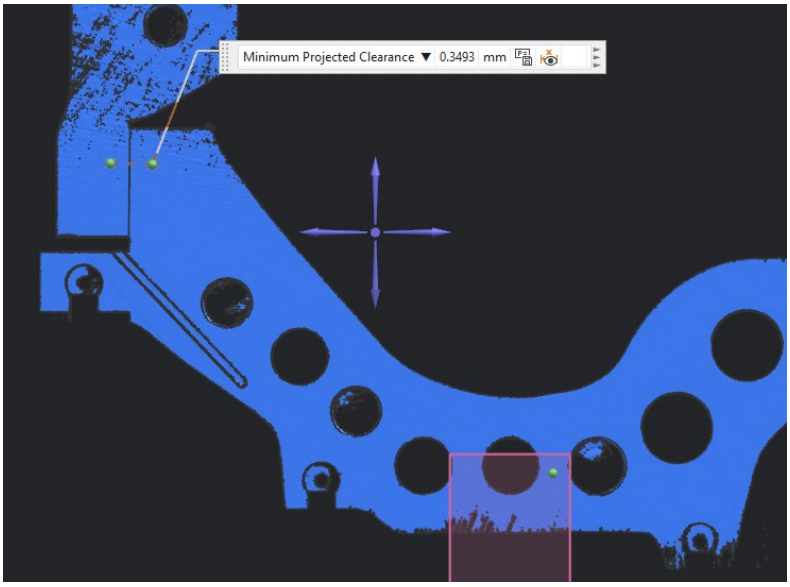

Figure 3: Uneven surface condition between the HP lower casing (left) to the LP lower casing (right).

2. REPAIR PREPARATION

There are two main challenges in completing the repair. The first challenge involves obtaining accurate assessment of the flatness of split line surfaces for both the upper and lower casings. This information is critical for final machining process to ensure effective contact in closing the leakage gaps. To achieve the highest accuracy possible, in addition to gap and contact inspections (with all bolts tightened), flatness check was conducted using portable vertical milling machine and 3D scanner.

The second challenge is to employ a dimensional restoration method that avoids significant side effects, such as distortion to critical dimensions like the casing inside diameter, split line, and casing bolt holes. To mitigate this risk, Laser Metal Deposition (LMD) was utilized, which is a low heat input restoration method.

It was observed the leaking issue on the turbine casing is primarily due to casing distortion, with a minor contribution from erosion or steam cuts. A thorough investigation is required to identify the root cause of the casing distortion. One potential scenario under consideration is the suspicion that the bolt joining the HP and LP casing may have loosened during operation. This potential loosening could lead to the HP casing (both upper and

lower halves) sliding downward relative to the LP casing, creating gaps as indicated in Figure 3. The specific reasons behind the bolt loosening remain unknown and further investigation is required.

Laser Metal Deposition (LMD) weld build-up was prepared and executed on the non-contact area and specifically targeted the lower casing due to practical and time constraint. The concept involved building up the non-contact surface by LMD and subsequently machining it until the contact and non-contact surfaces were leveled. Inconel powder, a material commonly used in geothermal applications for its superior corrosion and erosion resistance compared to the typical turbine casing material, was utilized. This approach enhances the integrity and reliability of the casing during operation.

A portable vertical milling machine was prepared to perform on-site machining with schematic shown in Figure 4. Since the HP casing was sliding downward relative to the LP casing, the lower half HP casing surface became positioned below the lower half LP casing surface level. Due to this suspicion, the plan was to use the LP casing surface as a datum for machining.

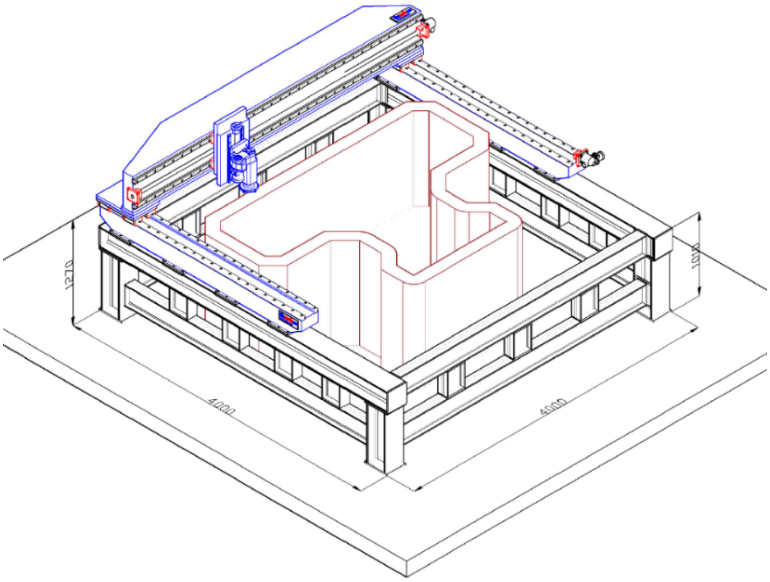

Figure 4: Schematic of portable vertical milling machine.

Figure 5: LMD build-up process on lower casing split line surfaces.

2.1 Initial Attempt Result

The initial repair attempt, which involved LMD build-up and machining, was performed on the lower casing split line surface, as shown in Figure 5 and Figure 6. Following the repair, contact, gap, and flatness checks were conducted to evaluate the results. During this phase, it was possible to perform gap check from the internal side of the casing. The results of the contact check are displayed in Figure 7.

Figure 6: On-site machining process on lower casing split line surfaces.

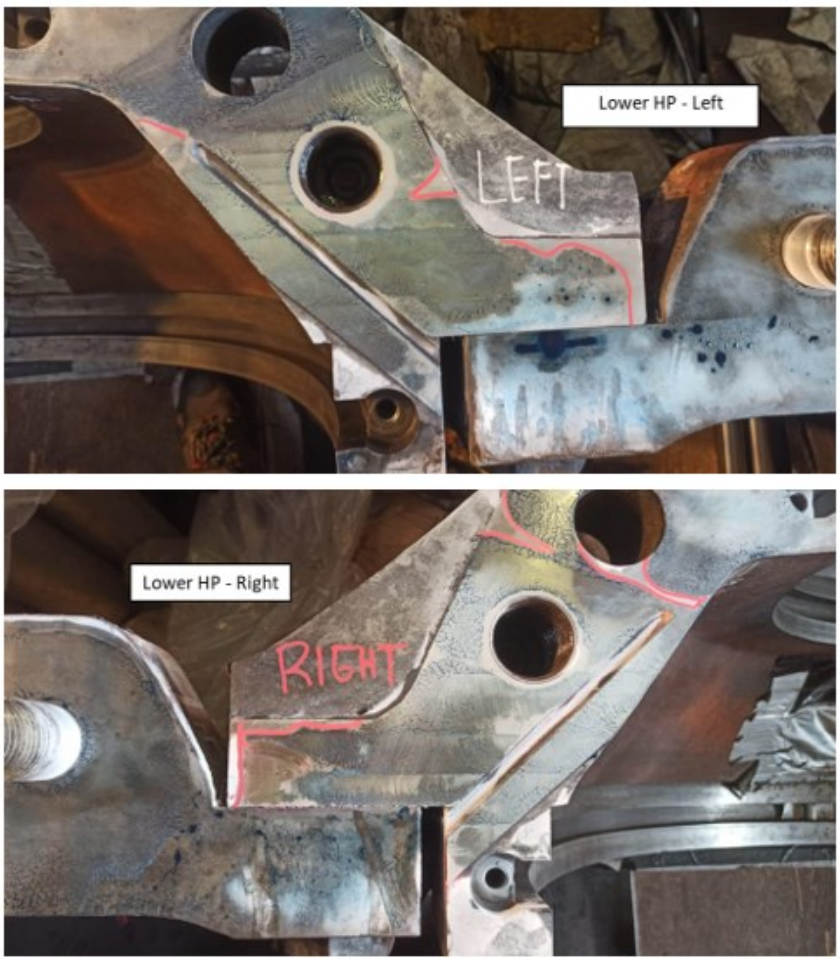

Figure 7: Initial repair attempt contact check results.

Several observations were made based on inspection results:

- The previous non-contact area on HP casing surface has now achieved contact.
- The LP casing surface away from the bolt hole area exhibited weak or was entirely non-contact.

Second repair attempt will be conducted according to the following plan:

- Further build-up LP casing surface that exhibited weak or entirely non-contact
- Shift the machining reference datum to the LP casing surface near the bolt hole area, which has strong contact.

2.2 Second Attempt Result

Several observations were made based on inspection results after second attempt repair:

- Certain areas are still lack of contact as shown in Figure 8.
- Upon conducting gap check with feeler gauge from internal side of the LP casing, a 0.03 mm thick feeler gauge cannot enter certain split line surfaces with weak contact.

As a result of these conditions, following conclusions were drawn:

- Contact classifications were defined, as shown in Figure 8.
- Since the upper-half HP is also observed to be sliding downward, the final machining target on the lower casing should compensate the contour of the upper half HP casing.
- The upper half LP casing surface displays a slope from outward to inward, resulting in larger gaps compared to those formed on the HP casing.
- The upper casing appears to have some degree of uneven surface at random locations.

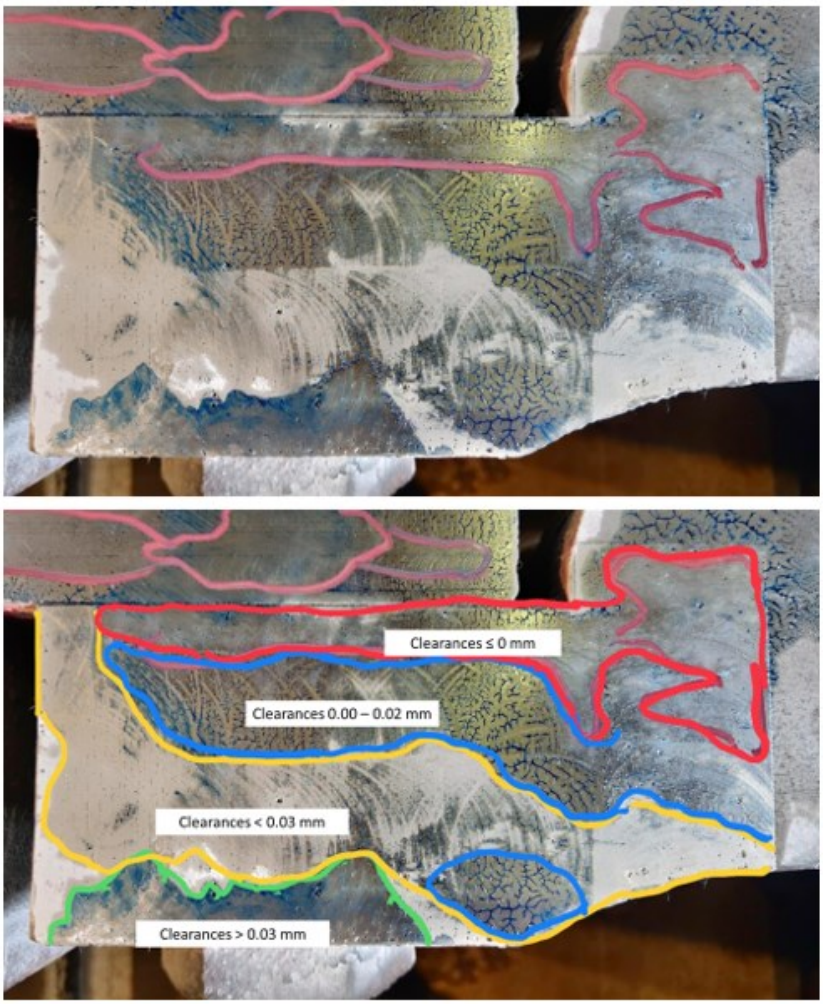

Figure 8: Classification of contact surfaces. Green mark indicates borderline of 0.03 mm feeler gauge penetration.

Following the above conclusions, below repair strategy is planned:

- Conduct rough cutting to a thickness of 0.05 mm in the area below the upper half HP casing.
- Perform rough cutting to a thickness of 0.2 mm in the area below the upper half LP casing.
- Following the rough cutting process, manual finishing was carried out by hand to achieve contact between the lower and upper half casing. The finishing involved stoning, polishing, and dressing. Every after each finishing iteration, contact check will be conducted to evaluate the result.

2.3 Final Attempt Result

LMD build-up was once again performed on the still non-contact area, followed by machining and series of iterations of manual finishing and inspection. While the general idea of the process is to make the majority of non-contact surface become contact, the more important objective is to block the steam pathway from reaching the outside of the casing.

Final contact check result is shown in Figure 9:. Certain areas suspected to have clearances of up to 0.03 mm were observed and subsequently addressed using high-temperature sealing.

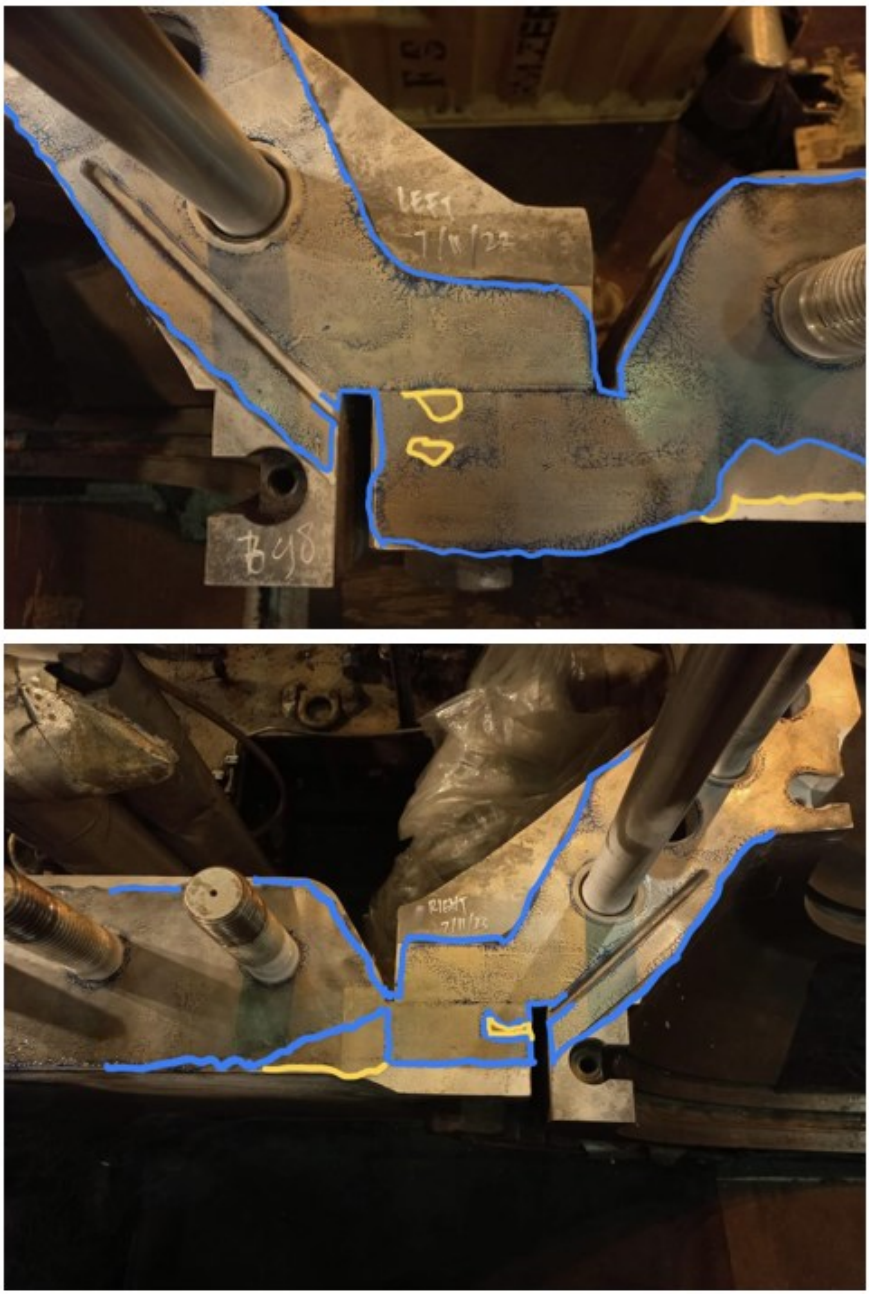

Figure 9: 3rd repair attempt contact check result .

Based on inspection results of repair final attempt, following conclusions were drawn:

- The steam pathway is already sealed as shown in Figure 9. Contact check comparison is shown in Figure 10.
- Certain areas that are suspected to have clearances of up to 0.03 mm are observed. While these particular areas do not compromise the sealing of steam pathway, they have also been addressed through high temperature sealing.

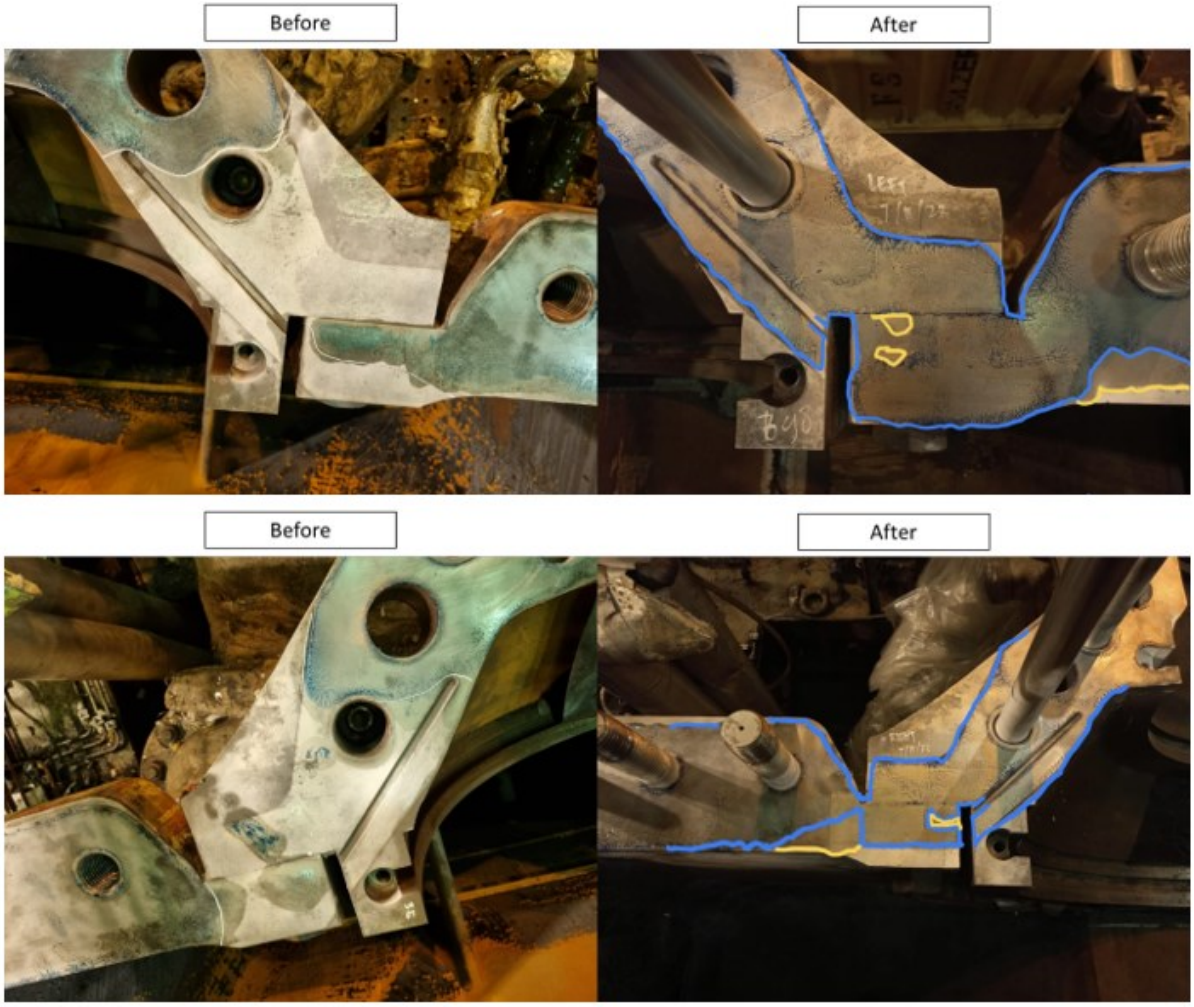

Figure 10: Contact check result comparison before and after repair.

3. CONCLUSION

With the steam path sealed, the leakage issue in the turbine casing has been resolved. The repair process was completed on time and fit for purpose. Through the application of LMD, it becomes evident that the significant risk of casing distortion as a side effect of dimensional restoration method can be avoided.

The on-site machining process, which accelerates the repair duration, contributes to the prompt installation of the rotor, thereby enabling customers to quickly resume their production operations. Consequently, this allows them to recover lost production time during the downtime period.

ABSTRACT

Effective cooling water management is vital for geothermal power plants, ensuring optimal performance and minimizing corrosion, scaling, and fouling within the heat transfer system. This paper presents a rigorous five-year evaluation of open cooling water treatment strategies implemented at Darajat Units 2 and 3. Geothermal cooling water treatment faces unique challenges due to complex water chemistry. Factors like temperature, flowrate, non-condensable gas (NCG) content, and organic bacterial presence significantly influence treatment efficacy. In the case of Darajat Unit-2 and Unit-3, high ammonia and sulfate levels provide sustenance for microbial growth. To address these complexities, SEGD have developed and optimized a tailored treatment program incorporating biocides, dispersants, and corrosion inhibitors. This multi-pronged approach effectively controls microbial growth within the cooling water system. Following a five-year treatment period, key parameters like Total Aerobic Bacteria (TAB) have been maintained below 10,000 cfu/ml, Sulfate-Reducing Bacteria (SRB) below 325 cfu/ml, and fungal presence has been significantly reduced. Our findings emphasize the critical role of long-term cooling water treatment in geothermal power plant operations. Effective management strategies directly impact plant efficiency, reliability, and environmental sustainability. Notably, the successful utilization of non-oxidizing biocides has minimized microbial growth and prevented foaming. This paper underscores the importance of continued treatment optimization to address the unique challenges inherent to geothermal cooling waters. By doing so, SEGD can ensure the long-term viability of geothermal energy as a clean and renewable power source.

1. INTRODUCTION

1.1 Cooling Systems

The Darajat Power Plants, Unit 2 and Unit 3, exemplify the potential of geothermal energy. Situated at Gunung Darajat, Garut, West Java, Indonesia, these facilities house 96 MW and 121 MW (gross) capacity steam turbine-generators, respectively, within a single building at 1723 m asl. By utilizing a dry steam geothermal resource and transmitting electricity to the national grid, SEGD provides a clean and reliable energy source to the region. Key features of the plant include surface condensers, hybrid gas removal systems, and crossflow cooling towers, highlighting the technology employed in geothermal power generation.

Cooling water systems are integral to geothermal power plants, enabling steam condensation and waste heat dissipation. However, the efficiency of these systems, particularly the cooling towers, hinges on effective water treatment. Untreated cooling water can lead to scaling, corrosion, and biological fouling, which hamper heat transfer efficiency and damage equipment. Implementing appropriate treatment methods ensures optimal water quality, promoting high operational efficiency, extended equipment life, and reduced environmental impact.

In the Darajat Power Plants, a steam condensing and cooling system is essential for achieving acceptable plant cycle efficiency. Due to the absence of a large water body nearby, cooling towers serve as the primary source of cooling water. The condensed steam is also source of make-up water for the cooling system, compensating for water loss due to evaporation. Notably, normal plant operation results in a surplus of make-up water, with the excess directed to the condensate injection system. Both Unit 2 and Unit 3 utilize two cooling systems: an open-loop circulating water (CW) system and a closed-loop component cooling water (CCW) system.

Figure 1: Aerial Photograph of Darajat Power Plant Units 2 and 3. (From top to bottom: the interface area, cooling towers, and the power generation building)

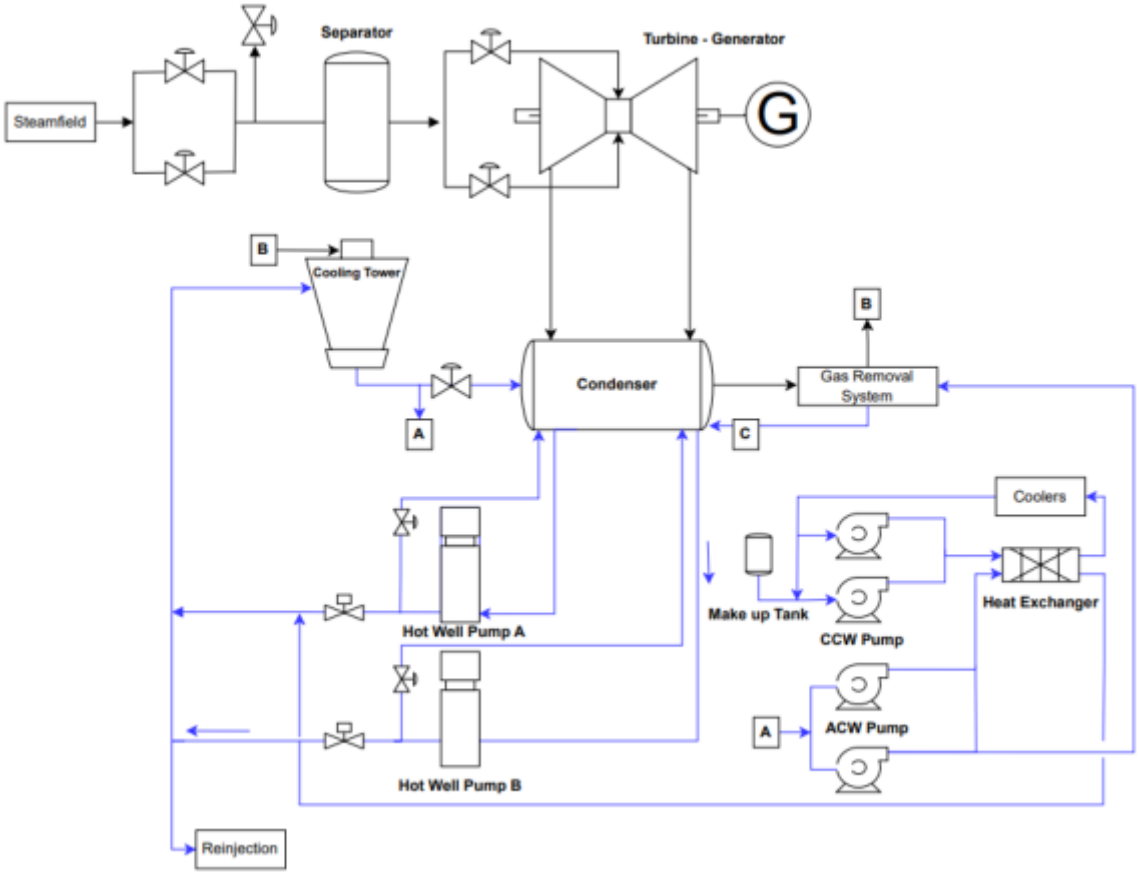

Figure 2: Open loop circulating water systems of Darajat Unit-2 and Unit-3.

The open-loop CW system is an evaporative cooling cycle designed to condense steam turbine exhaust and cool auxiliary plant systems. Hotwell pumps transfer hot water from the condenser to the cooling tower, where it is cooled through evaporation and returned to the condenser.

At each unit, steam exhaust from the turbine is cooled in direct contact with main condensers. Cooling water is drawn in by the condenser vacuum and sprayed into the condenser. A control valve regulates cooling water flow. Two hotwell pumps transport circulating water from the condenser to the crossflow cooling tower, where it is cooled by evaporation. The tower is designed for optimal performance at 100% plant load at 15.5°C wet bulb temperature. Flow regulating valves balance flow to the cooling tower hot basin. Cooling tower fans draw air through the tower splash bar fill, cooling the circulating water, which collects in the cooling tower basin.

The component cooling water (CCW) system of each unit is a secondary fresh water closed loop circuit that supplies all heat exchangers not supplied by the circulating water system, including lube oil, generator air, hotwell pump motors, and air compressor coolers. The closed-loop system minimizes fouling of the associated equipment heat exchangers. Two 100% duty pumps circulate water throughout the loop. The system rejects heat through two 100% duty titanium plate heat exchangers to auxiliary cooling water.

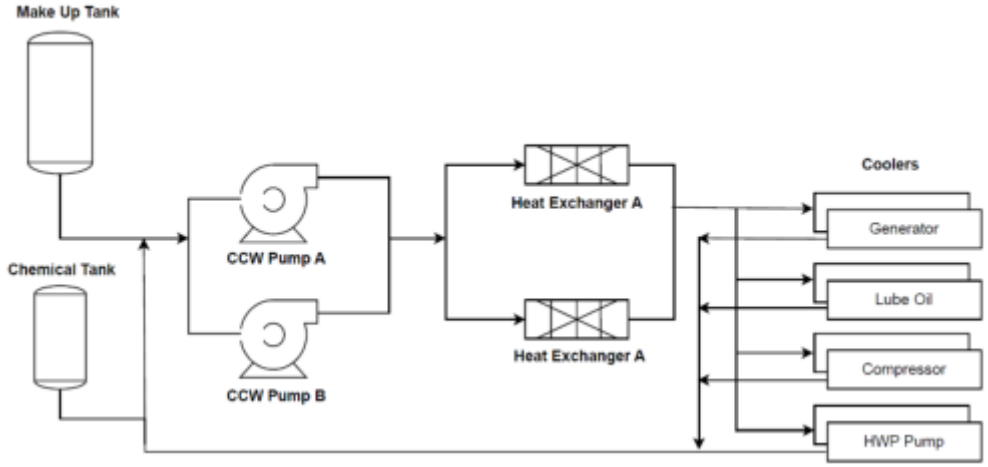

Figure 3: Closed-loop Component Cooling Water (CCW) system of Darajat Unit-2 and Unit-3.

The component cooling water head tank provides sufficient net positive suction head for the CCW pumps. The head tank also is set such that the pressure in the CCW system is greater than the pressure in the open loop cooling system, so that any leaks in the heat exchanger will not introduce geothermal condensate into the predominantly carbon steel CCW system. Makeup water is provided from domestic water.

1.2. Chemical Dosing System

Geothermal fluids, characterized by their unique chemical composition and varying thermodynamic conditions, pose inherent challenges to the operational integrity of geothermal power plants. The presence of soluble species and dissolved gases within these fluids can lead to scaling (fouling) and corrosion of metallic surfaces in contact, thereby necessitating chemical treatment strategies tailored to each specific geothermal site.

Corrosion, a pervasive issue in geothermal facilities, can manifest in various forms across the production well, surface equipment, piping, steam turbine, reinjection line, and other components interacting with geothermal fluids. The severity of corrosion is exacerbated by site-specific factors such as elevated concentrations of corrosive agents (H2S, Cl-, SO42-, CO2), high temperatures, and cathodic reactions with metal surfaces. In severe cases, corrosion can induce catastrophic equipment failures, exemplified by pipe ruptures or bursts, with potential ramifications for safety, health, the environment, and surrounding communities. Moreover, the degradation of equipment due to corrosion can significantly impact plant reliability, leading to increased downtime (Loss Production Opportunity) and escalating operational costs for corrective measures.

The Chemical Dosing System is designed to control the microbiological activity and pH of the circulating water, auxiliary cooling water, and condensate reinjection systems to maintain their optimum performance and material protection. The cooling water chemistry will be controlled and monitored by measuring pH, conductivity, microbiological count, and blowdown rate. Cooling water is treated with a mastered injection of biocide for microbiological control, caustic soda solution for pH control and corrosion inhibitor for corrosion control specially for the reinjection line and wells.

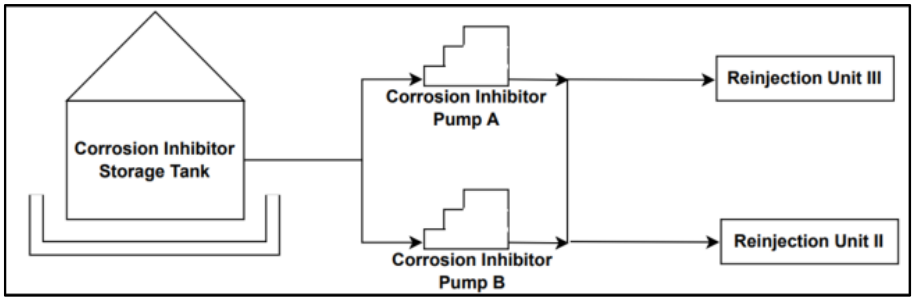

Figure 4: Chemical Dosing System.

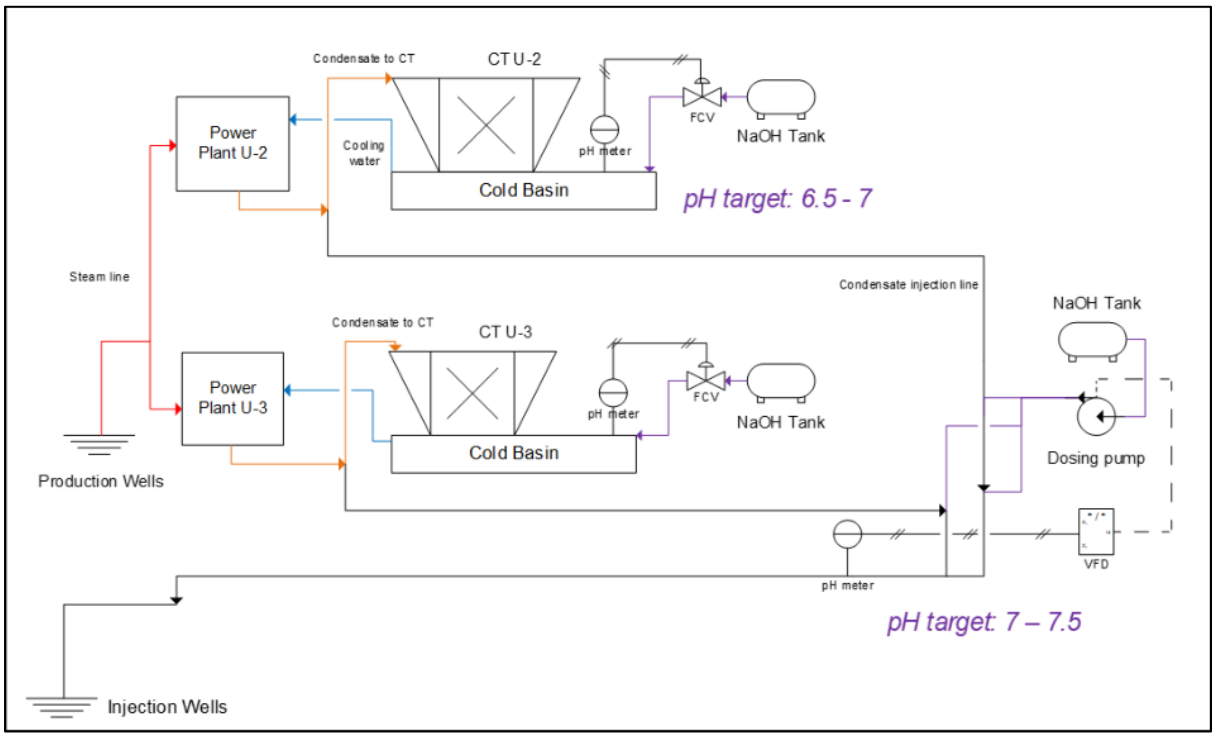

Figure 5: Caustic Soda Dosing System.

The caustic soda dosing system can raise the pH of condensate circulated within the power plant from its natural level of 3.5 to within the range 6.5 to 7. It can also raise the pH of reinjection condensate to 7 – 7.5. The existing biocide system consists of two 100% capacity pumps and two biocide tanks. Discharge lines to the cooling towers are cross connected by additional piping to be able to add biocide to both unit's cooling tower. Microbiological control is monitored through manual and visual cooling system inspections and microbiological plate counts. System inspections provide evaluation of sessile organisms and cooling system conditions. Performance criteria are established using inspection results along with the microbiological plate count data.

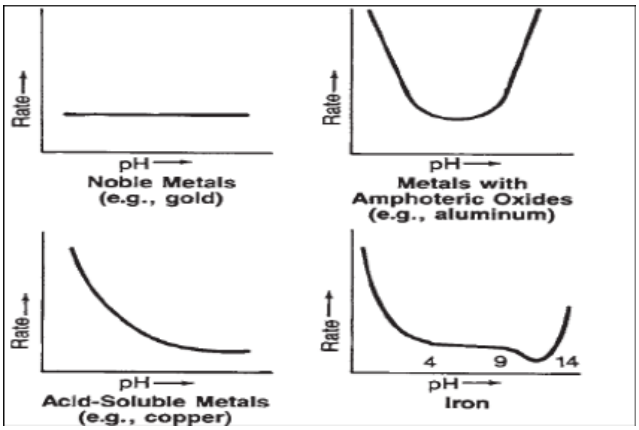

Figure 6: General Influence of pH on Corrosion Rate.

Given the complex interplay of factors influencing the performance of cooling water systems in geothermal power plants, this paper presents a comprehensive five-year review of the open cooling water treatment strategies implemented at Units 2 and 3. By analyzing the operational data, chemical treatment methodologies, and lessons learned, this study aims to provide valuable insights into the challenges and best practices for maintaining efficient and reliable cooling water systems in geothermal power generation facilities.

2. CHALLENGES OF GEOTHERMAL COOLING WATER TREATMENT

2.1 Challenges in Unit-2 and Unit-3 Plants Open Cooling Systems

Open cooling water systems in geothermal power plants face four primary challenges: corrosion, scale, fouling, and microbiological contamination. If left unaddressed, these issues can lead to reduced heat transfer efficiency, equipment failures, and even plant shutdowns, resulting in lost production opportunities and increased maintenance costs.

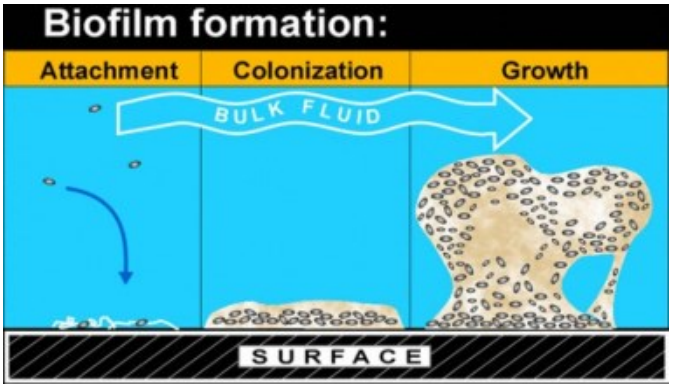

Figure 7: Progression stages of growth of a bacterial biofilm. (Kashef, et al. 2017)

Microbiological growth poses a significant challenge in geothermal power plant cooling water treatment due to the high levels of nutrients, particularly sulfur and ammonia, present in the condensate used as cooling water makeup. These nutrients create an ideal environment for the proliferation of microorganisms, which can cause a variety of problems:

1. Aerobic Slime Formers

Ubiquitous in the environment, these bacteria readily colonize open systems, adhering to surfaces throughout the cooling circuit, including heat exchangers. Encapsulated in slime layers, they form biofilms that impede heat transfer and may promote corrosion.

2. Anaerobic Corrosive Bacteria (e.g., Sulfate-Reducing Bacteria)

These bacteria utilize sulfate ions, producing hydrogen sulfide as a metabolic byproduct. This highly corrosive acid generates sludge, contributing to fouling and corrosion in the cooling tower basin and downstream equipment.

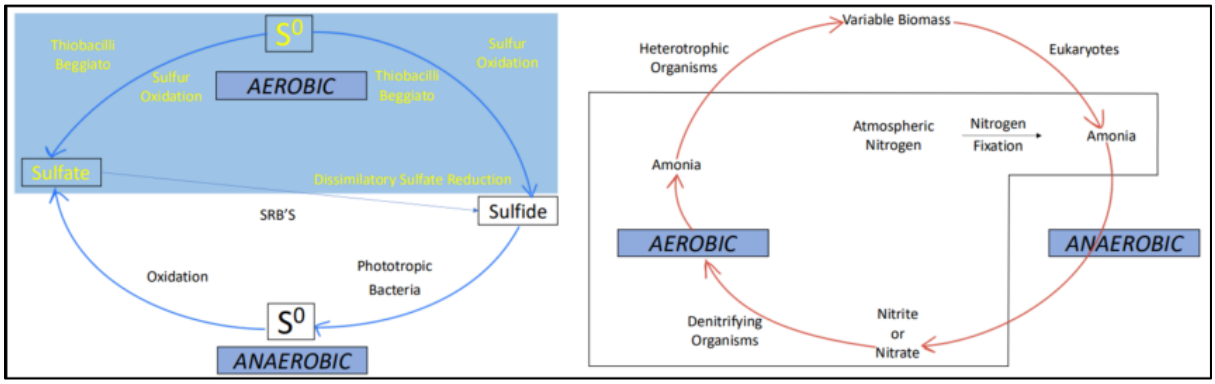

Figure 8: Microbiological Transformations of Sulfur and Nitrogen in Geothermal Systems. (Nalco Water Handbook, 2018)

3. Nitrifying Bacteria

Nitrifying bacteria metabolize ammonia, converting it to nitrates, a process implicated in corrosion and scaling in systems susceptible to ammonia contamination.

4. Algae

Flourishing in sunlight, algae mainly colonize open cooling tower decks, causing plugging of distribution decks. Excessive growth can lead to detachment and subsequent fouling of heat exchangers.

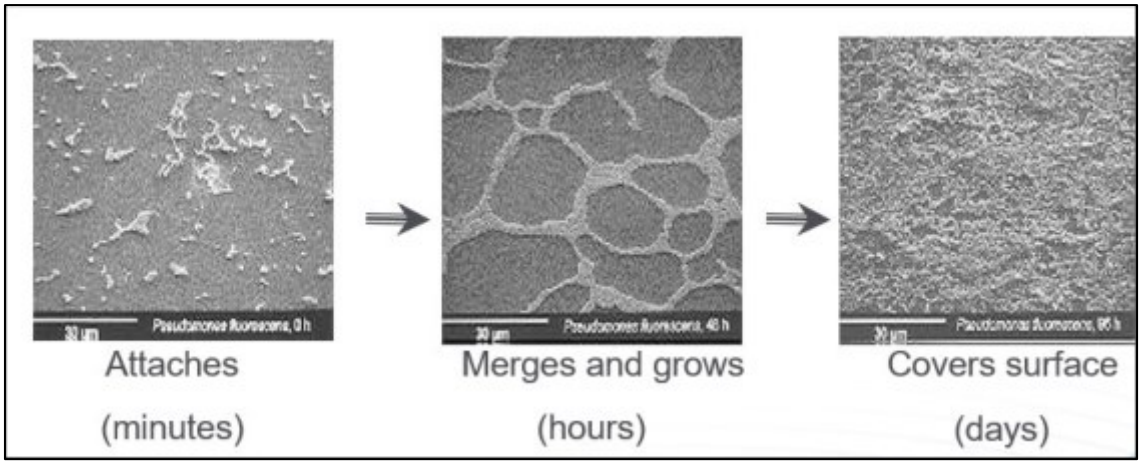

Figure 9: Microbiological growth in metal (Nalco Water Handbook, 2018).

The presence of these diverse microorganisms necessitates continuous chemical treatment to maintain the operational efficiency, integrity, and longevity of cooling system components.

While the Unit 2 and Unit 3 cooling system predominantly employs corrosion-resistant materials such as stainless steel (SS), fiberglass-reinforced plastic (FRP), and ceramics, minimizing corrosion risk remains a priority for maximizing equipment lifespan and maintaining system integrity. Corrosion management practices, adhering to equipment design specifications, are implemented to mitigate potential corrosion issues.

2.2 Challenges in Unit-2 and Unit-3 Plants Closed Cooling Systems

Closed recirculating cooling systems in geothermal power plants, while generally considered more stable than open systems, are nonetheless susceptible to corrosion, fouling, and microbiological growth. These issues are interdependent, as corrosion can be exacerbated by fouling and microbial activity, leading to a cascade of problems that can compromise system efficiency and longevity.

1. Corrosion

In closed systems, the absence of blowdown for removing corrosion products can lead to the accumulation of suspended solids, increasing the risk of clogging, erosion, and localized corrosion under deposits. Oxygen ingresses through makeup water or air leakage, along with the deposition of solids, can further accelerate corrosion processes.

2. Fouling

Fouling deposits, composed of suspended solids, scaling products, corrosion byproducts, and microbial growth, can hinder system performance by obstructing valves, orifices, and recirculating lines. The build-up of foulants can also impede heat transfer, reducing overall system efficiency.

3. Microbiological Growth

Microbial activity can thrive in closed systems due to the introduction of oxygen, debris, and nutrients from various sources, including makeup water, process leaks, and open make-up water tanks. Microbial growth contributes to fouling, corrosion, and impaired heat transfer due to the formation of insulating biofilms.

The specific treatment requirements for the closed-loop cooling system are informed by the presence of carbon steel components within the circuit, necessitating targeted strategies to mitigate corrosion and fouling risks.

Table 1: Specification of Unit-2 and Unit-3 closed-loop system.

PARAMETER	UoM	CCW Unit 2	CCW Unit 3
Total System Volume	m^3	7	7
Recirculating Rate	m^3/hr	477	466
Material		Carbon Steel, Copper	Carbon Steel, Copper

2.3 Challenges in Condensate Reinjection Lines

Maintaining the heat and mass balance of geothermal power plants necessitates the continuous reinjection of condensate into the reservoir. However, this process presents operational challenges, particularly corrosion in reinjection lines, which can significantly impact plant reliability and potentially lead to environmental concerns.

In the Darajat geothermal field, a 4.5 km, 12-inch carbon steel pipe transports condensate from the power plants to the reinjection well (Pad-19). Any disruption to this system, such as leaks or damage requiring offline repairs, necessitates unit shutdowns, impacting power generation and revenue. Additionally, leaks in the reinjection line, which traverses through community plantation areas, pose environmental risks due to potential liquid spills.

Figure 10: Condensate Reinjection Piping (under Steam Pipeline).

Table 2: Specification of PLTP Darajat Condensate Reinjection Lines.

PARAMETER	UoM	Value
Distance	km	4.5
Temperature	°C	40 – 50
Total Condensate	lps	130
Pipeline Material	-	Carbon Steel

Due to the pipeline's considerable length and associated costs, complete replacement with corrosion-resistant materials, such as stainless steel, is not economically feasible. Therefore, the company has employed a more cost-effective mitigation strategy: the application of chemical corrosion inhibitors. This approach effectively mitigates the risks of corrosion-induced leaks and subsequent environmental damage, while ensuring the continued operation and integrity of the reinjection system. Given the financial and environmental implications, ensuring the integrity and availability of the reinjection system is crucial.

Four primary factors influence the type, rate, and inhibitor selection for corrosion mitigation in reinjection systems: temperature, dissolved solids concentration, pH, and dissolved oxygen concentration. Understanding these parameters is key to developing effective corrosion management strategies that ensure the longevity and reliability of reinjection infrastructure in geothermal power plants.

3. METHODOLOGY

3.1 Chemical Treatment Selection in Geothermal Cooling Systems

Selecting the appropriate chemical treatment for geothermal cooling systems is crucial to ensure optimal performance, minimize corrosion and fouling, and maintain operational efficiency. This section discusses the selection process for both condensate reinjection and open and closed cooling systems, highlighting the specific challenges and treatment options in the context of the SEGD geothermal power plant.

3.1.1 Open Cooling System – Microbial Growth Control

Microbiological growth in open cooling systems can lead to fouling, corrosion, and reduced heat transfer efficiency. Non-oxidizing and oxidizing biocides are commonly used to control microbial growth, each with distinct characteristics:

Table 3: Characteristic of non-oxidizing and oxidizing biocides.

PARAMETER	Non-Oxidizing Biocides	Oxiding Biocides
Consumption of Contaminants (H_2S & NH_3)	Not consumed, less reactive	Consumed, very reactive
Halogen Demand Consideration	No issue	Requires careful management of halogen demand to maintain free residual chlorine (FRC) levels between 0.2 - 0.5 ppm
Microbiological Control	Excellent	Less effective
Chemical Consumption	Lower	Consumed, very reactive

To address the challenge of microbial growth in the open cooling system, a comprehensive biocide selection process was undertaken. Given the superior performance of non-oxidizing biocides in geothermal applications, the focus was on evaluating different non-oxidizing biocides against the SEGD's specific microbial growth targets:

- Total Aerobic Bacteria (TAB): < 10,000 cfu/mL
- Sulfate-Reducing Bacteria (SRB): < 325 cfu/mL

Laboratory tests were conducted to assess the efficacy of various non-oxidizing biocides in controlling TAB and SRB populations. The test results indicated that biocide N7330 exhibited the highest efficacy, consistently achieving near-complete removal of TAB and a significant reduction in SRB levels, surpassing the SEGD targets. Based on the laboratory findings, N7330 was selected as the optimal biocide for microbial control in the SEGD open cooling system. Field implementation has further validated this choice, with actual performance data consistently demonstrating effective control of microbial growth within the specified targets. The biocide dosage is adjusted as needed to maintain optimal performance, facilitated by a performance-based contract with the chemical supplier.

3.1.2 Closed Loop Cooling System – Corrosion Control

Corrosion is the deterioration of materials, typically metals, caused by chemical reactions with their environment. This process often leads to component failure. Essentially, corrosion reverses the extractive metallurgy process, returning the metal to a more thermodynamically stable compound form. Several factors influence corrosion, including:

- Metal properties: Position in the galvanic series, purity, surface layer characteristics, and corrosion product properties.
- Corrosive environment properties: Concentration, stress, erosion, and temperature.

Corrosion generally involves a chemical reaction between the metal and its surroundings (like oxygen or water), producing more stable compounds. The flow of electrons from the less noble metal (anode) to the more noble metal (cathode) drives the corrosion of the less noble metal. (Kumat et al., 2021).

Closed recirculating cooling systems are effectively protected from corrosion through the application of various chemical inhibitors. Among the most widely utilized are passive film-forming inhibitors, including PSO-based treatments, Boron-nitrite formulations, and molybdate blends.

In these closed systems, complete corrosion prevention is achieved by maintaining higher inhibitor concentrations, a practice proven to be more cost-effective than in open recirculating systems due to reduced water loss and lower chemical consumption. Preventing corrosion is of paramount importance in closed loops, as the accumulation of insoluble corrosion products can lead to fouling, flow restrictions, and accelerated localized corrosion.

The primary objective of corrosion control in closed systems is to establish near-complete (approaching 100%) protection for all metal surfaces. Effective treatment programs, when diligently monitored and maintained, can closely achieve this goal. Common Corrosion Inhibitors in Closed-Loop Cooling Systems:

1. Phospinosuccinic Oligimer (PSO-Based)

PSO is a type of corrosion inhibitor known for its effectiveness in forming a protective film on metal surfaces. This film acts as a barrier against corrosive agents, preventing or slowing down the corrosion process by forming

a protective layer at the anode, the site where metal corrosion typically begins. This helps to prevent further metal loss.

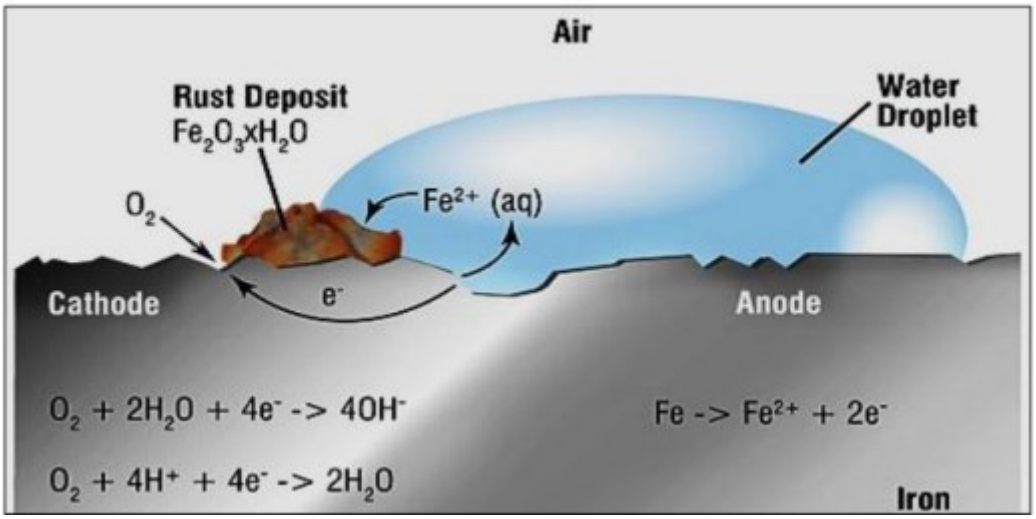

Figure 11: Mechanism of corrosion in metal (Aljamali et al., 2019).

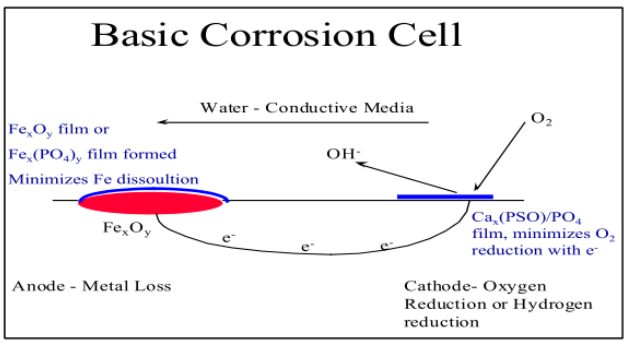

Figure 12: PSO-Based Corrosion Inhibition Mechanism (Nalco Water Handbook, 2018).

2. Boron-Nitrite Based

Boron-nitride (BN) is increasingly being explored as a component in corrosion inhibitor formulations. It exists in various forms, including hexagonal boron nitride (h-BN) and cubic boron nitride (c-BN). This chemical encourages the formation of a thin, protective film of iron oxide on metal surfaces, effectively shielding the metal from corrosive elements and minimizing metal loss.

3. Molybdate Blends

Molybdate blends typically contain molybdate ions along with other inhibitors. Molybdate ions form a protective film on metal surfaces by reacting with the metal itself and with corrosion products. This film is often described as a "self-healing" layer, meaning it can repair itself if damaged.

To assess the efficacy of various corrosion control chemicals for the closed-loop cooling system, laboratory tests were conducted. The performance of three chemicals was evaluated: a blank (untreated) sample, TRAC-109, and a molybdate-based inhibitor. The SEGD target corrosion rate for the closed-loop system is ⩽10 mpy (mils per year).

Table 4: Comparative Study of Corrosion Inhibition Effectiveness.

No	Sample Code	Dosage (ppm)	Corrosion Rate (mpy)	Iron Concentration (ppm)		
				Initial	Final	Additional
1	Blank	-	1.87	0.423	23.148	22.725
2	TRAC-109	2000	0	0.423	0.429	0.006
3	Molybdate Base	800	1.19	0.423	15.072	14.649

The results demonstrated that TRAC-109, at a dosage of 2000 ppm, completely inhibited corrosion, achieving a corrosion rate of 0 mpy and minimal iron concentration increase. The molybdate-based inhibitor, while reducing corrosion compared to the blank, did not meet the SEGD target.

Based on these findings, TRAC-109 was selected as the most effective corrosion inhibitor for the SEGD closed-loop cooling system. In field applications, the dosage of TRAC-109 is adjusted to maintain the target corrosion rate, ensuring optimal performance and longevity of the system.

3.1.3 Condensate Reinjection System – Corrosion Control

Corrosion attack that occurs within a geothermal plant may result in severe equipment damage whether in the production well, surface equipment and piping, steam turbine, reinjection line and all the equipment which handle condensate, steam, and condensate/steam mixtures. There are 4 (four) main factors influenced the corrosion type, rate and inhibitors type use in surface/reinjection system of geothermal plant:

1. Temperature
2. Dissolved Solids concentration
3. pH
4. Dissolved Oxygen concentration

High corrosion potential and aggressive attack in the steam and condensate often cause catastrophic failure, low reliability, and high total operating cost in geothermal plant. In the past corrosion has been dealt with by using corrosion resistant materials and nowadays corrosion inhibitor application is one of the most cost-effective solutions.

Corrosion control is a prominent part of maintaining a cooling water system (Nalco Water Handbook, 2018). It can be the most complex to solve; thus, it is important to observe all the possible parameters for control. A complete solution involves a combination of possible ways to minimize corrosion. They are:

1. Use of corrosion resistant materials, such as stainless steel, copper-nickel alloys, or plastic.
2. Use of coatings such as paint, epoxy coatings, and metal cladding.
3. Cathodic protection.
4. Sacrificial anodes reduce corrosive attack.
5. Application of chemical corrosion inhibitors.

In reinjection systems, corrosion can significantly impact pipe and wellbore lifespan, leading to costly repairs and downtime. Nalco 3DT129, a multifunctional corrosion and scale inhibitor, has been effectively used to mitigate this issue. By forming a protective film on metal surfaces, it acts as a barrier against corrosive elements in the water, reducing metal loss and extending the life of critical equipment. This chemical is well-suited for low hardness/low alkalinity environments and is often used with a dispersant polymer to enhance protection and ensure optimal performance. Injecting 3DT129 so far has succeeded in protecting the reinjection line through possibility of corrosion.

3.2. Parameter Monitoring

To monitor the parameters, there are some indicators that we need to observe. We divide the control parameters into two indicators:

Table 5: Key Indicators of Control Parameters for Cooling System Performance Evaluation.

Leading In dicator	**Lagging Indicator**
Water chemistry	SSC (specific steam consumption)
Bacterial count	Approach temperature
Filler Weight	Cooling system efficiency
Temperature data	Cooling water temperature

3.2.1 Leading Indicator

Leading indicators are proactive measures that can predict future performance and potential issues in the cooling water system. They often indicate conditions that could lead to problems if not addressed promptly. For example, monitoring water chemistry parameters like pH, conductivity, sulfate, iron, and microbiological content is crucial for preventing scaling, corrosion, and biofouling. Deviations from the optimal range can signal the need for adjustments in the treatment program, thus preventing issues such as reduced heat transfer efficiency or equipment damage, which are reflected in lagging indicators like temperature data.

The following are Key Performance Indicators for open loop cooling water treatment:

Table 6: Key Performance Indicators for open loop cooling water treatment.

Parameters	Value	Unit
pH	6.5 - 7	
Total Aerobic Bacteria	10,000	cfu/mL
SRB	325	cfu/mL
Turbidity	<5	NTU
Total Suspended Solids	<5	mg/L
Total Alkalinity	<100	mg/L as CaCO3
Free Chlorine	<1	mg/L as C12
Chloride	<10	mg/L as CCl
Total Hardness	<30	mg/L as CaCO3
Total Dissolved Solids	<200	mg/L as NaCl
Total Iron	<0.5	mg/L as Fe
Dissolved Silica	<10	mg/L as SiO2

3.2.2 Lagging Indicator

Lagging indicators reflect past performance and are used to measure the impact of the treatment program over time. These reactive measures provide data on the outcomes of various operational conditions and maintenance practices. For instance, Specific Steam Consumption (SSC) measures the steam used per unit of electricity generated, with higher values indicating inefficiencies in the cooling system or potential steam leaks. An increase in SSC can trigger investigations into cooling system performance and maintenance needs. Additionally, Approach Temperature, the difference between the cooling water outlet temperature and the ambient wet-bulb temperature, is a key indicator of heat exchange efficiency. A higher approach temperature can signal fouling or inefficiencies in the heat exchanger. Other lagging indicators include overall cooling system efficiency, encompassing factors like heat transfer rates, energy consumption, and operational uptime. Monitoring these lagging indicators helps identify areas for improvement and evaluate the effectiveness of the implemented treatment program over time.

4. RESULTS AND DISCUSSION

4.1 Leading Indicators

During five years of treatment, the challenge found in the cooling water SEGD is the common problem in most cooling water systems, such as microbial, increasing sulfate, and corrosion. High ammonia and sulfate are the cause of increased microbial growth. Increasing sulfate can be caused due to an increase in NCG levels. And the corrosion may happen due to increased level of dissolved oxygen in the basin. The presence of algae, sulfur, and mud (dead bacteria) can inhibit the performance of cooling water.

The chart below illustrates the effectiveness of the implemented biocide treatment program in controlling leading indicators such as Total Aerobic Bacteria (TAB), Sulfate-Reducing Bacteria (SRB), Total Suspended Solids (TSS), Total Dissolved Solids (TDS), Total Alkanity, Turbidity, Total Iron, Dissolved Silica levels within the open cooling water system. The data covers approximately five years, presenting leading indicator counts before and after treatment at both Cooling Water 2 (CW2) and Cooling Water 3 (CW3). The results consistently demonstrate attainment of the target leading indicator limits as shown in Figure 13.

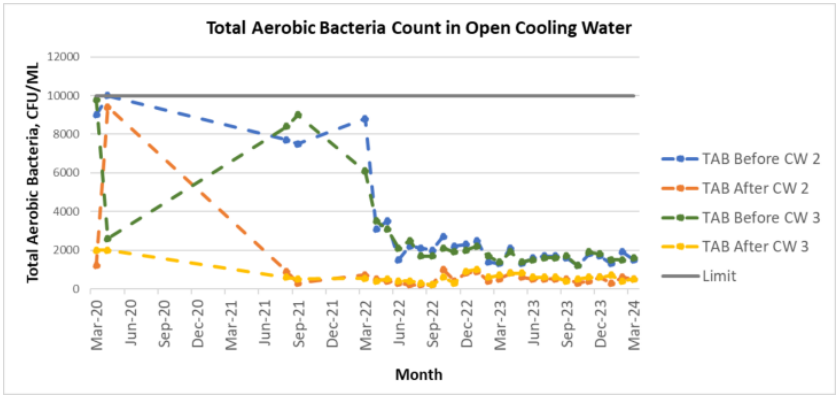

Figure 13: Total Aerobic Count in Unit-2 & Unit-3 Open Cooling Water.

The chart shows a significant decrease in Total Aerobic Bacteria (TAB) after the implementation of the cooling water (CW) treatment in both Unit-2 and Unit-3. The TAB count consistently remained below the specified limit after treatment, indicating the effectiveness of the chemical dosing system in controlling bacterial growth in the open cooling water. Overall, the CW treatment successfully maintained the TAB count within the desired range, ensuring the system's efficient and safe operation.

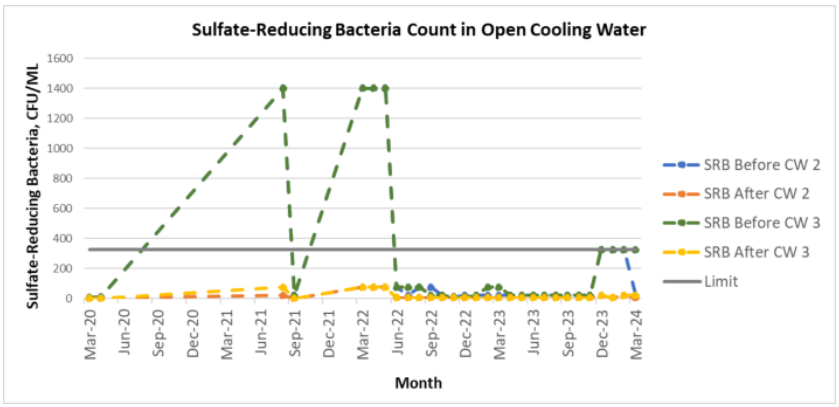

Figure 14: Sulfate-Reducing Bacteria in Unit-2 & Unit-3 Open Cooling Water.

The data indicates a significant reduction in Sulfate-Reducing Bacteria (SRB) after the implementation of the cooling water (CW) treatment in both Unit-2 and Unit-3. While SRB counts fluctuated before treatment, they consistently remained below the specified limit after treatment, highlighting the effectiveness of the CW treatment.

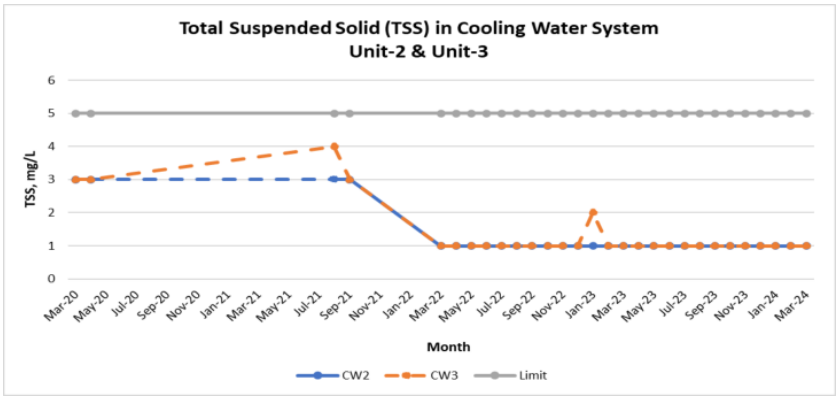

Figure 15: Total Suspended Solid (TSS) count in Unit-2 & Unit-3 Open Cooling Water.

Historical data shows a significant reduction in Total Suspendd Solids (TSS) in both cooling water systems after January 2022. Both systems consistently remained below the specified limit (4 mg/L) from January 2022 to March 2024, indicating the effectiveness of the treatment in controlling TSS levels.

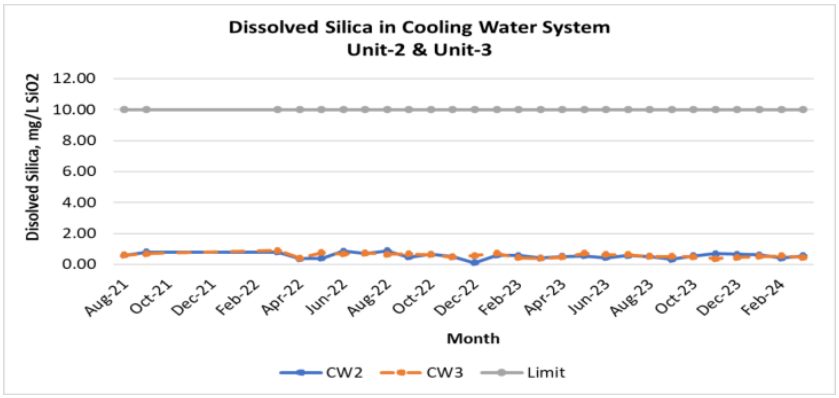

Figure 16: Total Dissolved Solid (TDS) count in Unit-2 & Unit-3 Open Cooling Water.

Figure 16 indicates a significant decrease in Total Dissolved Solids (TDS) levels in both cooling water systems after January 2022. Both systems consistently maintained TDS levels below the 200 mg/L limit after this period,

signifying the effectiveness of the implemented treatment in controlling TDS. In contrast, Figure 17 shows that turbidity levels in both systems have remained consistently low throughout the entire monitoring period, well below the 5 NTU limit, suggesting that turbidity has not been a significant concern in these cooling water systems.

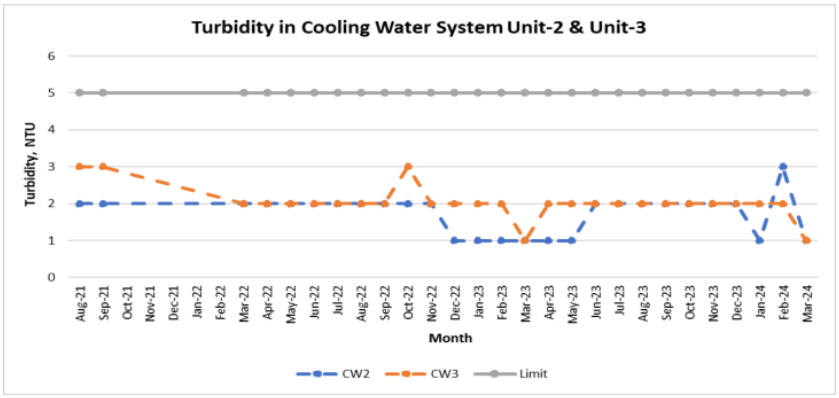

Figure 17: Turbidity in Unit-2 & Unit-3 Open Cooling Water.

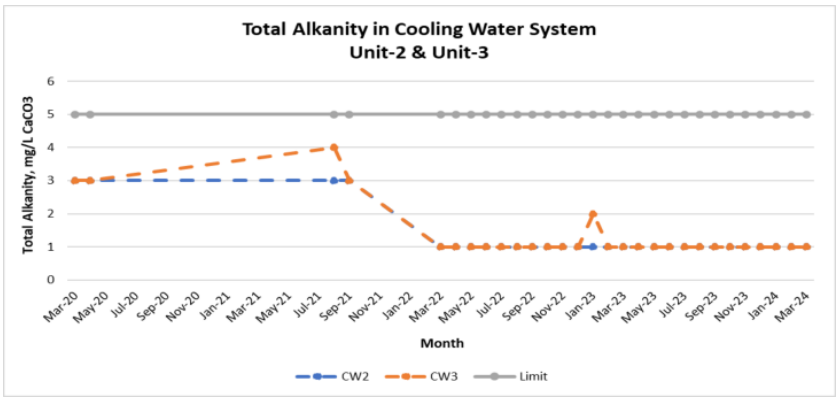

Figure 18: Total Alkanity count in Unit-2 & Unit-3 Open Cooling Water.

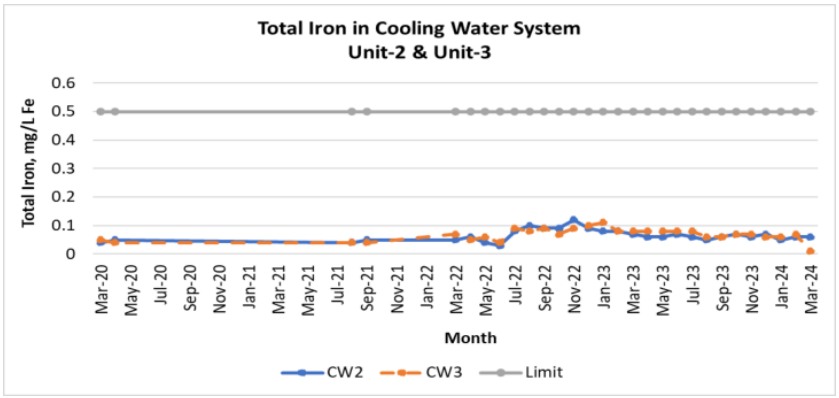

Figure 19: Total iron in Unit-2 & Unit-3 Open Cooling Water.

Figure 19 shows a significant decrease in Total Iron levels in both Unit-2 and Unit-3 after the implementation of the cooling water (CW) treatment in March 2020. The Total Iron levels have remained consistently below the 0.5 mg/L limit since then while Dissolved Silica levels as shown in Figure 20 have remained consistently below the 10 mg/L limit. These indicate the effectiveness of the CW treatment in controlling iron and silica deposition in the cooling water systems.

Based on the performance above, it is shown that TAB, SRB, and fungi can be reduced below the threshold during five years treatment. This microbial is important to be suppressed with non-oxidizing biocide as the outgrowth of bacteria can reduce cooling water performance and not causing foaming in the basin and condenser. Foaming is affected by clogging the filler which can impact increasing approach temperature.

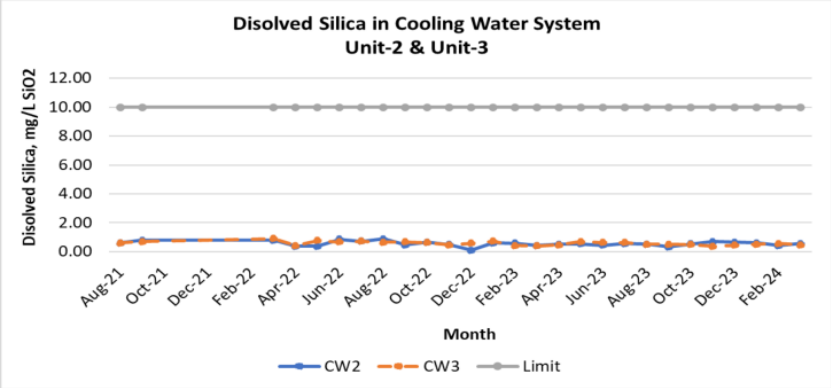

Figure 20: Dissolved Silica in Unit-2 & Unit-3 Open Cooling Water.

Non-oxidizing biocides are often chosen over oxidizing biocides due to their cost-effectiveness. Here are a few reasons for this preference:

1. Lower Dosage Requirements

Non-oxidizing biocides generally require lower dosages to achieve the same level of microbial control, leading to cost savings on the quantity of chemical used.

2. Extended Residual Effect

These biocides tend to have a longer residual effect, meaning they remain active in the system for a longer period. This reduces the frequency of application, thereby lowering overall treatment costs.

3. Equipment Longevity

Non-oxidizing biocides are less corrosive compared to oxidizing biocides, which can prolong the life of equipment and infrastructure, reducing maintenance and replacement costs. Non-oxidizing biocides is also didn't impact to the water chemistry, unlike the cleaning chemical.

4. Reduced By-product Formation

They produce fewer harmful by-products during their use, which can decrease the need for additional treatments and the handling of hazardous waste, contributing to cost savings in waste management and environmental compliance.

5. Compatibility with Other Chemicals

Non-oxidizing biocides often have better compatibility with other chemicals used in industrial processes, minimizing the risk of adverse reactions and the need for additional corrective treatments.

In summary, the implemented cooling water (CW) treatment has effectively controlled various parameters in both units, including significant reductions in bacteria, solids, iron, and silica. This successful control has prevented corrosion, equipment damage, and

ensured safe and efficient operation. Additionally, the use of non-oxidizing biocides has proven cost-effective, reducing chemical usage and overall costs.

4.2 Lagging Indicators

Lagging indicators provide valuable insights into the past performance of the cooling water system and the effectiveness of the treatment program. During five years of treatment, lagging indicators such as steam consumption, cooling tower efficiency, and cooling water temperatures are used to evaluate the historical performance of the cooling water system. These metrics serve as benchmarks for identifying areas requiring improvement and assessing the efficacy of the treatment program.

The steam consumption rate, defined as the steam mass flow per unit power output (kg/s/MW), is a critical performance indicator for power plants. Figure 21 illustrates the effectiveness of the cooling water system treatment program as one of important factors in maintaining steam consumption rates within the desired range for Units 2 and 3 over five years. The data shows that steam consumption rates for both units generally remained below the lower limit during this period. Occasional instances of exceeding the upper limit were attributed to issues with the Liquid Ring Vacuum Pump, which necessitated switching to a standby ejector system requiring additional steam. Conversely, instances of falling below the lower limit occurred during steam flow meter calibration.

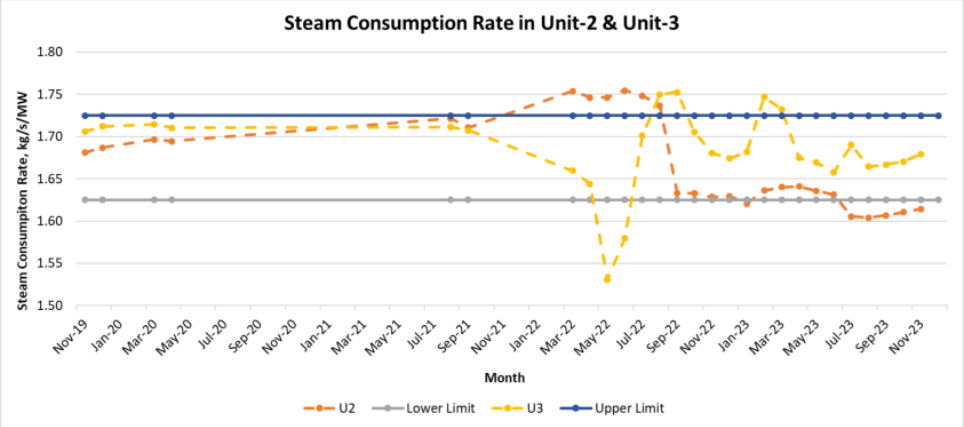

Figure 21: Steam Consumption Rate in Unit-2 & Unit-3.

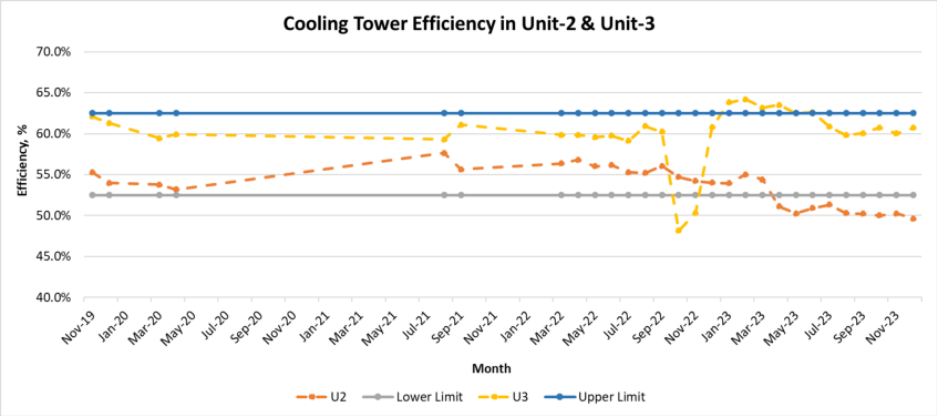

Figure 22: Cooling Tower Efficiency in Unit-2 & Unit-3.

Figure 22 illustrates the impact of the cooling water system treatment program on the efficiency of cooling towers in Units 2 and 3 over a five-year period. Overall, both units maintained cooling tower efficiencies above the minimum threshold throughout the observation period. Instances where efficiency dipped below the lower limit coincided with scheduled online maintenance of the cooling tower fan motors, which were performed alternately for each unit. This data suggests that the cooling water system treatment program has been effective in sustaining optimal cooling tower performance in both Units 2 and 3.

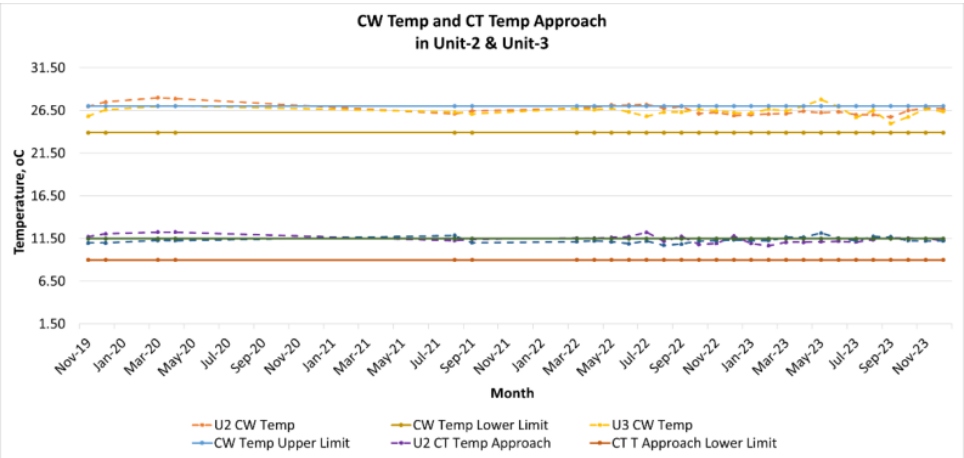

Figure 23: CW Temp, CT Temp Range, CT Temp Approach in Unit-2 & Unit-3.

Figure 23 illustrates the impact of the cooling water system treatment program on the cooling water temperature and approach of cooling towers in Units 2 and 3 over a five-year period. Overall, both units maintained cooling water temperature and approached within the expected range (CW temperature between 23.9 to 27°C and Approach between 9 to 11.5°C) throughout the observation period. Instances where CW temperature and approach

exceeded the upper limit coincided with scheduled online maintenance of the cooling tower fan motors, as discussed previously.

The cooling water treatment program helps maintain the cooling water temperature at the outlet of the cooling tower by preventing the buildup of scale, deposits, and microbiological growth. These factors can hinder heat transfer efficiency, leading to increased cooling water temperatures. By controlling these issues, the treatment program ensures optimal heat exchange between the cooling water and the ambient air, resulting in the desired outlet temperature. Additionally, the program may include corrosion inhibitors that protect the cooling tower components, further contributing to efficient operation and consistent temperature control.

5. CONCLUSION AND RECOMMENDATION

Based on the analysis conducted, the following conclusion can be drawn:

1. The cooling water treatment program has successfully controlled microbial growth, scale, corrosion, and other fouling issues in SEGD Units 2 and 3, leading to improved system performance and efficiency.
2. The use of non-oxidizing biocides has been instrumental in maintaining microbial control without adverse effects on water chemistry or equipment.
3. Long-term monitoring and a comprehensive treatment strategy incorporating biocides, dispersants, and corrosion inhibitors are crucial for sustaining optimal cooling system performance and longevity.
4. Maintaining cooling water parameters within specified limits has resulted in significant benefits, including reduced corrosion, improved operational efficiency, and cost savings through decreased chemical usage and equipment maintenance.
5. The implemented program has successfully addressed challenges such as increased sulfate and corrosion, ensuring the continued reliable operation of the cooling water systems.
6. The program's effectiveness is further validated by the consistently acceptable levels of lagging indicators like steam consumption, cooling tower efficiency, and water temperature.
7. By preventing the buildup of scale, deposits, and microbiological growth, the program has maintained optimal cooling water temperature, maximizing heat transfer efficiency.

Overall, the five-year data demonstrates the cooling water treatment program's success in optimizing system performance, reducing costs, and ensuring long-term operational reliability.

The following recommendations are proposed to further enhance the performance and efficiency of the cooling water system in SEGD units 2 and 3:

1. Implement online monitoring of condenser performance and utilize sulfur dispersants in the cooling water system to further enhance plant efficiency and water quality.
2. Continue the comprehensive cooling water treatment program, incorporating regular monitoring and adjustments as needed, to ensure long-term system reliability and cost-effectiveness.

Keywords: Chemical dosing system, PLTP Darajat II, NaOH fluctuations, Condensate pH, Metering pump, Ultrasonic level transmitter

ABSTRACT

The chemical dosing system at PLTP Darajat II currently faces challenges in maintaining condensate pH, leading to inefficiency and corrosion issues. The control valve system used to deliver NaOH solution to neutralize condensate water causes significant fluctuations in NaOH solution flow, resulting in up to five times the daily requirement being wasted. This occurs due to the strong influence of the NaOH solution level in the tank on the flow rate from the control valve. Additionally, the small (1-inch) valve is prone to freezing the NaOH solution in cold temperatures ($10° - 11°C$), hindering or stopping the flow. Moreover, NaOH level measurement in the tank still uses a level gauge that is not monitored by the DCS, leading to undetected NaOH solution depletion during flow fluctuations. The current chemical dosing system causes condensate pH at PLTP Darajat II unstable which results in a severe corrosion rate on the injection pipe of 32 mpy as measured on the corrosion coupon. Such a high corrosion rate will cause pipe leaks, infrastructure damage, and disruption of PLTP operations. Leaks in condensate pipe will cause spills that pollute the surrounding environment, adversely affecting ecosystems and public health due to the presence of heavy metals such as arsenic, sulfide, boron, and mercury. This pollution has the potential to cause social conflict and violates Indonesian government regulations, particularly Law No. 32 of 2009 on Environmental Protection and Management, which can result in criminal penalties and fines.

The corrosion rate on the injection pipe can be reduced by maintaining a stable flow rate of NaOH, which can be achieved by using a metering pump. A metering pump allows for more precise and stable flow control, minimizing NaOH fluctuations and waste as it is not affected by the NaOH level. This study will evaluate the effectiveness of a metering pump for a chemical dosing system with field trials. This study will also evaluate the metering pump control system with MATLAB simulation. Furthermore, the use of NaOH concentration of 48% makes maintenance of level gauge difficult and hazardous. Therefore, this study will also provide a comparative analysis between non-contact transmitters (i.e., ultrasonic) and level gauge (currently in use). The combination of a metering pump and non-contact transmitter on the chemical dosing system at PLTP Darajat II will minimize NaOH fluctuations, prevent waste, and ensure stable condensate pH. Effective implementation of this system will protect infrastructure, preserve the environment, and ensure regulatory compliance, allowing the PLTP to continue its contribution to sustainable and environmentally friendly renewable energy.

1. INTRODUCTION

Corrosion is a significant challenge in the infrastructure of geothermal power plant pipelines, particularly in PLTP Darajat II. The presence of acidic condensate water due to the presence of $CO2$ and $H2S$ is a major factor contributing to the corrosion rate (Tang et al., 2015; Buzăianu et al., 2016). To address this issue, PLTP Darajat II employs a chemical dosing system. This system injects sodium hydroxide (NaOH) solution to neutralize the acidity of the condensate water, thereby reducing the corrosion rate. However, in practice, the chemical dosing system at PLTP Darajat II experiences several operational constraints that lead to non-optimal and fluctuating NaOH solution consumption. This has repercussions not only on the economic side but also on the effectiveness of condensate pH control, ultimately affecting the corrosion rate.

The dosing system at PLTP Darajat II is a multi-stage system with two treatment stages (Fig. 1). The first treatment is carried out at the cooling basin cooling tower (downstream of cooling tower) before the condensate is sent to the power plant. The target pH for this system is 6.2. In this first treatment, NaOH flow is controlled by a control valve, by which the opening is regulated by a pH transmitter using feedback control. The second treatment is performed at the condenser outlet. The condensate water leaving the condenser is divided into two streams one to the cooling tower and one to the injection well. The second dosing treatment is carried out along the pipeline to the injection well, where the target pH is 7. In this second treatment, NaOH flow is controlled by a metering pump, by which the pump speed is regulated by a pH transmitter using feedback control. Despite having a multi-stage

control system, the corrosion rate at PLTP Darajat II reaching up to 32 mpy as measured on the corrosion coupon, which falls into the severe category (NACE SP0775, 2013). The failure to achieve the desired pH has been considered as one of key contributing factors to the high corrosion rate at PLTP Darajat II.

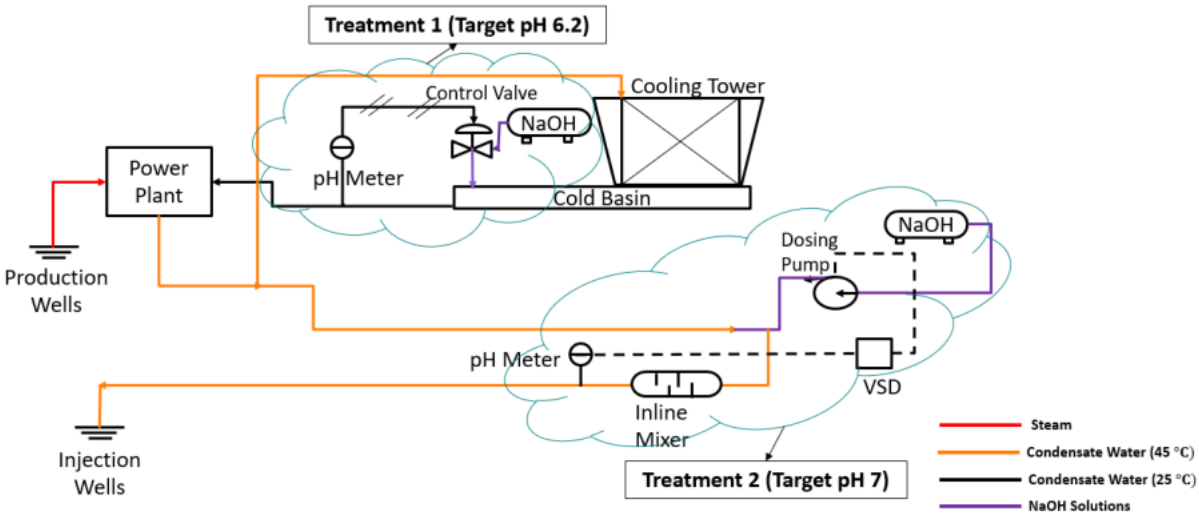

Figure 1: Chemical dosing system at PLTP Darajat II.

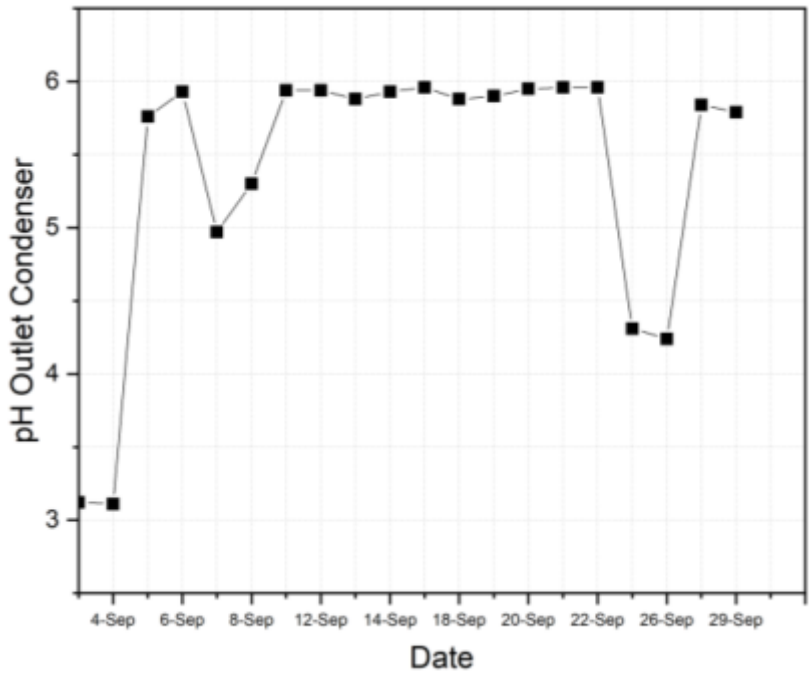

Figure 2: pH outlet condenser on December 2023.

One of the problems that hinders the achievement of the desired pH is the limitation in the chemical dosing system, particularly in the first treatment stage. This system utilizes gravity to deliver NaOH. Consequently, the flow of NaOH fluid varies even at a fixed valve opening. This variation in NaOH flow depends on the level of NaOH in the storage tank. Variations in NaOH flowrate are influenced by Torricelli's law, the higher the NaOH level in the storage tank, the faster the NaOH flowrate (Fox et al., 2011). Additionally, since NaOH tends to freeze at temperatures close to 10-11°C, this freezing also impedes the flow rate of NaOH (Hou, 1942). Meanwhile, the ambient temperature in the PLTP Darajat II environment can reach 8.4 °C.

Furthermore, the control system of the chemical dosing system at PLTP Darajat II still employs conditional control. For instance, if the pH read by the pH transmitter is 6, the valve opening is 80%. The conditional control system at PLTP Darajat II only utilizes three condition variations pH 6, pH 6.1, and pH 6.2. The use of these three pH conditions is ineffective since the condenser outlet pH varies daily ranging from 3.11-5.96 (Fig. 2). Additionally, the NaOH level is still monitored using a level gauge that is not integrated into the DCS. Consequently, during long holidays and SDTA, NaOH depletion is not uncommon.

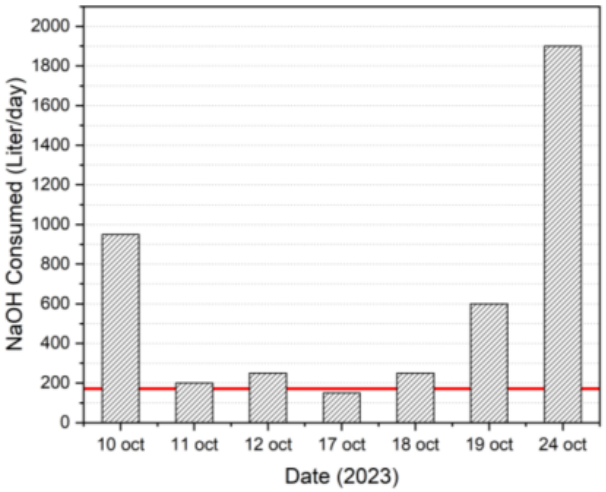

Figure 3: Consumption of NaOH for 7 days in the month of October 2023.

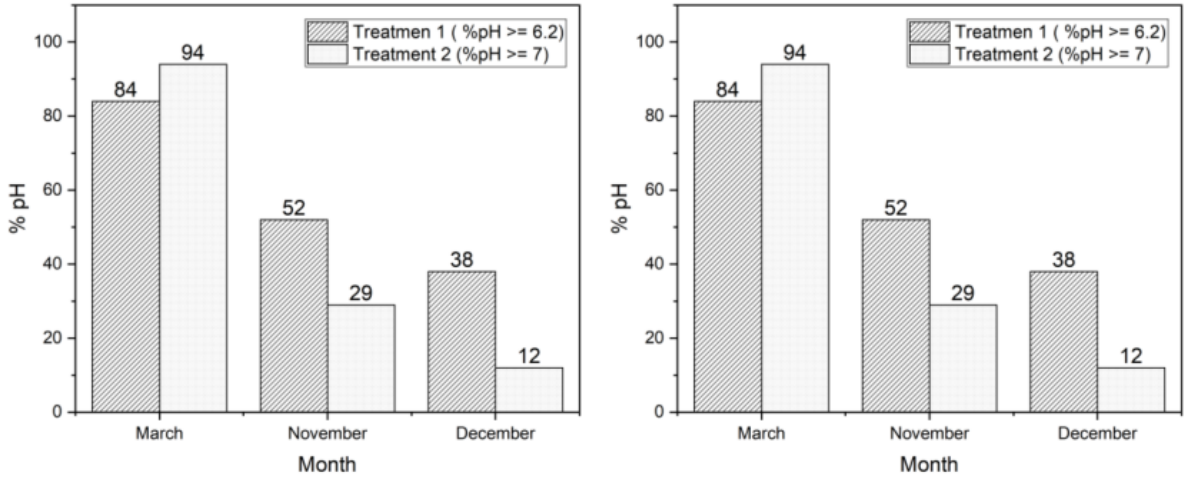

Figure 4: (a) Correlation between the pH value in treatment stage 1 and in treatment stage 2 in the year 2023, (b) Corrosion rate in the year 2023.

The combination of these three issues has detrimental consequences for the economics and reliability of the equipment. From an economic standpoint, based on data collected over seven days (Fig. 3), NaOH consumption exhibits both excesses and deficiencies, as indicated by the graph fluctuating above and below the red line. The excess consumption of 3,118 liters over seven days results in a loss of $893.76. Conversely, insufficient NaOH consumption leads to inadequate condensate water pH control, resulting in a high corrosion rate at PLTP Darajat II, which can lead to reduced expected lifetime of the pipes. Figure (4) shows that if the pH obtained in treatment 1 does not reach 6.2, then the pH obtained in the second treatment has the possibility of not reaching 7. These conditions ultimately leading to an increase in the corrosion rate. Moreover, this high corrosion rate has the potential to cause pipe leaks, which could lead to condensate contamination of the environment due to the presence of heavy metals such as arsenic, sulfide, boron, and mercury (Ellis, 1997). The potential for condensate contamination of the environment could result in violations of Regulation 32 of 2009 on Environmental Protection and Management, potentially leading to fines and imprisonment.

To achieve pH stability in a chemical dosing system, a stable flow rate of NaOH is essential. However, in practice, maintaining a constant flow rate is often challenging due to the influence of Torricelli's law from the NaOH tank and low ambient temperatures. To mitigate these conditions, appropriate valves and metering pumps are necessary. This study aims to analyze the effectiveness of the valves and metering pumps currently used in the chemical dosing system at PLTP Darajat II by utilizing operational data collected over 1.5 years. Additionally, an analysis will be conducted on the existing control system and a simulation using MATLAB software to evaluate the effectiveness of the control system on treatment 1 when using a metering pump and PI control. The study will conclude which between the valves and metering pumps is most suitable for the dosing system. Moreover, due to

frequent NaOH depletion during long holidays and SDTA, a comparative study will also be conducted to determine the most suitable level transmitter for the NaOH storage tank.

2. METHOD

2.1 Method for analyzing valve and metering pump

A comprehensive study was conducted to evaluate the effectiveness of a control valve and a metering pump in delivering NaOH solution within a chemical dosing system. Field data was collected from PLTP Darajat II over 1.5 years, encompassing normal power plant operations from January 2023 to July 2024. Two types of equipment were analyzed an EZ Fisher control valve (1 inch) with a pneumatic actuator for the valve and a peristaltic pump type Boyser AMP 10 B with an electric motor actuator for the metering pump. The control valve data exhibited greater variation compared to the peristaltic pump data. The control valve data was analyzed for valve opening variations of 30%, 40%, 70%, and 80%, while the peristaltic pump data was analyzed for variations of 22% and 33%. Additionally, the peristaltic pump was subjected to field trials with data variations of 22%, 30%, 33%, 40%, and 50%.

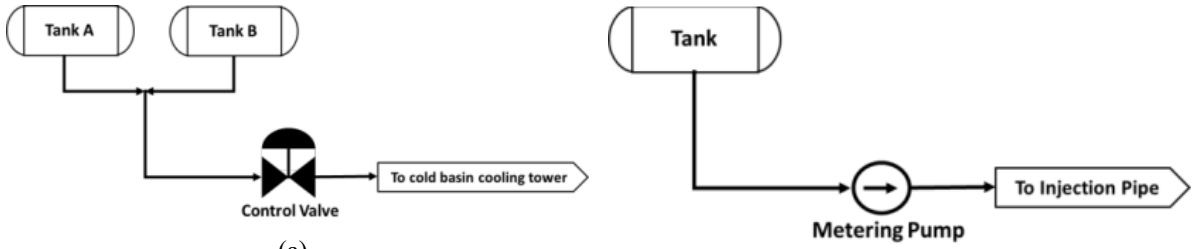

Figure 5: (a) Treatment 1 with double interconnected NaOH tank system, (b) Treatment 2 with single tank.

Treatment 1 used an interconnected double NaOH tank system, while treatment 2 used a single tank (Fig.5). To consider the slight variation in liquid level in the double tank system, the average liquid level was calculated and used as the representative NaOH level in the analysis. For the single tank in treatment 2, the liquid level was used directly. The collected data was analyzed using mean (equation 1) and standard deviation (equation 2).

$$\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n} \quad (1)$$

$$SD = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x})^2} \quad (2)$$

Here,
$\bar{x}$: Mean
SD : Standard Deviation
x_i : Individual data point
N : Total number of data points

2.2 Method for analyzing the control system of a valve and a metering pump

To analyze the control system for control valves and metering pumps, two approaches can be taken. The first approach involves analyzing the existing control system at PLTP Darajat II to determine whether the current system effectively controls the pH. The second approach involves simulating the control system using MATLAB software to observe the pH response in treatment 1 when employing a metering pump with PI control.

In the existing control system at PLTP Darajat II, the control valve (treatment 1) is regulated using conditional control (if-else), where the valve opening depends on three pH variations: 6, 6.1, and 6.2. On the other hand, the metering pump (treatment 2) is controlled using a PI controller. The analysis will focus on the response of the final elements (valve and metering pump) and the resulting pH response for both control systems implemented at PLTP Darajat II. Subsequently, MATLAB simulation will be conducted to examine the pH response in treatment 1 under the control of a metering pump and PI controller.

MATLAB Design Simulations

In the PLTP Darajat II, the mixing of condensate water and NaOH is carried out within an inline mixer. The inline mixer is a device that combines acidic and basic solutions by injecting the solutions into a pipe in a continuous

process (Fig. 6). Therefore, in this control simulation, an inline mixer system will be employed using Equation (3) (Lee & Choi, 2000).

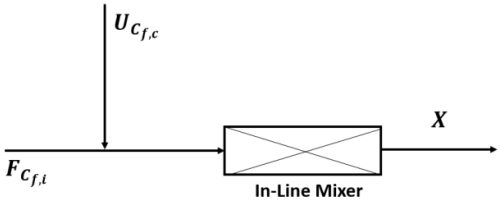

Figure 6: In-line mixer for mixing of acid and base solutions.

$$x_i(t) = \frac{Fc_{f,i}}{F + u(t-\theta)} + \frac{u(t-\theta)c_{c,i}}{F + u(t-\theta)}, \quad i = 1,2,3,\ldots,n \tag{3}$$

Here,

F : Flowrate of the influent stream
$c_{f,i}$: Total ion concentration of the *i*-th component in the influent stream
$c_{c,i}$: Total ion concentration of the *i*-th component in the titrating stream
u : Flowrate of the titrating stream
θ : Time delay due to the in-line mixer
x_i : Total ion concentration of the ith component in the effluent stream of in-line mixer

Furthermore, in this simulation, the neutralization process is assumed to be very fast, resulting in the output of the inline mixer being in equilibrium. Consequently, the pH can be calculated under this condition using Equation (4) (Wright et al., 1992). Additionally, this control simulation assumes the use of strong monoprotic and mono-hydroxyl acids and bases, namely HCl and NaOH.

$$\sum_{i=1}^{n} x_i(t) A_i\big(z_1(t)\big) + z_1(t) - K_w/z_1(t) = 0$$
$$pH_1 = -\log_{10}(z_1(t)) \tag{4}$$

Where $Ai(z)$ is, for an m-proatic acid,

$$A_i(z) = \frac{m + (m-1)z/K_{i,m} + \cdots + z^{m-1}/K_{i,m}K_{i,m-1}\ldots K_{i,2}}{1 + z/K_{i,m} + \cdots + z^{m}/K_{i,m}K_{i,m-1}\ldots K_{i,1}}$$

And, $Ai(z)$ for an m-hydroxyl base,

$$A_i(z) = \frac{mz^m + (m-1)K_w z^{m-1}/K_{i,m} + \cdots + {K_w}^{m-1} z/K_{i,m}K_{i,m-1}\ldots K_{i,2}}{z^m + K_w z^{m-1}/K_{i,m} + \cdots + {K_w}^{m}/K_{i,m}K_{i,m-1}\ldots K_{i,1}}$$

Here,

$Ai(z)$: Nonlinear function
m : Number of hydrogen ion or hydroxide ion which can be released
n : Number of components
Kw : Dissociation constant of water
Ki : Dissociation constant of the i-th component
z : Hydrogen ion concentration, in the in-line mixer

Due to its high accuracy of up to 1% in flow delivery, the flowrate of the metering pump is considered linear for the simulation (Garcia & De Godoy, 2011). Additionally, the pump dynamics are assumed to be very fast, and therefore the frictional forces within the pump are neglected. The pump design is illustrated in Figure 7.

The simulation of treatment 1, which employs a metering pump and PI control, utilizes HCl as a simplified representation of condensate water. This simplification was adopted to facilitate mathematical modeling. However, this simulation still uses some of the existing parameters at PLTP Darajat II such as 18 M NaOH and a condensate flow rate of approximately 3447 liter/s. The control system model is illustrated in Figure 8.

2.3 Method for the comparative study of contact and non-contact transmitters

A literature review was conducted to perform a comparative study for selecting the appropriate contact or non-contact transmitter for measuring NaOH level in the tank. The literature was analyzed based on several parameters

of accuracy, installation, maintenance, cost, environmental impact, calibration, sensitivity, interference, safety, measurement range, and suitability for NaOH.

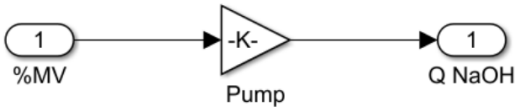

Figure 7: Model of the pump.

3. RESULT AND DISCUSSION

3.1 Analyzing Valve and Dosing Pump Effectiveness in Flowing NaOH

Despite the multi-stage chemical dosing system employed at the PLTP Darajat II, the corrosion rate, particularly on the carbon steel injection pipes, has reached severe levels. Consequently, this study aims to analyze the effectiveness of valve and peristaltic pumps in the NaOH dosing system of PLTP Darajat II. The data utilized in this study was collected during normal power plant operation.

In first treatment stage of the PLTP Darajat II chemical dosing system, gravity is employed to deliver NaOH. The control valve then regulates the NaOH flow. Various valve opening percentages have been implemented, including 30%, 40%, 70%, and 80%. As illustrated in Figure 9, the NaOH flow rate is inconsistent for the same valve opening percentage, regardless of whether the valve is opened at 30%, 40%, 70%, or 80%. This indicates fluctuations in NaOH flow. Further observation reveals that the NaOH flow rate fluctuation follows the NaOH level in the tank. The higher the NaOH level in the tank, the faster the NaOH flow rate. This phenomenon can be explained by Torricelli's Law. This law, an application of Bernoulli's principle, states that the fluid flow velocity is directly proportional to the square root of the fluid height. In other words, the higher the fluid is above the orifice, the greater the flow velocity. This can be understood because the higher fluid possesses greater gravitational potential energy, which is converted into kinetic energy as the fluid flows out of the orifice (Fox et al., 2011).

Apart from the influence of the NaOH level in the tank, Figure 10 demonstrates that the NaOH flow rate can also vary for the same NaOH level and valve opening percentage. The potential cause of this variation in NaOH flow rate is NaOH solidification within the valve or flow pipe, which impedes the flow rate. NaOH solidification is a frequent occurrence at PLTP Darajat II due to its mountainous location, where nighttime temperatures can reach 8.4 degrees Celsius, the freezing point of NaOH. Additionally, the unstable flow rate is another factor contributing to NaOH solidification. Unstable flow is often accompanied by pressure and flow velocity fluctuations. When the flow becomes slow or even stops momentarily, the NaOH within the pipe and control valve is more susceptible to reaching the low ambient temperature, particularly when the ambient temperature approaches or falls below the NaOH freezing point.

An examination of NaOH consumption data for valve opening percentages of 30%, 40%, 70%, and 80% in Figure 11 and Table 1 reveals that valve opening variation does not result in a significant difference in NaOH utilization. Theoretically, a larger valve opening should lead to a higher NaOH consumption rate. For instance, valve opening at 80% should result in higher NaOH consumption; however, the actual consumption is often similar to that of 70% and 40% valve openings. Furthermore, the standard deviation values also indicate significant variation in daily NaOH consumption, with daily consumption deviations reaching 406 liters from the average daily consumption. This high standard deviation demonstrates that daily NaOH consumption using the control valve is

highly variable and inconsistent, making it impossible to accurately predict daily consumption. This is likely due to NaOH solidification within the pipes and the NaOH level in the tank, which hinders the control valve's ability to effectively regulate the NaOH flow rate.

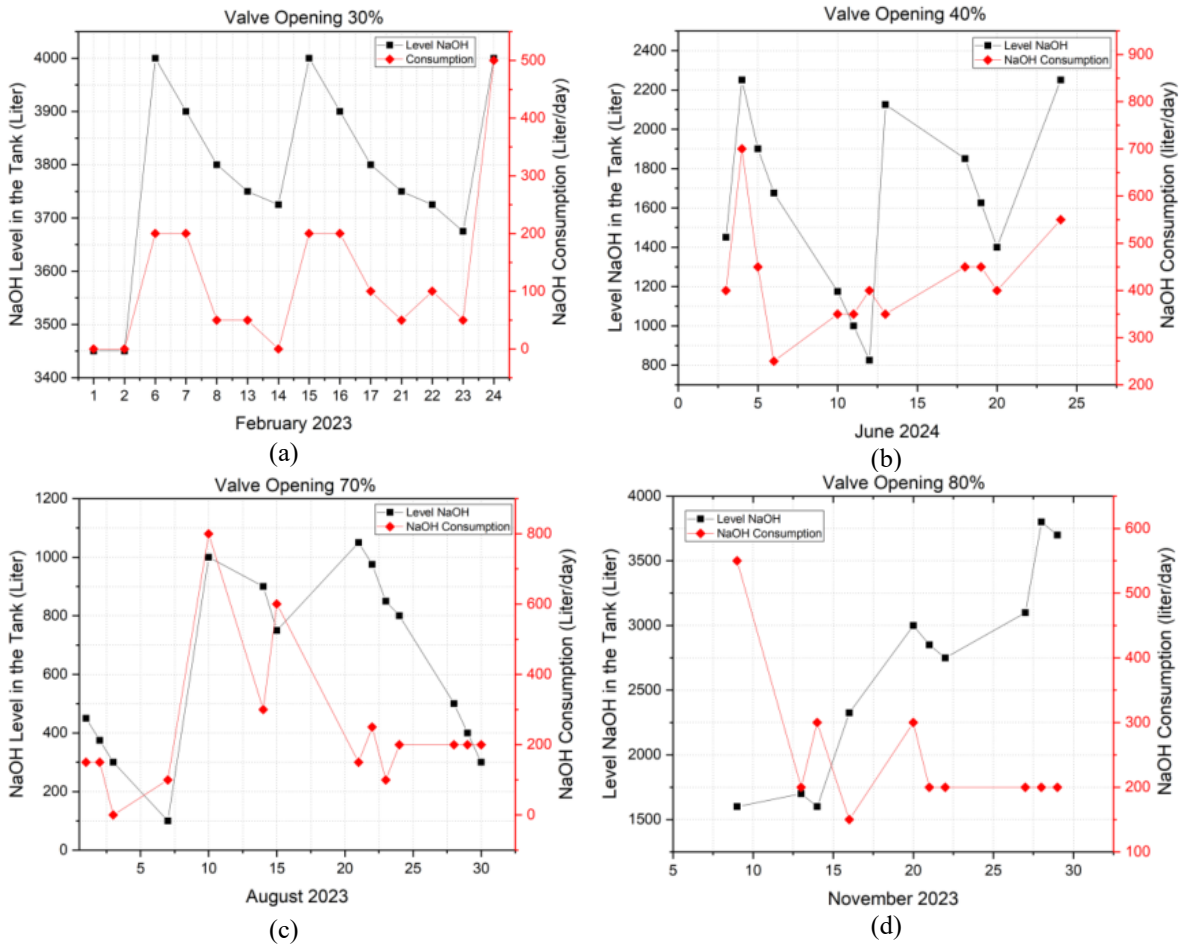

Figure 9: Relationship of the NaOH level in the tank to the daily consumption of NaOH (a) 30% valve open, (b) 40% valve open, (c) 70% valve open, (d) 80% valve open.

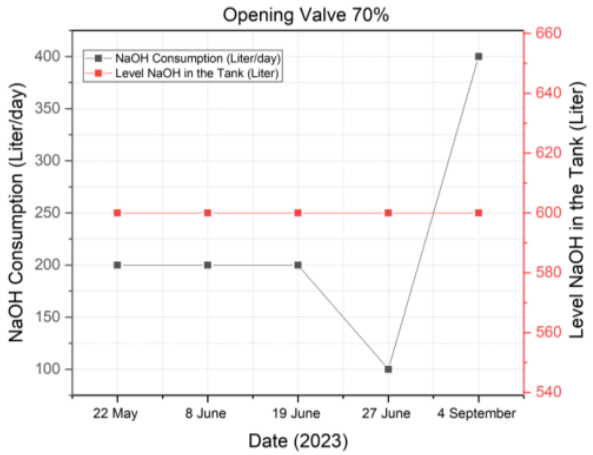

Figure 10: NaOH consumed at 70% valve opened on different days.

Table 1: Mean and standard deviation of NaOH consumption for 30%, 40%, 70%, and 80% valve opening variations.

Opening Valve	**30%**	**40%**	**70%**	**80%**
Days	26 days	16 days	82 days	39 days
Mean	144 liters	344 liters	246 liters	372 liters
Standard deviations	127 liters	176 liters	118 liters	406 liters

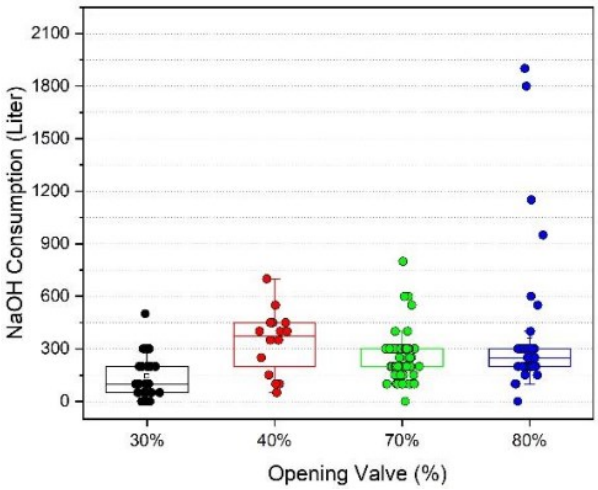

Figure 11: Rate of consumption of NaOH for variations in valve opening of 30 %, 40 %, 70 % and 80 %.

In second treatment stage, a peristaltic metering pump was employed. Field trial testing was conducted at motor speeds of 22%, 30%, 33%, 40%, and 50%. The data obtained in Figure 12 demonstrates a linear relationship between motor speed and NaOH consumption. The faster the motor speed, the higher the daily NaOH consumption.

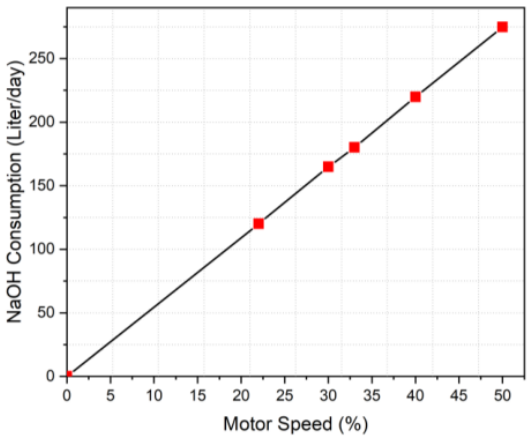

Figure 12: Relationship between the speed of the motor and NaOH consumption (field trial).

An analysis of the peristaltic pump's effectiveness using pump speed variations of 22% and 33% was conducted. Data from Figure 13 indicates that variations in the NaOH tank level do not influence NaOH consumption. Additionally, when using the peristaltic pump, solidification within the flow pipe is rare due to the stable flow, which reduces the contact time between NaOH and the low ambient temperature, thereby minimizing the risk of solidification. Figure 13 further demonstrates that the peristaltic pump delivers NaOH with stability and consistency, resulting in a significant reduction in NaOH consumption variation.

This study highlights the significant flow fluctuations experienced by the valve in the NaOH dosing system at PLTP Darajat II, influenced by the NaOH level in the tank and NaOH solidification phenomena. Conversely, the peristaltic pump exhibits superior stability and accuracy, demonstrating a linear relationship between motor speed and NaOH consumption while minimizing the impact of tank level variations and solidification. Therefore, the peristaltic pump is more strongly recommended for dosing applications that demand high precision and consistency.

Figure 14 is the response of the existing control system at PLTP Darajat II, the orange graph represents the response of the control valve and metering pump, while the blue graph represents the pH response generated by the control system. The pH response produced by the control valve (treatment 1) exhibits an unstable pH value at the setpoint with an average error of 1.24±1.1 pH (Fig. 14(a)). This significant error can be attributed to the system employing feedback control with conditional control, which utilizes only three pH conditions: at pH < 6, the valve opens 80%; at pH < 6.1, the valve opens 35%; and at pH > 6.2, the valve closes. Consequently, this conditional control system is similar to an on/off control system. On/off control systems do not consider how close the measured value is to the setpoint. On/off control systems only react to whether the output value is higher or lower

than the setpoint, causing the system to oscillate around the setpoint, often with a considerable amplitude, leading to a large error value. In addition to conditional control, the oscillation is also caused by the control valve utilizing gravity to flow NaOH. As discussed in section 3.1, at the same opening valve, the NaOH consumption rate varies due to the Torricelli law.

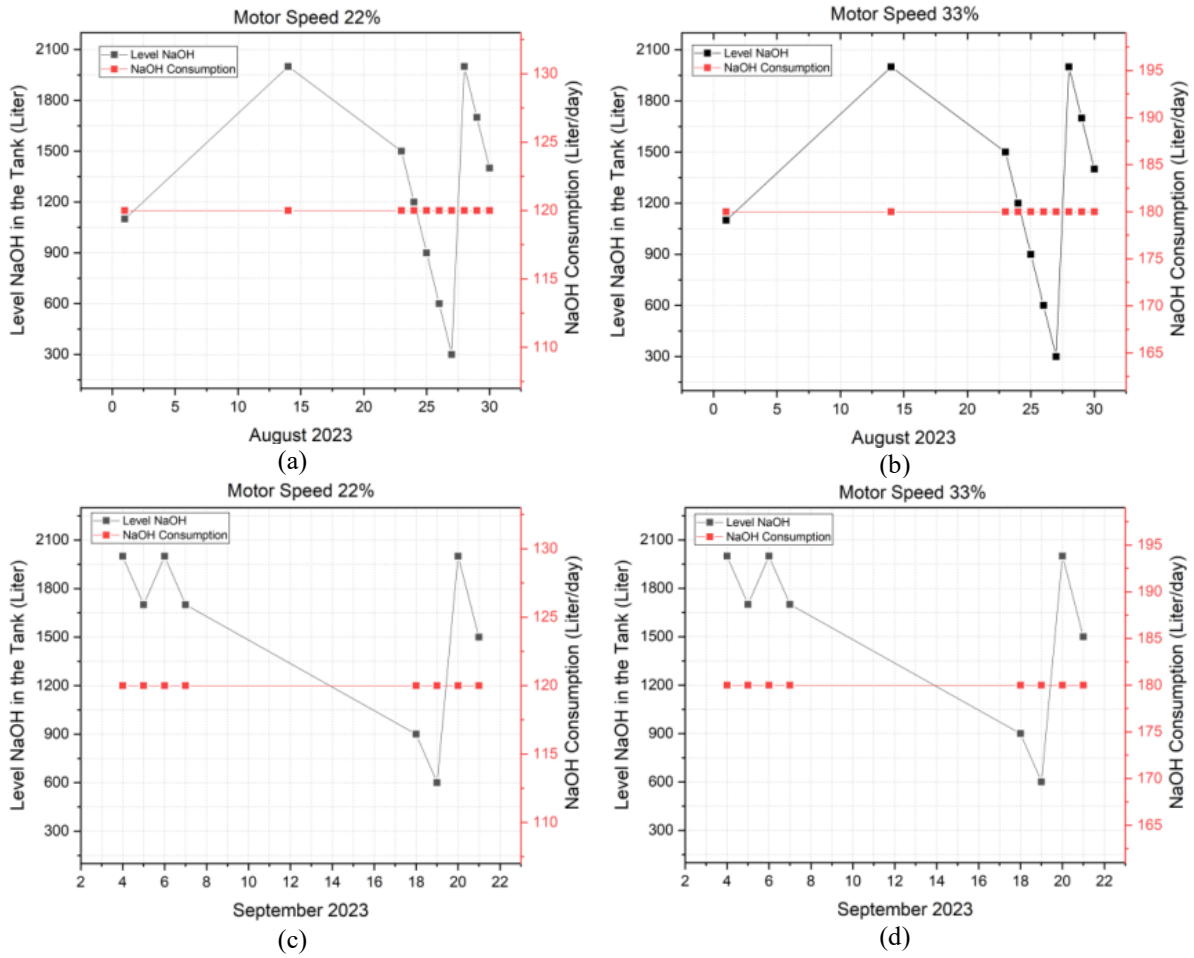

Figure 13: Relationship between NaOH level in tank and daily NaOH consumption (a) 22% motor speed in August, (b) 33% motor speed in August, (c) 22% motor speed in September, (d) 33% motor speed in September.

3.2 Analyzing the effectiveness of system control of valves and metering pumps in delivering NaOH

Subsequently, for the metering pump (treatment 2), utilizing feedback control with a PI controller, the pH remains stable at the setpoint with an average error of 0.06±0.05 pH (Fig. 14(b)). The relatively small error is attributed to the PI controller's (Proportional-Integral controller) ability to more smoothly control the process. The proportional portion of the PI controller responds to changes in the measured value relative to the setpoint, while the integral portion accumulates the error over time and adjusts the output to gradually eliminate the error. This enables the PI controller to stabilize the system closer to the setpoint with smaller oscillations and a lower error.

Therefore, since the pH produced in treatment 1 is unstable and oscillatory, to achieve a more stable pH, it is recommended to replace the valve with a metering pump to produce more accurate dosing and to modify the control system with feedback control utilizing a PI controller (Fig. 15).

Furthermore, a pH control simulation was conducted in accordance with the design in Figure 15, assuming the use of a strong acid (HCl) and a strong base (NaOH) to simplify the derivation of the system equation for simulation. The simulation results using MATLAB software are presented in Figure 16. Based on the simulation results, it is evident that under varying pre-treatment pH conditions, if a chemical dosing system with PI control is applied, the pH setpoint (pH 6.2) is achieved with an average error of 0.05±0.06 pH. Although the simulation results are not entirely representative due to the ideal conditions and the use of a strong acid, the simulation results demonstrate that employing a PI controller can yield a more stable pH when applied to treatment 1.

3.3 Comparative analysis of contact and non-contact level transmitters

In power plant operations, the pH of condensate water is not stable but fluctuates depending on steam conditions. This variability leads to unpredictable daily NaOH consumption, emphasizing the importance of NaOH level monitoring to prevent depletion. Figure 17 illustrates a 5-month NaOH depletion incident at PLTP Darajat II due to the use of non-integrated level measurement devices with the DCS. As a result, manual level checks were required, leading to frequent NaOH depletion during long weekends or SDTA periods. During these times, NaOH consumption is high and unpredictable, and other tasks often take priority, hindering proper level monitoring. Therefore, employing a level transmitter for NaOH monitoring is crucial to provide timely low-level alerts, ensuring timely NaOH delivery.

Various level transmitters are available; however, due to the highly concentrated and corrosive nature of NaOH solutions, a comparative study between non-contact and contact transmitters is essential, as shown in Table 2. Based on the Table 2, contact transmitters perform well for NaOH applications when using corrosion-resistant materials. However, they require frequent maintenance to prevent fouling and corrosion. While accuracy and initial costs are relatively favorable, long-term costs may be higher due to maintenance requirements. In contrast, non-contact transmitters are better suited for this application as they are unaffected by the corrosive properties of NaOH. Therefore, the preferred level transmitter for this application is a non-contact transmitter. The specific non-contact transmitters to be analyzed are ultrasonic, radar, and laser.

Table 2: Comparative study of contact and non-contact level transmitters (Lipták, 2003; Eccles, 2018).

Parameter	Contact Transmitter	Non-Contact Transmitter
Principle	Direct contact with the liquid	No direct contact with the liquid
Common Types	Float, Capacitive, Conductive, Hydrostatic	Ultrasonic, Radar (Microwave), Laser
Accuracy	Generally high, depends on the technology	High, but can be affected by environmental conditions
Installation	Requires penetration into the tank or vessel	Installed externally, no tank penetration needed
Maintenance	Higher maintenance due to potential fouling and corrosion	Lower maintenance, no direct contact with corrosive liquid
Suitability for NaOH	Must use materials resistant to NaOH corrosion (e.g., PTFE, stainless steel)	Not affected by NaOH corrosion since no direct contact
Cost	Generally lower initial cost ($100 – 1000)	Higher initial cost, but lower long-term maintenance ($100 – over 1000)
Environmental Impact	Potential leakage and contamination risk	No risk of contamination due to leakage
Calibration	Requires periodic calibration	Less frequent calibration, depending on the model
Sensitivity to Obstructions	Less sensitive, but float type can be affected by debris	Can be affected by foam, vapor, and obstructions in the signal path

Table 3: Comparative study of non-contact level transmitters (Lipták, 2003; Navaratne, 2023; Peterson, 2023).

Parameter	Ultrasonic	Radar (Microwave)	Laser
Operating Principle	Sound waves reflect off the liquid surface	Microwave signals reflect off the liquid surface	Laser beams reflect off the liquid surface
Accuracy	High, but can be affected by temperature and gas composition in the tank	Very high, less affected by temperature and gas composition	Very high, but can be affected by vapor and airborne particles
Measurement Range	Up to 10 meters	Up to 30 meters	Up to 100 meters
Installation	Easy to install on top of the tank	Easy to install on top of the tank	Requires precise alignment for optimal accuracy
Maintenance	Low, but sensor can be affected by dirt or buildup	Very low, sensor protected from dirt	Low, but lens must remain clean
Environmental Resistance	Less resistant to harsh environments and temperature changes	Very resistant to harsh environments and temperature changes	Moderate, can be affected by vapor and dust
Cost	More affordable than radar or laser ($100 – 1000)	More expensive than ultrasonic ($300 – over 1000)	Most expensive among the three (Over $1000)
Calibration	Requires periodic calibration	Less frequent calibration, depending on the model	Requires periodic calibration
Interference	Can be affected by foam, turbulence, and deposits on the sensor surface	Less affected by foam or turbulence	Can be affected by vapor, particles, and atmospheric conditions
Safety	Safe for use in various conditions	Safe and can be used in extreme conditions	Safe, but potential laser hazards must be considered

According to the comparative table in Table 3, for measuring NaOH level in a stable tank (without temperature changes, gas, turbulence, or foam changes), an ultrasonic transmitter is an excellent and economical choice. This

transmitter offers sufficient accuracy and lower costs under stable conditions. However, if higher accuracy is required and sufficient budget is available, a radar (microwave) transmitter is an excellent choice with superior accuracy and reliability. Laser transmitters can be considered for applications requiring very long-range measurement or very high accuracy, although these may not be necessary under stable conditions.

4. CONCLUSION

Based on the conducted analysis, the following conclusions can be drawn :

1. In the PLTP Darajat II, the NaOH flow controlled by valves shows significant fluctuations and often freezes due to low temperatures, while the NaOH flow controlled by the metering pump is more stable and consistent. Then, conditional logic-based control on the valve control results in rough and unstable control, while PI control on the dosing pump provides smoother and more precise adjustments.
2. The simulation results obtained from MATLAB Simulink show that by replacing the valve with a metering pump and using a PI controller, treatment 1 will be able to maintain a stable pH at the desired pH.
3. The use of non-contact level transmitters is strongly recommended for NaOH applications as they are unaffected by the corrosive nature of NaOH and require minimal maintenance. For measuring NaOH level in stable tanks (without temperature changes, gas, turbulence, or foam fluctuations), ultrasonic transmitters represent an excellent and economical choice.

RECOMMENDATIONS

Based on the analysis conducted, the following recommendations are proposed to enhance the stability and precision of pH and NaOH consumption in the chemical dosing system:

1. Implement metering pump with PI control for chemical dosing system: For precise and stable control of pH and NaOH consumption, it is recommended to employ a metering pump equipped with PI (Proportional-Integral) control.
2. Ultrasonic transmitter for level monitoring: For level monitoring of NaOH, the utilization of a non-contact ultrasonic transmitter is suggested when the tank conditions are stable (free from temperature changes, gas, turbulence, and foam) and an economical transmitter is desired.

Keywords: Drilling, Coring, Geothermal, High angle well

ABSTRACT

The Dieng Plateau in central Java, Indonesia, forms the floor of the caldera complex on the Dieng volcanic complex. This complex consists of stratovolcanoes, craters, and Pleistocene to Holocene-age volcanic cones that store natural wealth in the form of geothermal energy. For drilling within the Dieng area, the operator requires coring to check the distribution of diorite intrusion at the Merdada crater and Pagar Kendang volcanic necks.

The hard yet brittle formation presents a significant challenge to the coring process, particularly with the standard conventional system, as the core may slide and fall from the inner barrel assembly when pulling the coring assembly out of the hole. The challenge is further increased by the total loss circulation condition, which is preferred as the coring point zone. This means there are no pressure readings available, which would typically be used as one of the indications or coring parameters to spot any anomalies. Additionally, backside pumping is required to maintain the well's hydrostatic pressure to mitigate any steam kick while coring is in progress. Thus, more challenges arise.

To overcome the challenges, a full-closure system technology with a double-catcher assembly—comprising the clam shell catcher and the spring catcher—is required. However, this technology alone is insufficient in geothermal applications due to the type of non-cemented formation profile, which causes core jamming and results in very low to zero penetration during coring. To remedy this issue, an additional system, known as the Anti-Jamming System, is required. This system can alleviate internal friction within the core barrel assembly, specifically at the inner barrel assembly.

This paper provides detailed information about how the combination of anti-jamming system technology and full-closure system technology, along with certain key procedures, strategies, and lessons learned from the initial well, could mitigate the potential hazards or risks of a coring job in a geothermal application. Based on the recent coring operations in three wells, all coring jobs have successfully achieved 100% core recovery in the Dieng area with superior performance.

1. INTRODUCTION

PT Geodipa Energi is exploring the Dieng Plateau geothermal field onshore Indonesia **(**Figure 1**).** The Dieng area contains 10 core wells planned from June 2021 to May 2023; however, not all wells are cored, mainly because of the wellbore situation. This paper will discuss three core wells: Q-1, T-1, and T-2. All three are directional wells drilled using PT Plumpang Raya Anugrah's PRA-09, a 1,500-hp land rig.

Dieng Plateau's 9-7/8-in. hole section consists of interbedded formations of minerals, including illite, chlorite, first continuous epidote, wairakite, phrenite, and calcite, as shown in Figure 2. Diorite formations are known to be highly altered microdiorite intrusion; secondary mineral assemblages consist of epidote, actinolite, sericite, and an expected medium to hard andesite layer with possible high borehole temperature.

All three wells (Q-1, T-1, and T-2) were expected and considered to be hard or very hard formations that are non-cemented with high permeability formation profiles. Thus, the fluid loss circulating zone is the preferred depth for coring. Coring in non-cemented volcanic formations carries significant risks, such as core slip-off, core jamming, and milling of the core. Fortunately, these issues are frequently detectable at the surface gauge through two key parameters: torque and penetration rate (ROP). Standpipe pressure is ineffective because it would be zero at the total fluid loss zone.

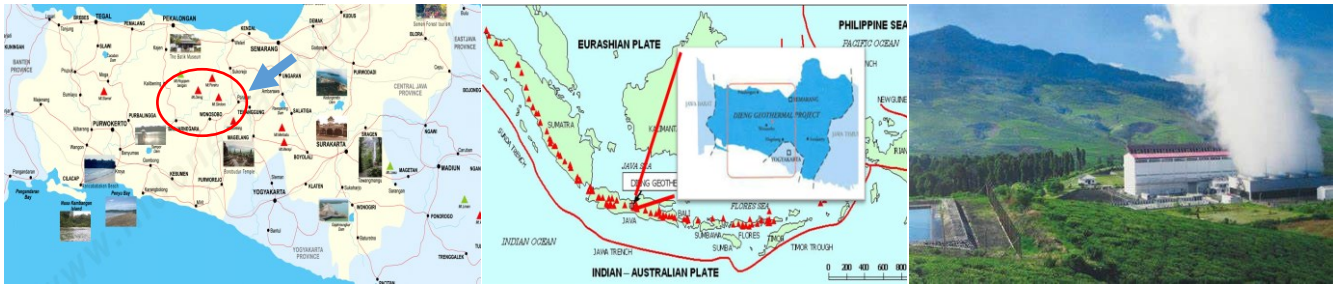

Figure 1: Well location.

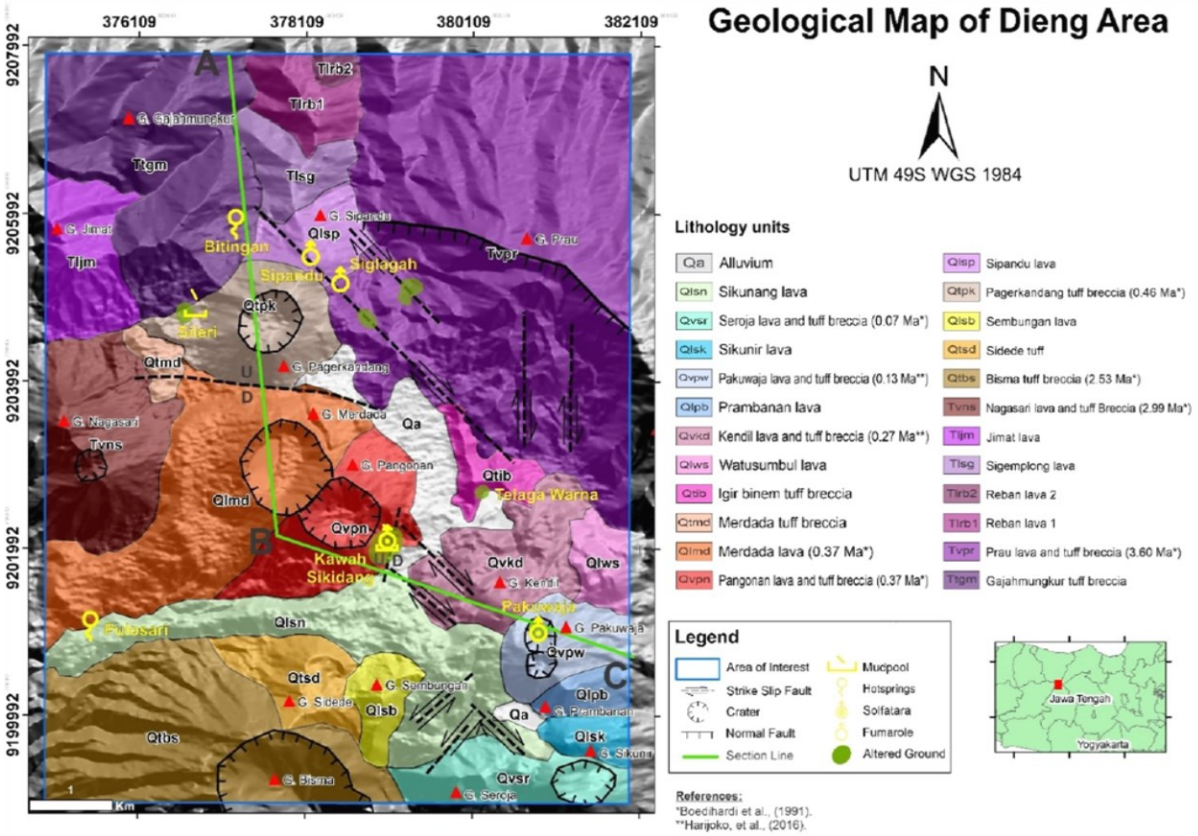

Figure 2: Geological map of Dieng Plateau (Ref. SGP-TR-223).

To mitigate or potentially eliminate the risks or expected hazards, both the operator and coring services contractor held technical meetings. They decided that the full closure system would be the main system for the core wells, as stipulated in the contract. Certain key parameters were also discussed and finalized in a written coring program.

Q-1 was the first well to core that had an issue with core jamming, and no penetration could be made despite changing a few key coring parameters. Due to the core jamming and the lack of decent core samples for analysis, the Q-1 well was deemed unsuccessful. Core samples are required to determine further planning of the Dieng Plateau area of the steam reservoir. Thus, all the lessons learned from the Q-1 well (Jan 2022) were then applied to the T-1 well (June 2022) and the T-2 well (July 2022). The T-1 and T-2 wells were then considered successful coring operations in terms of core quality and core length quantity for a 1x9m run. As a result, the T-1 and T-2 wells of the Dieng Plateau area serve as the basis for this paper.

2. CORE OBJECTIVES

The target was to check the distribution of Diorite Intrusion at Merdada crater and Pagar kendang volcanic neck. Coring procedures and programs were designed to obtain core samples with minimal to no mechanical damage from coring downhole until core retrieval, surface handling, and core packaging. Thorough preparations are crucial for achieving optimal results in any coring operation. The following key factors were considered:

- Coring tools type, completeness, condition, and assembly as per manual.
- Core head selection to achieve the best core quality and ROP.

- Inner barrel type of material and condition are based on the bottomhole parameter.
- Surface handling equipment completeness and condition.
- Core packaging items' completeness and condition.
- Coring bottomhole assembly (BHA) analysis on torque and drag parameter limitations.
- Apply lessons learned from previous wells in a nearby area.
- Other components at the surface that may be additional factors to consider, for example, air and fluid combination, etc.

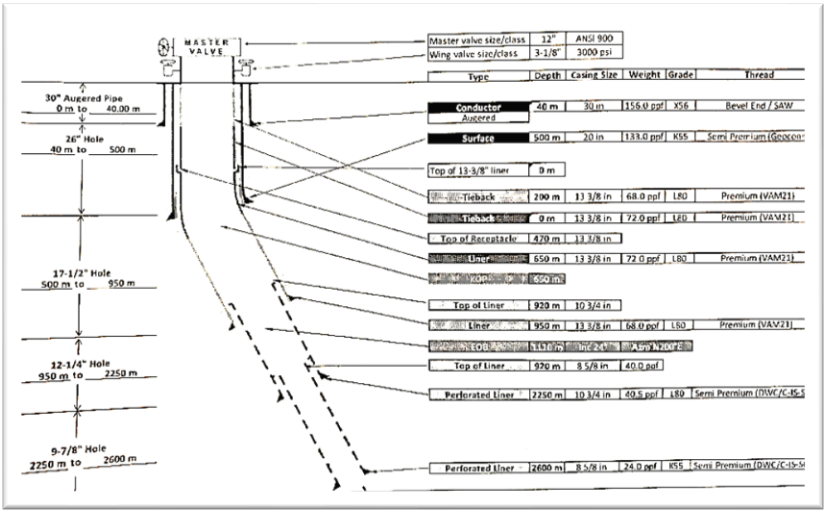

Figure 3: Well schematic of Q-1.

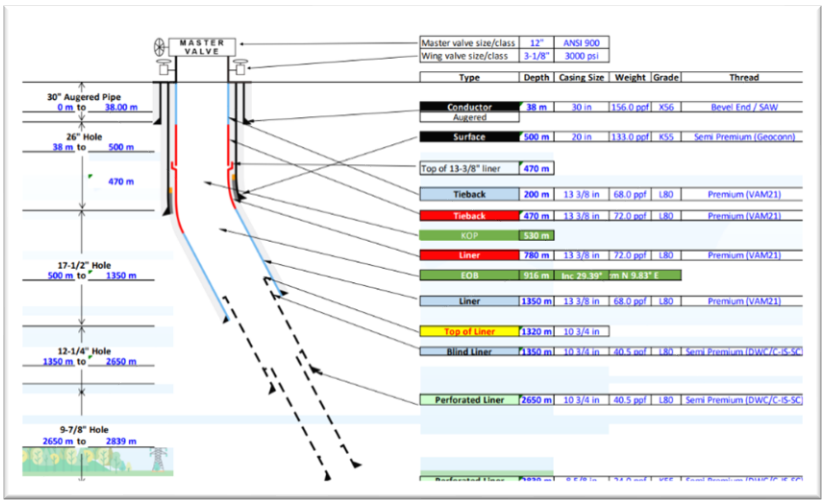

Figure 4: Well schematic of T-1.

3. EQUIPMENT IMPLEMENTATION

The non-cemented hard formations are problematic because:

- Jam when entering the barrel because of a non-cemented profile like boulders in many shapes.
- Fracture from the catcher forces.
- Fracture from column weight and vibrations.
- Slide out while retrieving barrel to surface.

Due to the risks mentioned above, a standalone single-spring conventional catcher will not be able to catch or grab the non-cemented but hard formations, especially while pulling the core barrel assembly out of the hole. Thus, the contract initially stated the use of a full closure system as part of the coring process solution, as shown in Figure 6.

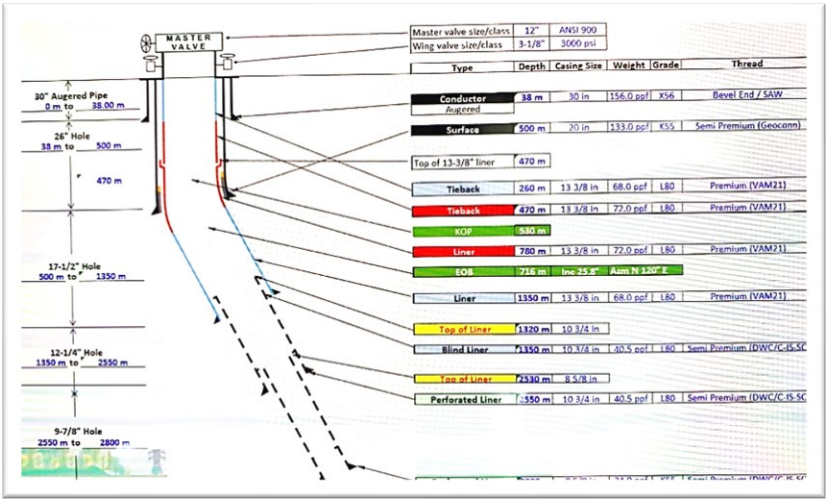

Figure 5: Well schematic of T-2.

3.1 Full Closure System

A full closure system, or the dual-core catcher system with a full closure mechanism, is designed for any applications related to unconsolidated formations, where poor core recovery is anticipated due to low rock strengths and/or when non-cemented fractured formations may potentially jam when only using a conventional catcher system. A full closure system is optimal when seeking to avoid short core runs, unscheduled trips, and loss of critical core data in unconsolidated formations. Given the profile of the aforementioned volcanic formation—which is non-cemented, as proven by a total fluid loss zone at the coring point depth—the formation category fits with the system's design and usage. The system is designed to prevent any core sample from falling and slipping out of the inner barrel assembly while pulling the core barrel assembly out of the hole.

Figure 6 shows the dual-core catcher system with a full closure mechanism, which enables the capture and recovery of the non-cemented formations that cannot be effectively retrieved using conventional equipment.

The following are the features and benefits of the dual-core catcher system with full closure:

- Complete capture – Full closure catcher system completely retains the core, even in problematic formations.
- Backup catcher – Secondary spring catcher secures core in place for cemented formation.
- Slick entry – Unobstructed entry prevents jamming.
- Efficient shearing – High-energy activation of clam shells cleanly shears core.
- At-will activation – Hydraulic drop ball system does not rely on inner barrel weight, allowing targeted activation.

The Full-Closure Core Catcher System enables full retrieval of unconsolidated, friable, fractured, and non-cemented formations. The system allows a smooth and unobstructed entry of the core into the barrel. At the conclusion of coring, the system is activated to release a pair of spring-loaded shells (*clam shell catcher*), securing the core in the inner tube. The shells prevent the core from falling out of the barrel while lifting the core barrel system off-bottom and out of the hole.

3.2 Anti-Jamming System

Core jamming is the main issue in geothermal applications that needs to be dealt with as well. While this anti-jamming system was not available within the contract for the Q-1 well, lessons learned and subsequent evaluations persuaded the client to implement it for the T-1 and T-2 wells.

This system—compatible with the Full Closure System—is designed to minimize and eliminate core jamming within the system for a certain number of times, depending on where core jamming occurs.

Liner anti-jamming was installed on the telescopic shoe and then located inside the aluminum inner barrel. If core jamming occurs near the friction holes, the friction holes will shear, as they are the weak point for releasing the friction building up within the inner diameter of the liner anti-jamming.

Figure 6: Dual-core catcher system with full closure.

Components of Full Closure System

The installing process is started by a drop ball sub connected to kelly/top drive at the surface (4-1/2-in. IF connections, with usage to drop activation ball already within the sub, without a need to disconnect drill pipe to drop the activation ball, coring BHA still at on-bottom depth).

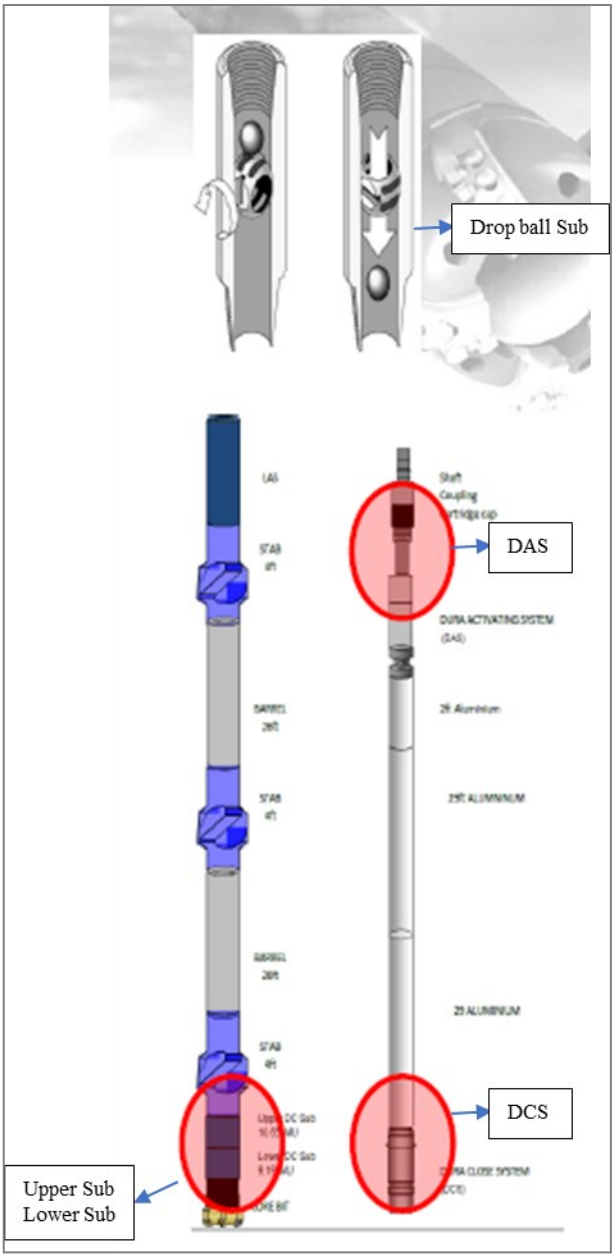

Figure 7: Added components *(in Red)* to the conventional core barrel to convert the standard conventional system into a full closure system.

3.3 Full Closure System Activation Steps

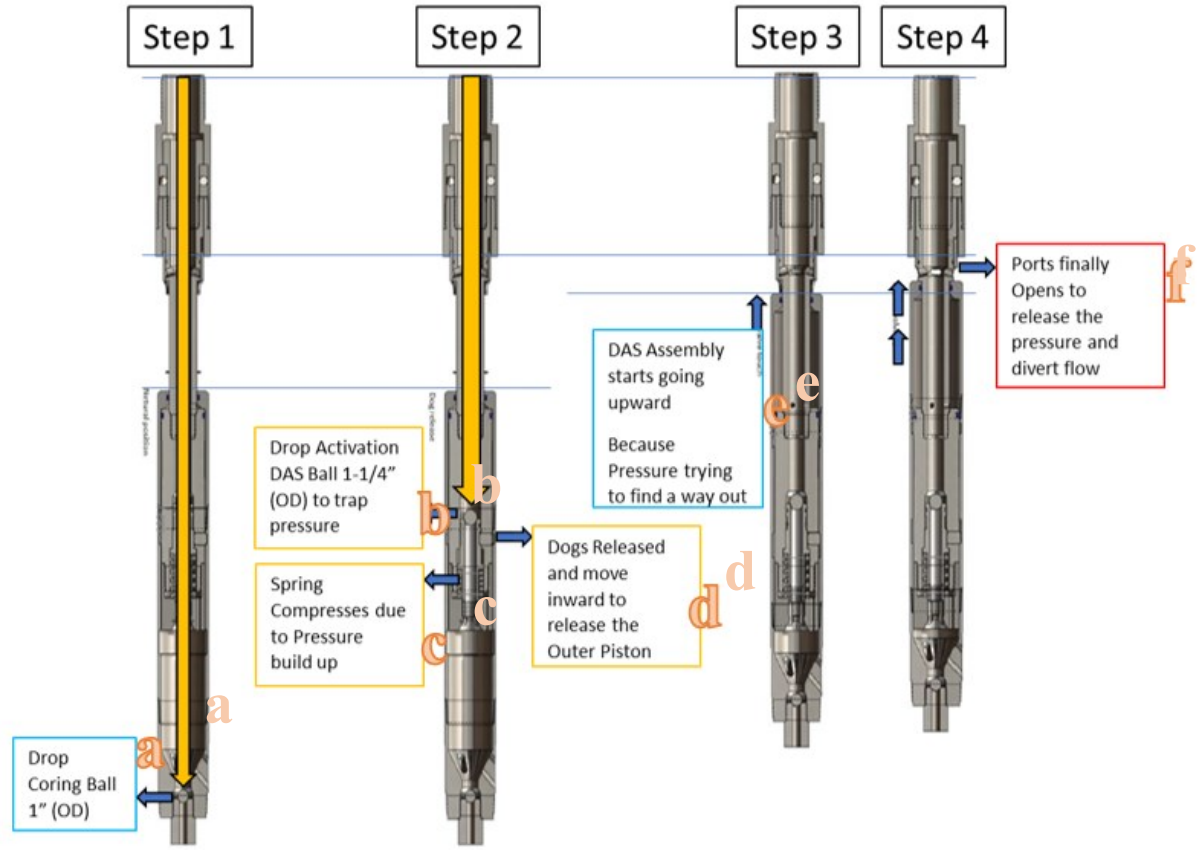

Figure 8: Top section (DAS).

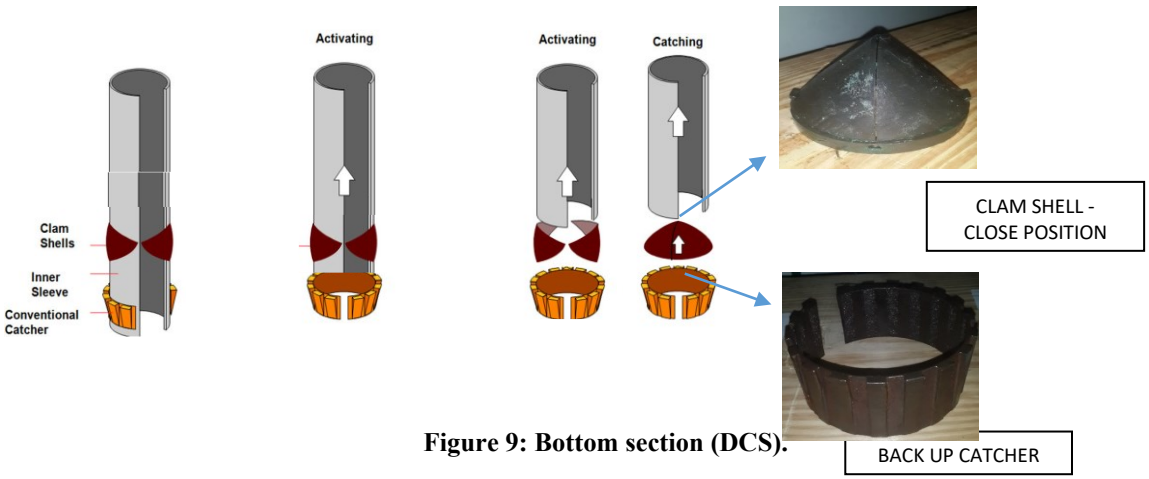

Figure 9: Bottom section (DCS).

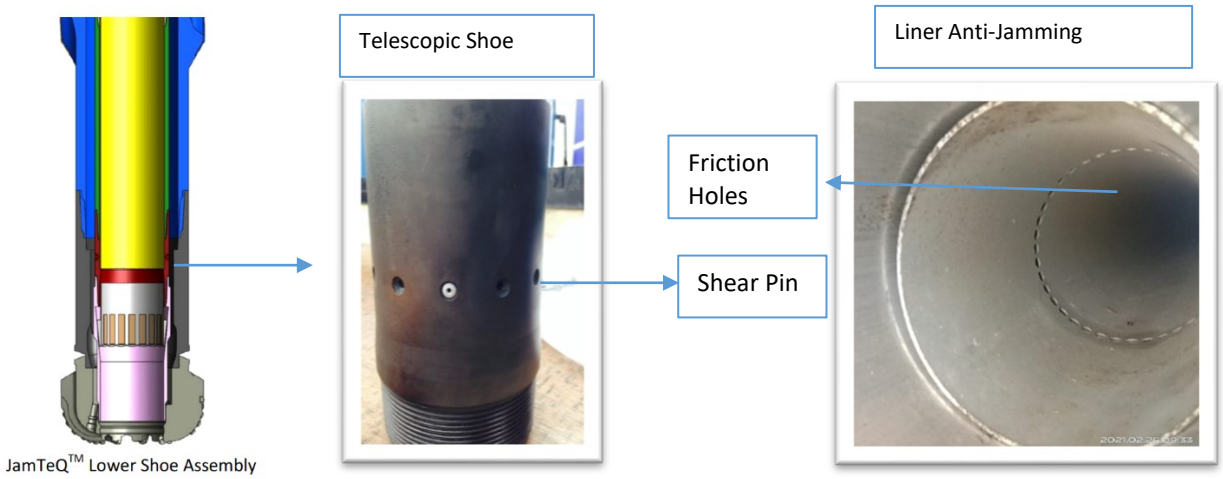

Figure 10: Anti-jamming system components.

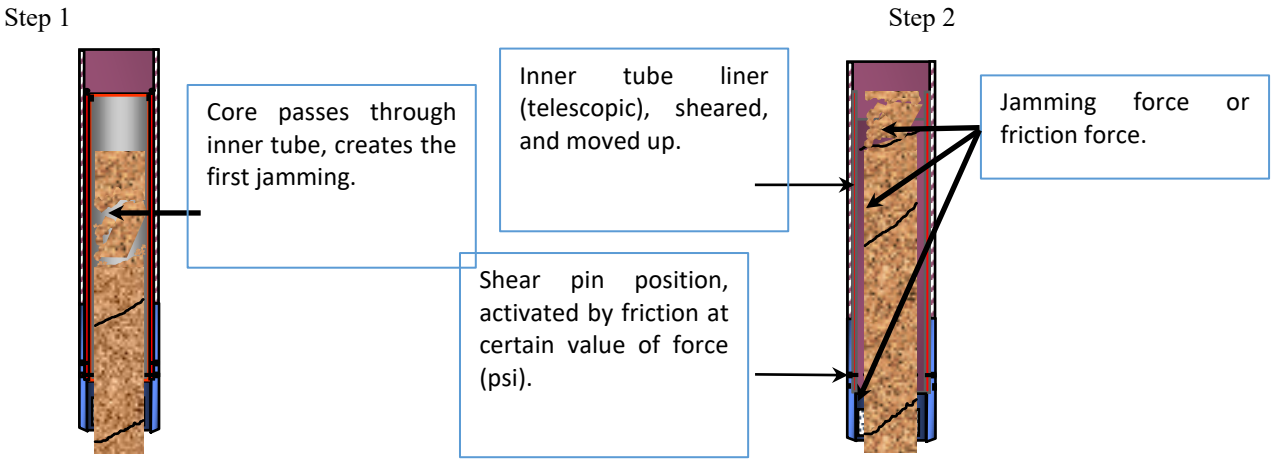

Figure 11: Anti-jamming activation steps.

The system activates downhole by the friction force; thus, it is not seen at the surface gauge parameter. Proof will be notified upon the core reaching the surface, and the liner anti-jamming will be spotted at a certain meterage of the inner barrel, either the liner still located at the bottom, middle, or top of the inner barrel along with the core sample. After the cutting process of the inner barrel with core and liner, the evidence will be seen clearly.

3.4 Core Head

At the Q-1 well, there is a high awareness of the core jamming anomaly in this type of formation. However, the contract with the client restricted the coring service provider from using only a standard conventional *or* full closure system. Given these constraints, core head selection was crucial. Applying general theory related to ROP, diamond and impregnated diamond core heads were not applicable to the project. Instead, a polycrystalline diamond compact (PDC) core head was selected. The chosen PDC core head had a design optimized for a good penetration rate and a medium number of cutters. This moderately aggressive core head design was recommended as the best available solution to minimize the chance of core jamming.

For Q-1, the 8-1/2-in. PDC core head steel body with seven blades and 13-mm (3D ION) cutters **(Figure 10).** This core head was selected because the shaped cutter design (3D ION) recently launched for geothermal applications, and its features support the best ROP mindset, based on the rule of thumb theory in drill bit designs, such as:

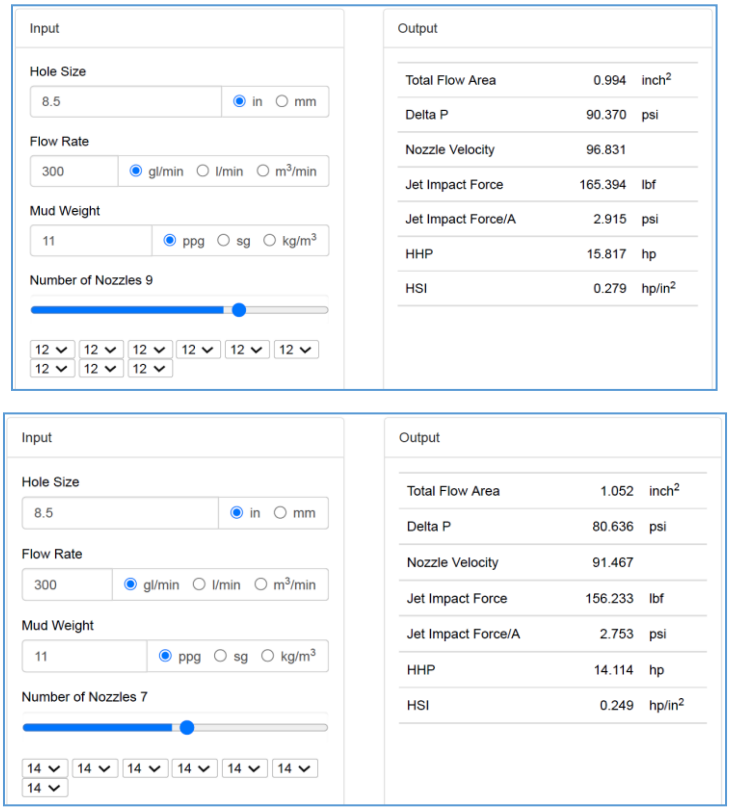
- Fewer blades equal aggressivity prior to better ROP
- Fewer blades equal bigger junk slot (10.240 $in.^2$) for better cleaning, which would help in ROP
- Bigger cutter size equals deeper depth of cut, which would increase ROP
- Seven bigger nozzles (14/32-in.) generate 0.249 $hp/in.^2$

For the T-1 and T-2 wells, the 8-1/2-in. PDC core head steel body with nine blades and 13-mm cutters. This core head was selected because the design supports the best stabilization mindset; thus, it has been proven to help reduce the chance of core jamming. Its features include:

- More blades equates to less aggressivity in ROP, reducing torque and vibration
- More blades equate to smaller junk slot (8.740 in.^{2}) and higher stability in hole
- Smaller cutter size equates to durability in hard formation, able to grind in high rotation
- Nine smaller nozzles (12/32-in.) generate a higher 0.279 hp/in.^{2} that helps in ROP downhole

Figure 12: 8-1/2-in. x 4-in. 713 PDC core head (3D ION).

Figure 13: 8-1/2-in. x 4-in. 913 PDC core head (4DXC ION).



8-1/2-in. 913

8-1/2-in. 713

Figure 14: Core head capabilities value (TFA, Velocity, JIF, HSI).

A few feature differences between the core head used at T-1 and T-2 (8-1/2-in. 913S) and the core head used at Q-1 (8-1/2-in. 713S) are:

- Core head 8-1/2-in. x 4-in. 913S has a better durability value in abrasiveness and a higher temperature limit because of the latest 4DXC ION cutter.
- Core head 8-1/2-in. x 4-in. 913S has a higher horsepower hydraulics per square inch (HHSI) value of 0.279 hp/in.^{2}, compared to core head 8-1/2-in. x 713, with an HHSI value of 0.249 hp/in.^{2}. Higher HHSI equates to better ROP.
- Core head 8-1/2-in. x 4-in. 913S has a smaller-size (12/32-in. OD) port nozzle, resulting in a higher jet impact force value of 165.394 lbf compared to 156.233 lbf from the 8-1/2-in. x4 in. 713S core head. Core head 713 was initially chosen for Q-1 due to fewer blades, with a bigger junk slot area for cleaning as the main reason.

4. RUN RESULTS

4.1 Coring Operation with the Full Closure System in the Q-1 well

On the first run at the Q-1 well, a 9-m core was planned and then ran from 2,260.6 m MD to 2,262.17 m MD (**Cored 1.5 m**). However, the core run was unsuccessful, with 0.65 m/43% recovery. From this run, we could identify the root cause and apply the lessons learned to the next well.

The first well parameters (Q-1 well) with recovery 0.65 m/43%:

1. Flow Rate: 250 gpm
2. WOB: 4–30 klbs
3. RPM: 60–90
4. Torque: 9–13 kft/lb (off bottom 11 kft/lbs)
5. SPP: 0 psi

4.2 The COMBO Full Closure System and Anti-Jamming System in the T-1 well

In the second run at the T-1 well, a 9-m core was planned and then ran from 2,463m MD to 2,471 m MD (**Cored 8.7 m**). The coring run was successful with 6.25 m/71.84% recovery. The root cause and all lessons learned were implemented on the next well.

The second well parameters (T-1 well) with recovery 6.25 m/71.84%:

1. Flow Rate: 300 gpm
2. WOB: 4–25 klbs
3. RPM: 60–90
4. Torque: 19–23 kft/lbs (off bottom 21 kft/lbs)
5. SPP: 0 psi

4.3 The COMBO Full Closure System and Anti-Jamming System in the T-2 well

A combination of the Anti-Jamming System and Full Closure System was also used to cut core in the T-2 well, building on a few lessons learned from the T-1 well. The key changes made included adjusting parameters and adding lubricant to the fluid program during the coring operation. The run was successful, achieving 100% core recovery of 8.43 m core from 2,570 m MD to 2,578.43 m MD.

The third run parameters (T-2 well) with recovery 8.43 m/100%:

1. Flow Rate: 300 gpm
2. WOB: 4–18 klbs
3. RPM: 60–80
4. Torque: 12–15 (off bottom 13 kft/lbs)
5. SPP: 0 psi

Figures 15 and 16 illustrate the core process, from making up the coring BHA to handling the core on the ground and packing the core.

5. OPERATIONAL CONSIDERATIONS/LESSONS LEARNED

- The combination of the Anti-Jamming System and Full Closure System has proven to be crucial in the success of the T-1 well and even more so at the T-2 well coring operation.
- Analysis of the three wells (Q-1, T-1, and T-2) revealed significant differences in procedures, informed by lessons learned and optimizations implemented at the next wells.

- Core jamming was the main issue during coring at the geothermal applications, not just the non-cemented formations that may cause the core to fall off from the inner barrel assembly. Core jamming occurred at the Q-1 well.

Make-Up Coring BHA Make-Up DAS Make-Up Inner Barrel Assembly

Figure 15: Make-up coring BHA combo full closure and anti-jamming system.

Core Marking and Condition of Inner Cutting the Core Packaging the Core

Figure 16: Core marking to packaging the core at the T-2 well.

- The coring flow rate is crucial for successful core retrieval in geothermal applications. The use of lubricant increased the elimination and success of the coring operation at the T-2 well. Other parameters may need to be adjusted on-site, as engineers must react to changes in the penetration rate.
- The combination of the aluminium inner barrel and the anti-jamming liner tube proved to be suitable and applicable and is highly recommended for coring operations with similar well profiles near the T-1 and T-2 wells.
- Key anomalies to closely monitor are:
    - Torque values: An on-bottom parameter torque value equal to or less than the off-bottom parameter torque value indicates core jamming.
    - ROP: A penetration rate of less than 10 fph, down to 0 fph, indicates core jamming.
    - Pressure: No pressure at geothermal applications, as coring point depth is preferred at either severe or, most likely, total fluid loss zones.

ACKNOWLEDGEMENTS

The authors would like to give gratitude to all the representatives involved in these projects, whose efforts contributed to the exceptional core quality and core length achieved at the T-1 and T-2 wells. The success of these wells is attributed to the use of the combined Anti-Jamming System and Full Closure System in one assembly run. The authors would also like to thank the Geodipa Energy Management and Coring Service Provider Director for the permission to present and publish this paper.

ABSTRACT

In geothermal power plants, Hot Well Pump (HWP), Component Cooling Water Pump (CCWP), Auxiliary Cooling Water Pump (ACWP), Liquid Ring Vacuum Pump (LRVP), and Cooling Tower Fan (CTF) are commonly driven by electric motors and considered as critical equipment. Therefore, motor mechanical faults such as misalignment, bearing problems, transmission element problems, and loose foundation can lead to equipment failure and Loss Production Opportunities (LPO). Therefore, appropriate Predictive Maintenance (PdM) of the motor is necessary to prevent such failures through condition monitoring. At PLTP Darajat II, motor condition monitoring activities like Vibration Analysis (VA) and General Motor Condition Monitoring (GMCM) are performed on those equipment. VA is a condition monitoring method to identify mechanical faults by evaluating the vibration frequency and amplitude from its frequency-domain vibration data. Meanwhile, GMCM is a new method that can identify both mechanical and electrical faults on a motor by measuring its terminal voltage and current. However, GMCM and VA measurement at the same time is considered to be cost-inefficient due to similar purposes. This study aims to enhance PdM cost-efficiency by investigating GMCM's effectiveness for early mechanical failure detection and exploring the possibility of reducing VA frequency for motor-driven equipment. The Matthew Correlation Coefficient (MCC) method is used to compare GMCM and VA data from HWP, CCWP, ACWP, LRVP, and CTF at PLTP Darajat II. Currently, VA is the most commonly used method to detect mechanical faults on motors. Hence, VA diagnostics data is used as a reference, with GMCM as a comparison. The number of samples used in this study is 41 with confidence level and margin of error value of 88% and 12.13%, respectively. The samples are obtained from GMCM and VA of those equipment within the same period of month, ensuring similar motor operating conditions. The results demonstrate a weak and negative correlation between the results of GMCM and VA (MCC = -0.307). GMCM exhibits low sensitivity and F1 score of 17% and 7%, respectively. The values demonstrate that GMCM often failed to detect motor mechanical faults similar to VA. Additionally, its low specificity (40%) and accuracy (37%) values, highlight its inability to accurately identify the non-faulty motors. These findings suggest that GMCM is currently not a viable replacement for VA in mechanical fault detection. More VA and GMCM samples can be added to improve the confidence level and margin of error used in the MCC. Further research is also necessary to improve GMCM's performance before considering it as an alternative to reduce VA frequency for motor-driven equipment.

1. INTRODUCTION

In a Geothermal Power Plant, electric motors play an important role in electricity production. Hot Well Pump (HWP), Component Cooling Water Pump (CCWP), Auxiliary Cooling Water Pump (ACWP), Liquid Ring Vacuum Pump (LRVP), and Cooling Tower Fan (CTF), which are considered as critical equipment, are commonly driven by electric motors. Failure of those equipment may result in Loss Production Opportunity (LPO) which has significant technical and economic consequences, such as lower plant availability-reliability factor and decrease in revenue, respectively. A predictive maintenance strategy that can prevent unforeseen failures on equipment is commonly known as condition monitoring. This strategy involves regular checking on an equipment to detect early signs of wear and potential failures that come along. In much bigger picture, condition monitoring can be implemented to ensure the reliability of a power plant. Even though there are additional expenses that have to be incurred along with the implementation of condition monitoring, these costs are significantly much lower compared to the cost of equipment replacement or the amount of LPO.

Vibration Analysis (VA) and General Motor Condition Monitoring (GMCM) are two condition monitoring methods that are used in PLTP Darajat II for motor driven equipment, such as HWP, CCWP, ACWP, LRVP, and CTF. Each method has its own approaches and advantages. VA (Vibration Analysis) and GMCM (General Motor Condition Monitoring) are methods used for condition monitoring to detect mechanical faults in motor-driven

equipment, such as those mentioned above. However, at the PLTP Salak and PLTP Wayang Windu, only VA is employed for the condition monitoring of these equipment.

VA is a process of analyzing anomalies and monitoring change from the established vibration signature of a motor driven equipment. The vibration of motor is characterized by its frequency, amplitude, and intensity. VA is a well-established and widely used method for identifying anomalies, such as mechanical faults in electric motors. VA can detect a range of mechanical faults such as misalignment, imbalance, bearing wear, and other mechanical problems. For instance, misalignment typically results from a combination of radial and axial components, while bearing wear often produces vibration spikes in high frequency.

On the other hand, GMCM offers a newer condition monitoring technology that can provide a more integrated approach for motor condition assessment. Unlike VA, which is predominantly mechanical, GMCM integrates both electrical and mechanical fault detection. GMCM can provide insights regarding the electrical and mechanical faults by measuring and analyzing the electric motor's terminal current. GMCM uses advanced algorithms to analyze the motor's electrical signal, enabling the detection of anomalies that might not be apparent through VA alone.

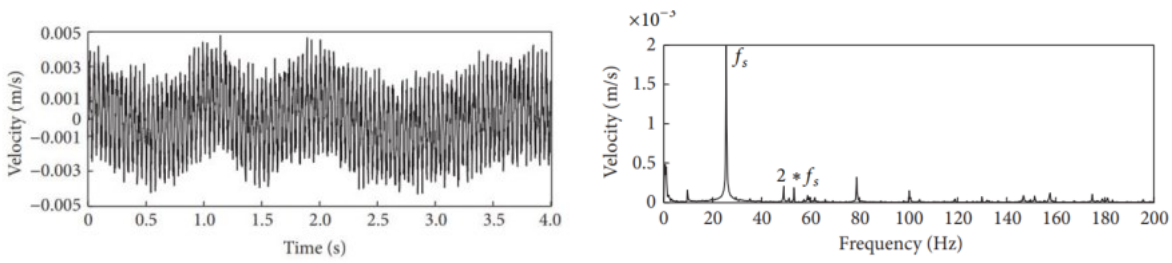
Currently, VA is the most used condition monitoring method, especially to detect mechanical faults on motors since the reliability of GMCM on detecting mechanical faults still remains under evaluation. At PLTP Darajat II, where both VA and GMCM are currently employed, the effectiveness of GMCM on early detecting mechanical faults is currently being evaluated by comparing it to the VA results. If GMCM is proven to be as effective as VA on detecting mechanical faults, GMCM can be considered to be installed online while reducing the VA frequency for motor-driven equipment at the same time. This strategy is expected to enhance the overall reliability and efficiency of predictive maintenance (PdM) programs in PLTP Darajat II. This paper will answer how effective GMCM can detect mechanical faults on motor-driven equipment in accordance with VA by using the Matthew Correlation Coefficients (MCC) approach.

2. LITERATURE REVIEW

2.1 Vibration Analysis

Vibration analysis (VA) is a powerful and effective predictive maintenance method utilized to detect mechanical faults by analyzing the vibration patterns of a machine (Mobley, 2002; Minette et al., 2016). Machine vibrations can be represented in various forms, including displacement, velocity, and acceleration (Chu et al., 2024). Displacement describes the distance of movement of the measurement point, velocity describes how fast a movement is, and acceleration describes the change in velocity in a given time unit. Vibration analysis can be performed on both time waveform and frequency spectrum of the vibration signal. Vibration signal's frequency spectrum is obtained by applying Fourier Transform to the signal's time waveform.

Time domain vibration analysis can be performed using parameters such as root mean square (RMS), standard deviation, peak amplitude, kurtosis, crest factor, slope, and many others (Yadav et al., 2020). An example of time domain vibration analysis interpretation can be seen in Figure 1(a) below. In addition to time domain analysis, frequency spectrum analysis is highly recommended for real-world vibration analysis applications, especially for rotating machinery. Frequency analysis decomposes the time waveform and represents the repetition of vibration patterns, allowing the investigation of frequency components corresponding to each component (Chu et al., 2024). Frequency domain vibration analysis is superior to time domain vibration analysis on detecting abnormal vibration patterns, since it allows the identification of specific frequencies associated with specific components or phenomena, such as machine rotation frequency, gear tooth frequency, or bearing damage frequency, which cannot be done in the time domain. An example of frequency domain vibration analysis interpretation can be seen in Figure 1(b).



(a) (b)

Figure 1: (a) Waveforms in Time Domain, (b) Waveforms in Frequency Domain (Patel et al., 2014).

2.2 General Motor Condition Monitoring (GMCM)

General Motor Condition Monitoring (GMCM) is a revolutionary technology that utilizes a single toolkit to detect both mechanical and electrical faults. Additionally, GMCM provides corrective recommendations upon detecting any malfunctions. Based on their installation method, GMCM can be categorized into two types: permanently installed and portable toolkit. In practice, portable GMCM toolkit is more preferrable to be utilized due to its better transportability and operability. This portability of GMCM toolkit can facilitate the evaluation of all 3-phase AC motors operating under low to medium voltage conditions, regardless of their specifications.

This portable and versatile toolkit empowers power plant to analyze the condition of all its motors. Operating the GMCM toolkit is straightforward and does not require specialized personnel for fault analysis. The toolkit independently identifies faults using an internal motor fault database and model, eliminating the need for trend data analysis. This database-driven approach enables fault detection within an hour, from measurement to report generation.

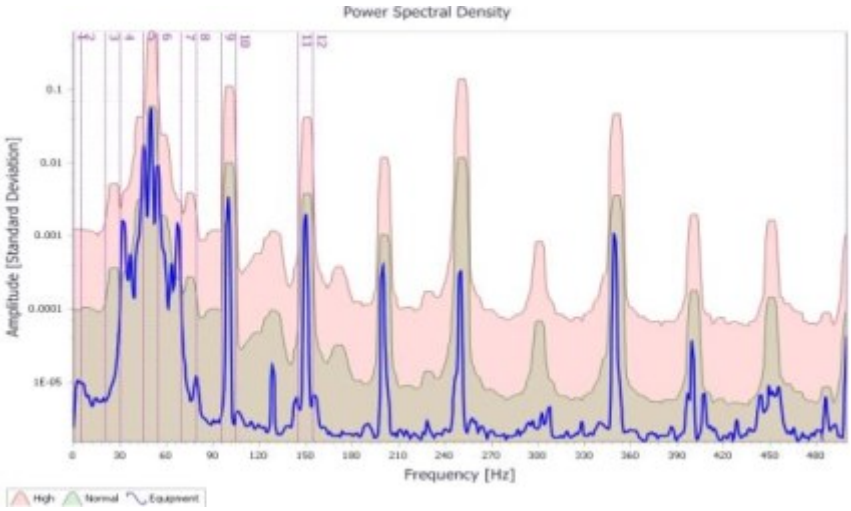


Figure 2: Comparison of Measured Power Spectral Density (PSD) of an Equipment (Blue Line) with PSD from GMCM Database. (Red and Green Lines) (Star Energy Geothermal, 2023)

The GMCM procedure begins with measuring the current at the motor terminals. This time-domain current data is then transformed into power spectral density (PSD) to analyze motor faults. The resulting PSD graph is compared to standard PSD graphs within the GMCM toolkit to determine the type of fault (Figure 2). The entire process, from time-domain to PSD transformation and motor condition assessment, is performed within the toolkit, limiting human involvement to setting up the equipment for current data acquisition.

2.3 Matthew Correlation Coefficient (MCC)

The Matthews Correlation Coefficient (MCC) is a statistical measurement utilized to evaluate the quality of binary classifications (Chicco et al., 2021). It has the advantage of being reliable even when the data used is imbalanced (Chicco & Jurman, 2020). MCC represents the correlation between observed and predicted results, resulting in a value between -1 and 1 (Chicco et al., 2021). An MCC value of 1 indicates perfect prediction, occurring when the model's predictions align with the actual truth labels. Meanwhile, an MCC value of 0 indicates that the model's predictions are no better than random chance, and the model performs the same as flipping a coin. In other words, it has no discriminatory ability. An MCC value of -1 indicates perfect inverse prediction, occurring when the model's predictions are completely opposite to the actual labels. For example, if the model predicts all positive samples as negative and vice versa, the model will result in a -1 MCC value. Since MCC is a binary classification, a confusion matrix (Figure 3) is used to represent how many elements are correctly predicted and how many are incorrectly classified. Figure 3 shows four terms:

1. The actual positives that are correctly predicted positives are called true positives (TP).
2. The actual positives that are wrongly predicted negatives are called false negatives (FN).
3. The actual negatives that are correctly predicted negatives are called true negatives (TN).

The actual negatives that are w Figure 4 illustrates the process of the research conducted in this paper. First, data from GMCM and VA testing on the same equipment and at close intervals is collected. Next, a confusion matrix is determined, which will then be used to evaluate the Matthew Correlation Coefficient (MCC) score. Once the confusion matrix results are obtained, MCC, Sensitivity, Specificity, Accuracy, and F1 score are calculated. The results of the survey/research can be visualized using a ROC curve. Finally, before drawing conclusions, a confidence level shall be determined to indicate the quality of the survey results.

4. rongly predicted positives are called false positives (FP).

Figure 3: Confusion Matrix (De Diego et al, 2022).

The MCC calculation can be done using equation (1) (De Diego et al., 2022).

$$MCC = \frac{TP\ x\ TN - FP\ x\ FN}{\sqrt{(TP + FP)(TP + FN)(TN + FP)(TN + FN)}} \quad (1)$$

In addition to the MCC method, there are several other statistical methods that can be used to evaluate the quality of binary classification, including sensitivity, specificity, accuracy, and F1 Score (Rainio et al., 2024). Sensitivity is a measure of the model's ability to correctly identify actual machine failure events (true positives). High sensitivity means the model rarely misses actual machine failures (true positives). The sensitivity calculation can be done using equation (2).

$$Sensitivity = \frac{TP}{FN + TP} \quad (2)$$

Specificity is a measure of the model's ability to correctly identify healthy machine signals (true negatives). High specificity means the model rarely misclassifies healthy signals as machine failures (false negatives). The specificity calculation can be done using equation (3).

$$Specitifity = \frac{TN}{FP + TN} \quad (3)$$

Accuracy is the proportion of overall correct model predictions (true positives and true negatives) divided by the total predictions. High overall accuracy indicates good model performance, but it should be considered along with sensitivity and specificity depending on the context. The accuracy calculation can be done using equation (4).

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (4)$$

F1 Score is a combined metric that combines sensitivity and specificity into a single score. High F1 Score indicates a good balance between sensitivity and specificity. The F1 Score calculation can be done using equation (5).

$$F1\ score = \frac{2 \times Sensitivity \times Specificity}{Sensitivity + Specificity} \quad (5)$$

3. METHODOLOGY

Figure 4 illustrates the process of the research conducted in this paper. First, data from GMCM and VA testing on the same equipment and at close intervals is collected. Next, a confusion matrix is determined, which will then be used to evaluate the Matthew Correlation Coefficient (MCC) score. Once the confusion matrix results are obtained, MCC, Sensitivity, Specificity, Accuracy, and F1 score are calculated. The results of the survey/research can be visualized using a ROC curve. Finally, before drawing conclusions, a confidence level shall be determined to indicate the quality of the survey results.

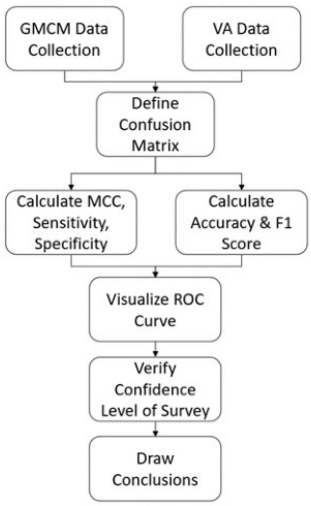

Figure 4: Research Methodology.

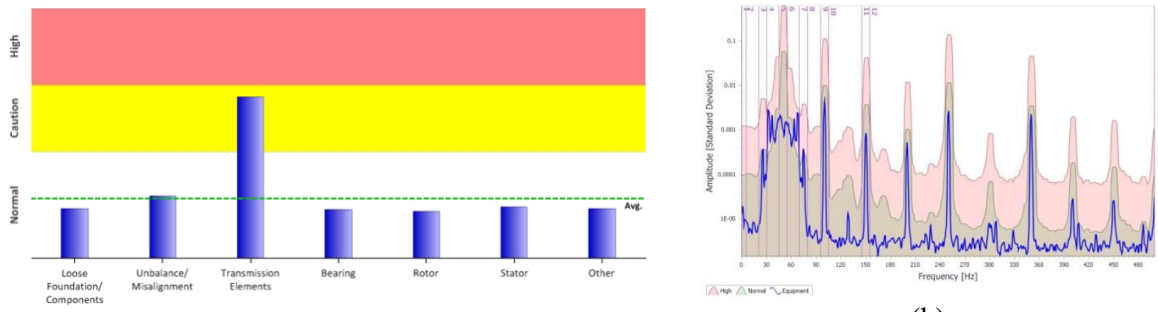
Figure 5: (a) GMCM Results in Normal Condition, (b) Power Spectral Density in Normal Condition (Star Energy Geothermal, 2023).



(a) (b)

Figure 6: (a) GMCM Results in Anomaly Condition, (b) Power Spectral Density in Anomaly Condition (Star Energy Geothermal, 2023).

The GMCM data were collected by measuring the current at the motor terminals using a clamp ampere meter. This method involves capturing the current signals directly, which initially are represented in the time domain. To gain deeper insights into the motor's operational characteristics, these time-domain signals were transformed into the frequency domain using techniques such as Fourier analysis. This transformation allows for a detailed examination of the signal's frequency components, which are critical for diagnosing the motor's performance and detecting potential issues.

Figure 5 shows one of the GMCM tests performed on the Hot Well Pump 3A, for example. In this test, the GMCM analysis indicated that the Hot Well Pump 3A is functioning normally. This conclusion is derived from analyzing the amplitude of the Power Spectral Density (PSD) at different frequencies. The PSD provides a representation of how the power of the current signal is distributed across various frequency components. To evaluate the operating condition of the Hot Well Pump 3A, the PSD obtained from its current measurements was compared to a benchmark PSD model. By comparing the pump's PSD to this standard model, it was possible to identify any deviations or anomalies that might suggest underlying issues with the equipment.

The General Motor Condition Monitoring (GMCM) indicates an anomaly or fault when the amplitude of the Power Spectral Density (PSD) of the measured current exceeds a threshold set by the model. GMCM can detect various mechanical faults such as loose foundations or components, unbalance or misalignment, issues with transmission elements, and bearing wear as shown in Figure 6 (a). It can also identify electrical faults like broken rotors and stator issues. Each type of fault is characterized by specific frequencies and amplitudes. Figure 6 shows an example of GMCM detecting an anomaly in a Liquid Ring Vacuum Pump U3.

In the context of Vibration Analysis (VA) testing, velocity measurements were carried out at several critical points on the Hot Well Pump 3A, for example. These measurements were taken in the horizontal, vertical, and axial directions to capture a comprehensive picture of the motor and pump vibrational behavior. Velocity measurements were taken in units of mm/s peak. To assess the severity of the detected vibrations, it is essential to classify the motor and pump according to recognized standards. For this purpose, the ISO 10816-1:1995 standard is used for motors, providing guidelines on evaluating mechanical vibrations in various machine components. Additionally, the ISO 10816-7:2009 standard applies to pumps, specifying the acceptable vibration severity levels for different pump types. This classification is critical for determining the acceptable vibration thresholds and for assessing whether the observed vibration levels fall within safe operating limits. If the vibration levels exceed the predefined acceptable limits, it could signal the need for further analysis or intervention to prevent potential damage or operational failure. Table 2 shows that Hot Well Pump 3A works on normal operation.

Table 1: ISO 10816 Standards for Motor & Pump (ISO 10816, 1995).

Standard	A	B	C	D
Motor	0.4 – 2.54	2.54 – 6.36	6.36 – 15.8	15.8 – 63.65
Pump	< 4.95	4.95 – 7.07	7.07 – 10.75	> 10.75

Table 2: VA Results for Motor & Pump in Normal Condition (Star Energy Geothermal, 2023).

Point	Value	Units	Standard by ISO 10816-1
Motor Outboard Y Direction	1.327	mm/Sec	A
Motor Outboard X Direction	0.838	mm/Sec	A
Motor Outboard Axial	2.091	mm/Sec	A
Motor Inboard Y Direction	0.633	mm/Sec	A
Motor Inboard X Direction	0.472	mm/Sec	A
Motor Inboard Axial	1.185	mm/Sec	A
Pump Inboard Y Direction	1.803	mm/Sec	A
Pump Inboard X Direction	2.397	mm/Sec	A
Pump Inboard Axial	1.006	mm/Sec	A
Foundation Y Direction	0.179	mm/Sec	A
Foundation X Direction	0.224	mm/Sec	A
Foundation Axial Direction	0.236	mm/Sec	A

If the vibration velocity measurements exceed the thresholds defined by these standards, it suggests that the equipment may be experiencing operational issues that could lead to further mechanical damage or failure. In the example of the Liquid Ring Vacuum Pump U3, high vibration levels were detected specifically at the Shaft Inboard Axial position, indicating potential problems.

Table 3: VA Results for Motor & Pump in Anomaly Condition (Star Energy Geothermal, 2023).

Point	Value	Units	Standard by ISO 10816-1
Motor Outboard Vertical	1.985	mm/Sec	A
Motor Outboard Horizontal	2.389	mm/Sec	A
Motor Inboard Vertical	1.915	mm/Sec	A
Motor Inboard Horizontal	2.352	mm/Sec	A
Motor Inboard Axial	2.188	mm/Sec	A
GB Input Shaft Inboard Vertical	3.952	mm/Sec	B
GB Input Shaft Inboard Horizontal	4.955	mm/Sec	B
GB Input Shaft Outboard Vertical	6.449	mm/Sec	C
GB Input Shaft Outboard Horizontal	5.261	mm/Sec	B
GB Int Shaft Inboard Vertical	4.732	mm/Sec	B
GB Int Shaft Inboard Axial	8.327	mm/Sec	C
GB Int Shaft Outboard Vertical	5.399	mm/Sec	B

Point	Value	Units	Standard by ISO 10816-1
GB Output Shaft Inboard Vertical	4.095	mm/Sec	B
GB Output Shaft Inboard Horizontal	3.334	mm/Sec	B
GB Output Shaft Outboard Vertical	2.968	mm/Sec	B
GB Output Shaft Outboard Horizontal	3.934	mm/Sec	B
GB Output Shaft Outboard Axial	5.197	mm/Sec	B
Pump Inboard Vertical	4.507	mm/Sec	B
Pump Inboard Horizontal	3.840	mm/Sec	B
Pump Inboard Axial	4.134	mm/Sec	B
Pump Outboard Vertical	3.910	mm/Sec	B
Pump Outboard Horizontal	3.911	mm/Sec	B

To determine the correlation between GMCM testing and VA, the Matthew Correlation Coefficient (MCC) statistical method is used by comparing the test results for each motor-driven equipment. VA data serves as the baseline to validate the GMCM because VA is a long-established and proven method. In this evaluation, 41 sets of VA and GMCM measurement data from Hot Well Pump (HWP), Component Cooling Water Pump (CCWP), Auxiliary Cooling Water Pump (ACWP), Liquid Ring Vacuum Pump (LRVP), and Cooling Tower Fan (CTF) were collected from 2022 until 2024. The measurements and health analysis of these equipment based on VA and GMCM were conducted nearly simultaneous, ensuring that the equipment was in similar conditions both externally and internally. In the MCC evaluation metrics, the results are categorized into four groups: True Positive (TP), False Negative (FN), False Positive (FP), and True Negative (TN). Table 4 shows the confusion matrix between VA & GMCM testing to identify the evaluation metrics group and Table 5 shows some results of the comparison of GMCM and VA data.

Table 4: VA & GMCM Confusion Matrix.

Vibration Analysis (VA)	General Motor Condition Monitoring (GMCM)	Results
Fault	Fault	True Positive (TP)
Fault	No Fault	False Negative (FN)
No Fault	Fault	False Positive (FP)
No Fault	No Fault	True Negative (TN)

Table 5: Results of VA & GMCM Correlation Evaluation.

Motor Driven Equipment	VA Results	GMCM Results	Remarks
Liquid Ring Vacuum Pump U2	B	Normal	True Negative
Liquid Ring Vacuum Pump U3	C	Caution	True Positive
Cooling Tower Fan U3	B	High	False Positive
Auxiliary Cooling Water Pump	C	Normal	False Negative

4. RESULT AND DISCUSSION

They obtained 41 VA and GMCM testing data on the same motor-driven equipment. From these data, there were 14 True Negatives, 1 True Positive, 5 False Negatives, and 21 False Positives (Table 6). These data were then applied to calculate the Matthew Correlation Coefficient (MCC). These numbers are crucial for calculating the Matthew Correlation Coefficient (MCC), which is used to evaluate how well the methods (VA and GMCM) correlate with each other in identifying the equipment's condition (normal or faulty).

From Table 7, the MCC (Matthews Correlation Coefficient) value obtained is -0.3071. This value indicates that the relationship between GMCM (General Motor Condition Monitoring) and VA (Vibration Analysis) in detecting mechanical faults is weak and negative. This suggests that the predictions made by GMCM for detecting mechanical faults tend to not align with the results from VA. Additionally, to provide a more comprehensive understanding of GMCM's effectiveness in detecting mechanical faults, other evaluation metrics were assessed. Based on the data in Table 7, GMCM has a sensitivity of 17% and an F1 score of 7%, indicating that GMCM is not sensitive enough in detecting the presence of mechanical faults, meaning it tends to miss many mechanical faults. Furthermore, with a specificity of 40% and an accuracy of 37%, GMCM is not accurate in identifying motors that are not faulty.

Table 6: VA & GMCM Confusion Matrix Results.

Confusion Matrix	Value
True Negative (TN)	14
True Positive (TP)	1
False Negative (FN)	5
False Positive (FP)	21

Table 7: Calculation Results of MCC, Sensitivity, Specificity, Accuracy, and F1 Score.

Parameter	Value
Matthew Correlation Coefficient	-0.3071
Sensitivity	17%
Specificity	40%
Accuracy	37%
F1 Score	7%

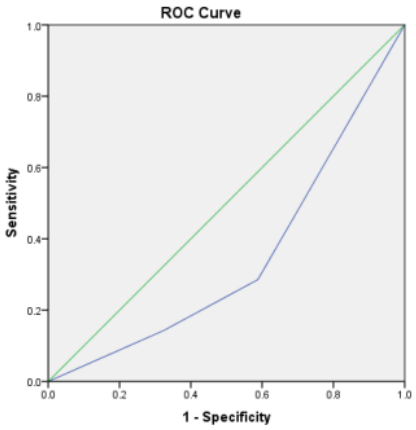


Figure 7: ROC Curve.

Furthermore, ROC curve analysis was conducted to evaluate the effectiveness of the GMCM (General Motor Condition Monitoring) model in identifying actual mechanical faults (sensitivity) and how well GMCM avoids identifying the absence of mechanical faults as mechanical faults (specificity). Based on Figure 7, the area under the ROC curve (AUC) is 0.345, indicating that the performance of GMCM in detecting the presence of mechanical faults falls below the unsatisfactory threshold. This suggests that the GMCM method cannot effectively distinguish between the presence and absence of mechanical faults. From various evaluation metrics conducted above, it is evident that the performance of GMCM in detecting mechanical faults is still low. Therefore, for now, if GMCM is to beused to reduce the number of VA measurements, it needs to be reconsidered due to the low sensitivity and specificity values of GMCM.

When assessing the Matthew Correlation Coefficient (MCC), the confidence level plays a crucial role in gauging the certainty of the evaluation results. It indicates how closely the MCC calculated from a sample reflects the true value within the entire population. The confidence level, typically presented as a percentage, represents the probability that the calculated confidence interval accurately contains the actual MCC. This metric is essential for understanding how reliable and precise the MCC estimate is from the sample data. By providing insights into the expected range of values, confidence levels aid in making well-informed and confident decisions regarding the correlation between variables.

Based on the selected values, the sample size n and the margin of error E are determined Equation 6, 7, and 8.

$$x = Z\left(\frac{c}{100}\right)^2 r(1-r) \tag{6}$$

$$n = Nx/((N-1)E^2 + x)) \tag{7}$$

$$E = \sqrt{\frac{(N-n)x}{n(N-1)}} \tag{8}$$

Where the N is population size, r is the fraction of responses that interested in, and $Z(c/100)$ is the critical value for the confidence level c. The margin of error E is the level of error that represents the acceptable degree of uncertainty in survey results. For instance, if 90% of the respondents say "yes" and only 10% say "no". To achieve a lower margin of error, a larger sample size is necessary. The confidence level represents the degree of uncertainty that can be accepted in the survey. For instance, if a survey includes 20 yes-no questions and is set a 95% confidence level, it means that for one of these questions (about 1 in 20), the percentage of "yes" answers will probably differ from the true population percentage by more than margin of error. The "true answer" represents the actual percentage that would be obtained if every individual in the population were surveyed. Achieving a higher confidence level requires a larger sample size.

To determine the confidence level and margin of error, a sample size n of 41 and a fraction of responses r of 0.5 (a conservative assumption) were used. Calculation of x shown in Equation 9.

$$x = (1.5548)20.5(1 - 0.5) = 0.6041 \tag{9}$$

A Z-value of 1.5548 was used, assuming that with a sample size n of 41, an 88% confidence level can be achieved. This assumption was validated by calculating the sample size n to match the relationship between the confidence level c and the given sample size.

The calculation process shown in Equation 10.

$$n = \frac{20000\ x\ 0.6041}{(20000 - 1)\ x\ (0.12)^2\ x + 0.6041} = 41.87 \tag{10}$$

Thus, the required sample size was calculated to be approximately 41.87. Since this closely aligns with the available sample size of 41, it can be concluded that the confidence level is 88%.

Calculation of margin of error E shown in Equation 11.

$$E = \sqrt{\frac{(20000 - 41)0.6041}{41(20000 - 1)}} = 0.1213 = 12.13\% \tag{11}$$

Hence, with 41 data points for VA and GMCM, a confidence level of 88% and a margin of error of 12.13% were obtained. To achieve a more accurate survey result, typically a confidence level of 95% with a margin of error of 5% is preferred, where a higher confidence level and a smaller margin of error will yield better survey results. To achieve the confidence level and margin of error values mentioned above, 377 samples of VA and GMCM testing would be needed.

5. CONCLUSION

Based on the sampling and testing of 41 data points, it was concluded that there is no significant positive or negative correlation between VA (Vibration Analysis) and GMCM (General Motor Condition Monitoring); their results appear to be largely random. This conclusion was drawn with a confidence level c of 88% and a margin of error E of 12.13%. To achieve a higher confidence level c of 95% and reduce the margin of error E to 5%, 377 samples and tests would be required for both VA and GMCM at PLTP Darajat II. Therefore, with the current confidence level and margin of error, further sampling and testing data are necessary for researching the correlation between VA and GMCM, while maintaining the frequency of VA testing on HWP, CCWP, ACWP, LRVP, and CTF.

ABSTRACT

In October 2022, Darajat II Geothermal Power Plant Unit 2 (DRJ U2) was shutdown due to planned overhaul. Two weeks into the shutdown, Darajat II Geothermal Power Plant Unit 3 (DRJ U3) tripped due to High-High level of condensate at Unit 3 separator that resulted in Loss Production Opportunity (LPO) with estimated total amount of 120k USD. Based on the Root-Cause Analysis (RCA) result, the trip was caused by loss of power supply to Automatic Drain Pot (ADP) and other instrumentation devices in Pad S1 and S4 area. These two pads were put into service in 2020 and powered by DRJ U2 through 6.3 kV common service bus. The power redundancy for Pad S1 and Pad S4 is designed to be provided by DRJ U3 through online power maneuver into the 6.3 kV common service bus. Meanwhile, the online power maneuver could not be performed because DRJ U2, 6.3 kV common service bus, and DRJ U3 were unable to synchronize. Based on the RCA result, a portable diesel generator set was prepared as a backup power supply to mitigate the loss of power supply to Pad S1 and S4. The power maneuver was then successfully performed manually, allowing Pad S1 and S4 to be powered by DRJ U3. The portable diesel generator set was still prepared as a stand-by power supply in case of a power supply failure from DRJ U3 to Pad S1 and S4 occurs. Portable diesel generator set was chosen since the existing DC UPS of ADP needs to be charged to provide continuous power supply. Meanwhile, the portable diesel generator set has many drawbacks such as fluctuating fuel prices, lack of auto power transfer ability, and a relatively high carbon footprint. With the increase of Photovoltaic-Battery's (PV-Battery) technology, this paper evaluates the use of PV-battery system as a greener stand-by power supply alternative with the auto start capability, and can also to be operated as a house load compensator for existing Pad S1 and S4, new condensate re-injection pump, and future house load around the wellpads area. Comparative study between PV-battery system and diesel generator as stand-by power supply alternatives is also provided in this paper. This study shows that the proposed PV-battery system can provide better operability, better maintainability, better reliability, greener, and slightly more economical stand-by power supply alternative for Pad S1 and S4.

1. INTRODUCTION

In a multi-unit power plant, power maneuver or bus transfer system is commonly employed to continuous power plant operation by preventing critical power plant auxiliaries system to trip when the primary power source shutdown due to disturbances or maintenance activities (Kansara, 2017). On the other words, power maneuver system is employed to provide power redundancy for critical power plant house load system by switching the power supply from one source to another. Ideally, the power maneuver is performed online where the source transfer is initiated at the Distributed Control System (DCS) by operator. This method is usually known as online power maneuver or fast bus transfer system.

Unfortunately, that was not the case in Darajat II Geothermal Power Plant Unit 2 (DRJ U2) and Unit 3 (DRJ U3). Back in October 2022, DRJ U2 was shutdown due to planned overhaul, which is commonly known as Shutdown Turnaround (SDTA). Two weeks into the shutdown, DRJ U3, which was operating normally, tripped unplannedly due to High-High level of condensate at its separator. This accident resulted in Loss Production Opportunity (LPO) with estimated total amount of 120k USD. Besides LPO, an accident such this unplanned trip also decreases the availability and reliability factor of power plant, since the power plant was not able to generate electricity for about several hours due to forced outages. Based on the Root-Cause Analysis (RCA) result, it was identified that the High-High level of condensate was caused by loss of power supply to Automatic Drain Pot (ADP) and other instrumentation devices in Pad S1 and S4 area. For additional information, Pad S1 and S4 were put into service in 2020 as steam production facilities for DRJ U3.

Power of Pad S1 and S4 has been supplied by DRJ U2 since the first time those two wellpads were put into service. When DRJ U2 shutdown, online power maneuver was supposed to be performed by switching electrical load from DRJ U2 to DRJ U3 on the 6.3 kV common service bus in order to provide power redundancy for Darajat S1 and S4 wellpads. There are two online power maneuver methods that can be used on the Darajat 6.3 kV common service bus, namely bumpless transfer (make-before-break) and override. Bumpless transfer will cause a brief parallel connection between U2 and U3, before one of them is opened. Meanwhile, override will cause U2 and U3 a continuous parallel connection between U2 and U3. Unfortunately, these online power maneuver methods could not be performed at that time. Then, the power maneuver was tried to be performed manually using break-before-make method. A portable generator set is prepared to be utilized as a backup power supply for Pad S1 and S4 in case of a failure in the manual power maneuver execution. Fortunately, the manual power maneuver was successfully performed right before the latest DRJ U2 SDTA in May 2024. For additional information, power maneuver or bus transfer between DRJ U2 and DRJ U3 6.3 kV system has never successfully performed since the common service bus 6.3 kV was operated for the first time in 2009. Since the manual power maneuver has only been performed once, the portable diesel generator set is still prepared as a stand-by power supply in case of a power supply failure from DRJ U3 to Pad S1 and S4 occurs. However, a portable diesel generator set has several drawbacks such as fluctuating fuel prices (Lau et al, 2015; Zhu et al., 2018; Farnoosh, 2022), lack of auto power transfer ability, and greenhouse gas emissions (Jakhrani et al., 2012; Yilmaz and Dincer, 2017; Barbosa et al., 2021).

This paper shows that PV-battery system is a doable stand-by power supply alternative other than diesel generator set, which both can be utilized in a geothermal power plant to prevent unplanned trip during power maneuver. This paper also reveals several benefits that can be obtained from the utilization of PV-battery system as a stand-by power supply, which can not be obtained by diesel generator set utilization such as increasing asset revenue due to its houseload compensating ability and boosting company image due to its “greener” power generation process. Even though a PV-battery system takes longer installation time and may not be yielding significant economic benefits if compared to a diesel generator, its overall benefits make the PV-battery system worth to be considered as a stand-by power supply alternative in a geothermal power plant.

2. LITERATURE REVIEW

(Reshid, Majid and Muhammad, 2014) state that power redundancy strategy can be classified as an important aspect in a power plant operation to ensure its performance and reliability. Power redundancy refers to the availability of the backup power supply to replace the primary power supply during a disturbance. Power redundancy failure, especially on critical system or equipment in a power plant, can cause problems such as unplanned unit shutdown, which can furtherly lead to Loss of Production Opportunity (LPO) and decrease in unit reliability factor. According to ISO 3997-9 (Farhat, 2021), reliability factor is defined as complement of the Forced Outage Rate (FOR) which is considered as one of the indicators used to evaluate the performance of a power plant, based on SPLN K7 001:2007 about Indikator Kinerja Pembangkit (Power Plant Performance Indicators).

Regarding to the idea of proposed power redundancy strategy, a study by (Hwang, Tongsopit and Kittner, 2023) has shown that replacing diesel backup generators to PV-plus-storage microgrids in one building not only able to increase or maintain its reliability, but would also save public expenditure cost and reduce CO2 emissions. A study by (Thomsen et al., 2019) also shows that a PV array and battery storage system could maximize reliability, and also could be a cost-effective replacement for diesel generators at remote locations, with the fuel savings quickly outweigh the initial cost.

Regarding to the strategy implementation, several research have discussed the implementation of PV system in a geothermal power plant area through the studies about the combination of geothermal power plant and PV system. (Zhou et al., 2011) explored the potential benefits from utilizing solar energy resources for a solar heating system in a Organic Rankine Cycle (ORC) or binary geothermal power plant, which resulted in increasing thermal efficiency and net power output. (Hameed et al., 2019) also studied the utilization of PV system to supply power for injection pumps and feed pumps, and to provide additional heat for the working fluid in a binary geothermal power plant. That study resulted in power plant efficiency improvement by 35%. Furthermore, a study by (Vidyanandan, 2017) shows that the efficiency and power output of a PV cell will be higher in lower module temperature. If module temperature falls below 25oC, the efficiency will increase about 0.5% per degree Celsius increase of temperature. It can be comfortably said that the proposed PV-Battery system is suitable enough to be implemented in Darajat geothermal area, which is located in highlands with relatively low air temperature around 16.44oC. Based on global horizontal irradiation (GHI) and air temperature data in proposed location, also based on the normal operating cell temperature (NOCT) of the chosen PV module, the estimated module temperature is around 21°C (Duffie and Beckman, 2013).

3. METHODOLOGY

Electrical loads in Darajat Pad S1 and S4 are supplied by S4-SS Substation which is located in Pad S1. The S4-SS substation consists of a 125 kVA two-winding transformer (S4-T1), which currently is utilized to step-down 6.3 kV from the common service bus into 400V. The single line diagram and load demand of S4-SS substation are shown below in Figure 1 and Table 1, respectively.

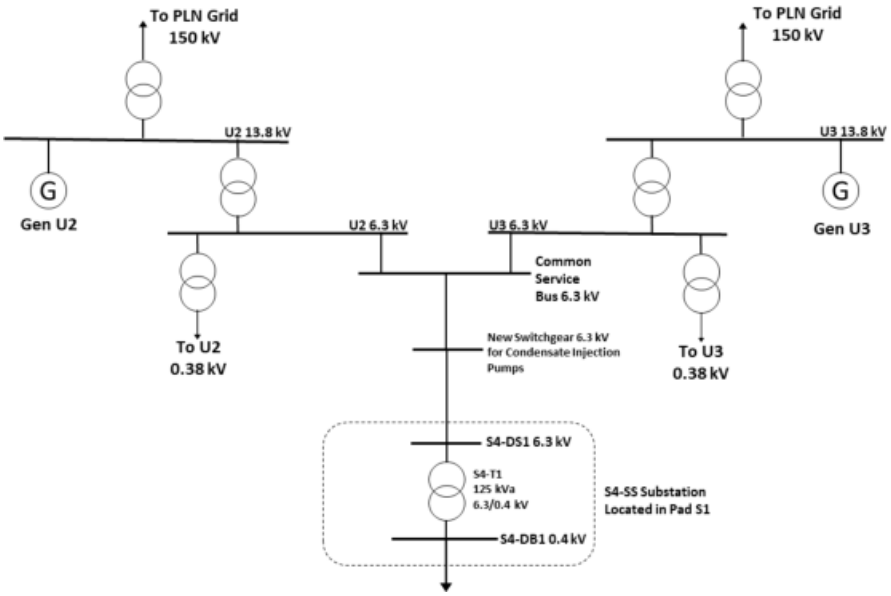

Figure 1: Single Line Diagram of Pad S1 and S4 Power Supply.

Table 1: Load Demand in S4-SS Substation.

Load Demand	Power Consumed (kW)
Auxiliary Control Supply (ADP, Phase Fault Relay, Surge Protection, and External Lights Control)	0.8
Control Panel (PLC)	0.5
Space Heater	0.2
Lighting	1.5
Total	**3**

The most concerning load in in S4-SS substation is the auxiliary control supply which supply power the valve actuator of ADP K001. Therefore, when a loss of power supply occurred like what happened in October 2022, the ADP will not be able to work automatically. Hence, there will be less liquid separation/disposal in pipelines, which leads to higher liquid carry over to downstream equipment of DRJ U3 steam production system. In order to prevent such thing for the upcoming DRJ U2 SDTA, Darajat Team has prepared a 10 kVA diesel generator set to be located in the S4-SS substation to substitute the role of S4-T1 transformer in supplying power to the S4-DB1, in case a failure regarding to the newly-tried manual power maneuver occurs. As mentioned in the earlier section, the utilization of this diesel generator set comes along with several drawbacks.

In this section, the idea of using PV-Battery system to replace portable diesel generator set as a stand-by power supply alternative for Pad S1 and S4 will be reviewed through a compact comparative study. The comparative study will be conducted by considering two different point of views, quality and economy. From a quality point of view, the comparative study will be conducted by considering several aspects such as system design, installation time, operability, maintainability, reliability, and its environmental impact during operation. The results will be portrayed through a strategy table in order to examine the advantages and disadvantages between those two alternatives. Meanwhile, several economical aspects such as Levelized Cost of Energy (LCOE), Net Present Value (NPV), and payback period of those two alternatives are considered to compare them from economical point of view.

3.1 Strategy table

Strategy table is a decision-making tool that provides a visual framework to help choose between two or more alternatives by considering multiple factors. The strategy table used in this study can be seen in Table 2 below. The results of each assessment will be stated in “High,” “Medium,” and “Low,” where “High” represents the best

result and “Low” represents the worst. The assessment results will be categorized as "High," "Medium," and "Low," with "High" indicating the best outcome and "Low" the worst. A plus symbol (+) indicates the proposed solution outperforms the existing solution in a specific aspect. Conversely, a delta symbol (Δ) will indicate areas where the existing solution is superior. If the proposed solution possess more plus symbols than delta, it will be identified as more preferrable stand-by power supply alternatives for Pad S1 and S4.

Table 2: Strategy Table.

	Alternative 1 (Existing)	Alternative 2 (Proposed)	Remarks (+/Δ)
Aspect 1	Low	High	+
Aspect 2	High	Medium	Δ
Aspect 3, etc...	Low	Medium	+

3.2 Levelized Cost of Energy (LCOE)

Levelized cost of energy (LCOE) is defined as the discounted lifetime cost of ownership and use of a generation asset which is converted into an equivalent unit of cost of generation in price per energy unit. LCOE can also be expressed as the ratio of the total costs of a power plant to the total amount of electricity expected to be generated over the plant’s lifetime, which both are expressed in net present value terms (UK Department for Business Energy and Industrial Strategy, 2020). According to the Department of Business, Energy, and Industrial Energy of United Kingdom, LCOE calculation is shown below (Eq. 1).

$$LCOE = \frac{Capital\ Investment\ Cost\ +\ \sum_{t=1}^{n} \frac{O\&M\ Cost\ +\ Fuel\ Cost}{(1+d)^t}}{\sum_{t=1}^{n} \frac{Et}{(1+d)^t}} \quad (1)$$

where E_t is the annual energy generation of the power plant expressed in kWh.

Value of LCOE is widely used as a comparative measurement between alternative sources of energy since it can be determined as the minimum price or break-even price at which energy must be sold to adequately compensate a project’s suppliers, employees and investors for their contributions within a period of time (Massachusetts Institute of Technology, 2007); UK Department for Business Energy and Industrial Strategy, 2020). With this comparison method, an alternative with smaller LCOE will be identified as more preferrable stand-by power supply alternatives.

3.3 Cash Flow Analysis

Cash flow analysis is an economical analysis process of examining and evaluating a company’s inflows and outflows of cash over a specific period of time. Cash flow analysis consists of several parameters calculation such as Net Present Value (NPV), Internal Rate of Return (IRR), and Payback Period. The cash flow is calculated by subtracting cash inflows or benefits, with cash outflows or cost. In this study, investment cost and annual O&M cost of the proposed PV-Battery system is considered as annual cash out flows. Meanwhile, capital investment cost, additional revenue, O&M cost reduction, and fuel cost reduction between the proposed PV-battery system and existing diesel generator set is considered as annual cash inflows.

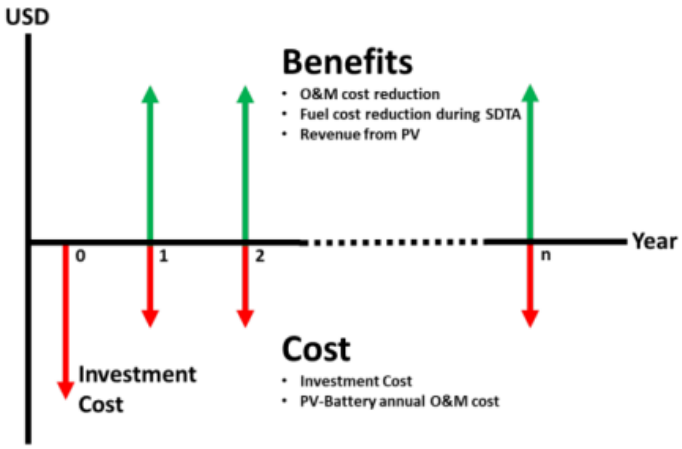

Figure 2. Cash Flow Model.

NPV is commonly used to estimate if a project is economically feasible to be executed or not, by predicting if its financial return will be more than the current investment or not. The project financial return is calculated by summing each year's discounted cash flow with the investment expenditure (Shou, 2022). The expression of NPV calculation is shown in Eq. 2 below:

$$NPV = -CF_0 + \frac{CF_1}{(1+d)^1} + \frac{CF_2}{(1+d)^2} + \cdots + \frac{CF_n}{(1+d)^n} \quad (2)$$

where $CF_{(t)}$ is the net cash flow in period t, d is discount rate, and n is the project lifetime. If the proposed alternative's NPV is positive, it can be identified that the project is economically feasible to be executed.

It represents the discount rate at which the NPV of an investment or project equals zero. In other words, IRR can be identified as the rate of return at which the present value of future cash flows equals to the initial investment. Meanwhile, the payback period is the length of time or years it takes to recover the investment cost from the discounted cash flows. The proposed alternative's IRR is considered to be acceptable when it exceeds the required discount rate set by the company of investor, while the payback period is considered to be acceptable if it takes less than the project lifetime.

LCOE, NPV, IRR, and Payback Period are calculated based on several parameters such as the investment cost, annual O&M cost, fuel cost, annual revenue, annual energy generation, and project lifetime, and discount rate which values can be seen in Table 3.

Table 3: Economic Analysis Parameters.

	Diesel Generator set	PV-Battery
Investment Cost (USD)	7437	8500
Annual O&M Cost (USD)	1124	238
Fuel Cost (USD)*	8367	-
Annual Energy Generation (kWh)**	28280	8800
Annual Revenue (USD)	-	645
Project Lifetime (years)	15	15
Discount Rate (%)	10%	x

*Fuel cost of diesel generator set if operated only during DRJ U2 SDTA (30 days) to supply Pad S1 & S4
**Annual energy generation of diesel generator set if operated to supply Pad S1 & S4 for a whole year

The investment cost and annual O&M cost are gathered from disclosed asset's and manufacturer's information. The calculation of diesel generator set fuel cost can be seen below in Eq. 3 and Eq. 4, respectively, with the fuel price is assumed to be the same as Pertamina Dex prices for West Java Area which is 0.93 USD/liter.

$$Fuel\ Cost = Load\ (\%) \times Fuel\ Consumption\ at\ 100\%\ Load\ (ltr/h\ ) \times Operating\ Time\ (h) \times Fuel\ Price\ (USD/ltr) \quad (3)$$

$$Fuel\ Cost = (3kW/8kW) \times 2.74\ (ltr/h) \times 720\ h \times 0.93\ (USD/ltr) = 688\ USD \quad (4)$$

Calculation of diesel generator set annual energy generation can be seen below in Eq. 5 and Eq. 6, respectively.

$$Annual\ Energy\ Generation_{DG} = Load\ (kW) \times Operating\ Time\ (h) \quad (5)$$

$$Annual\ Energy\ Generation_{DG} = 3\ kW \times 8760\ h = 28280\ kWh \quad (6)$$

The calculation of annual revenue and annual energy generation of proposed PV-battery system can be seen later in 4.1.2 PV-Battery. The project lifetime is assumed to be 15 years according to the shortest equipment lifetime in the proposed PV-battery system, which is the battery module. Lastly, the discount rate is assumed as 10% according to company's best practice.

4. ANALYSIS

4.1 System Design

The existing stand-by power supply for Pad S1 and S4 consists of a portable 10 kVA diesel generator set, while the proposed PV-battery system will consist of a 5.95 kWp PV system and an energy storage system with 5 kW maximum capacity.

4.1.1 Diesel Generator Set

The existing diesel generator set has a total 8 kW capacity consists of one unit of HARTECH 10KVA Silent Type (HT10Y). The generator set display and its technical specification are shown below in Figure 3 and Table 4, respectively.

Figure 3: HARTECH 10 kVA Silent Type (HT10Y).

Table 4: Technical Specification of Diesel Generator Set.

Parameter	Specification
Power Output	10 kVA / 8 kW
Voltage Output	220 VAC (1Ph), 380 VAC (3Ph)
Current	15.19 A
PF	0.8
Frequency	50 Hz
Fuel Capacity	45 Ltr
Fuel Consumption	2.74 Ltr/hr (100% Load) 2.05 Ltr/hr (75% Load)

The diesel generator set is located in Pad S1, beside the prefabricated S4-SS substation, where the diesel generator set will substitute the role of S4-T1 transformer in supplying power for all loads in S4-DB1, which includes the ADP. The system design is quite simple since it is only consisting of one equipment. System design and interconnection of diesel generator as stand-by power supply for Pad S1 and S4 is shown in Figure 4 below:

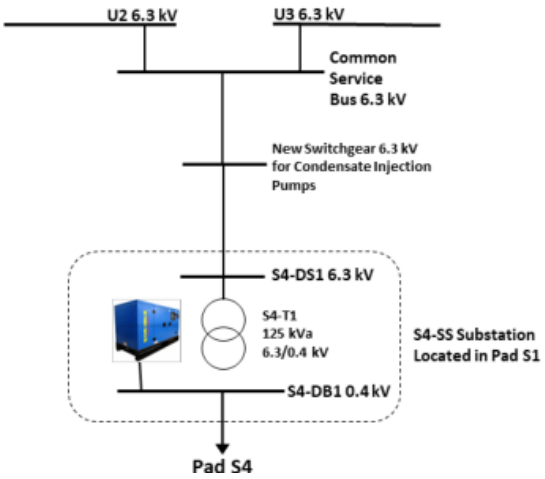

Figure 4: Diesel Generator Set System Design and Interconnection.

4.1.2 PV-Battery

The proposed PV-Battery system will consist of PV modules, three-phase hybrid PV inverter, energy storage system, and smart power/energy meter. The PV system will be roof-mounted with 5.9 kWp capacity consisting of 14 units of TrinaSolar Vertex S TSM-DE09R module with nominal power of 425 W. This module is chosen because it meets the specification needed and qualify the local content requirement. PV modules configuration will be divided into 2 strings, consist of 7 modules each, which will be installed in two orientations with azimuth angle of 135o and 315o, and tilt angle of 15o. Another source of energy, the energy storage system, will have a total capacity of 5 kW which consists of a unit of Huawei LUNA2000-5KW-C0 power module and a unit of

Huawei LUNA2000-5-E0 5 kWh battery module. The energy storage system technical specification is shown in Table. The product display and technical specification of designated PV module and energy storage system are shown in Figure 5, Table 5, and Table 6, respectively.

(a) (b)

Figure 5: (a) PV Module (TrinaSolar Vertex S TSM-DE09R), (b) Energy Storage System (Huawei LUNA2000-5KW-CO Power Module and LUNA2000-5-EO Battery Module).

Table 5: Technical Specification of PV Module.

Parameter	Specification
Solar Cells	Monocrystalline
Module Dimensions / Weight	1762 x 1134 x 30 mm / 21.8 kg
Peak Power (PMAX)	425 Wp
Maximum Power Voltage (VMPP)	42.2 V
Maximum Power Current (IMPP)	10.08 A
Open Circuit Voltage (VOC)	50.2 V
Short Circuit Current (ISC)	10.61 A
Module Efficiency	21.3 %
Operating Temperature	-40~+85°C

Table 6: Technical Specification of Energy Storage System.

Parameter	Specification
Battery Module Energy	5 kWh
Peak Output Power	3.5 kW in 10s
Operating Voltage Range	600 – 900 V

Both PV system and energy storage system will be connected to Huawei SUN2000-5KTL-M1 three-phase hybrid inverter with rated output power of 5 kW. The proposed system is also equipped with a unit of Huawei DTSU666-H smart energy meter. The product display and technical specification of the hybrid inverter and smart energy meter are shown in Figure 6, Table 7, and Table 8, respectively.

This proposed system design does not require to open any space since it is roof-mounted. However, it still requires some civil works for PV module roof mounting, earthing system, and for equipment installation. The proposed PV-Battery system location and design are shown in Figure 7.

(a) (b)

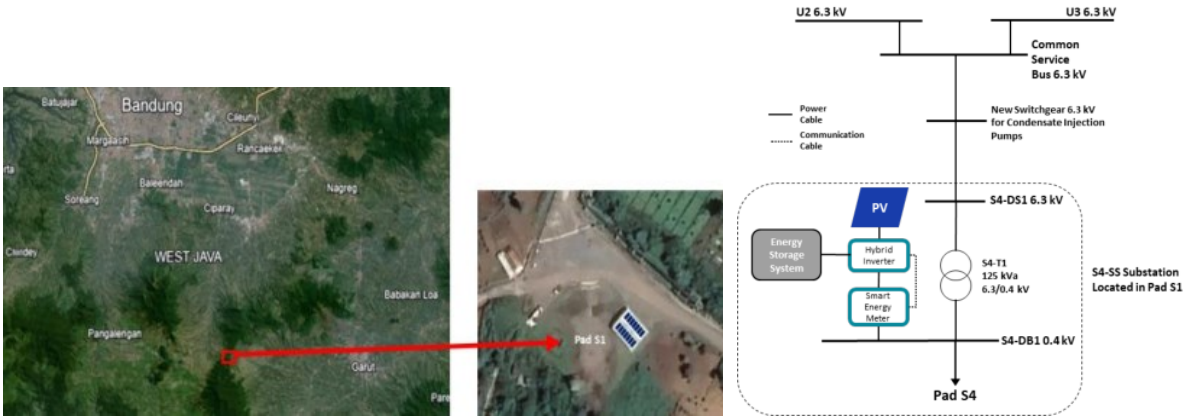
Figure 6: (a) Hybrid Inverter (Huawei SUN2000-5KTL-M1), (b) Smart Energy Meter (Huawei DTSU666-H).

Table 7: Technical Specification of Hybrid Inverter.

Parameter		Specification
Input (PV)	Max. PV Power Input	7500 Wp
	Operating Voltage Range	140 V ~ 980 V
	Max Input Current per MPPT	11 A
	Max Short Circuit Current	15 A
	No. of MPPT	2
Input (Battery)	Compatible Battery	5kWh – 30 kWh
	Operating Voltage Range	600 V ~ 980 V
	Max Operating Current	16.7 A
Output	Rated Output Power	5000 W
	Rated Output Voltage	380 VAC (3-phase)
	Rated Frequency	50 Hz / 60 Hz
	Max Output Current	8.5 A
	Power Factor	0.8 Lag to 0.8 Lead (Adjustable)

Table 8: Technical Specification of Smart Energy Meter.

Parameter	Specification
Line Voltage Measurement Range	304 Vac ~ 399 Vac
Phase Voltage Measurement Rang	176 Vac ~ 288 Vac
Current Measurement Range	0 ~ 100 A
Voltage and Current Measurement Accuracy	± 0.5%
Power and Energy Measurement Accuracy	± 1%
Frequency Measurement Accuracy	± 0.01 Hz



(a) (b)

Figure 7: (a) Proposed PV-Battery System Location; (b) Proposed PV-Battery System Design and Interconnection.

Furthermore, the proposed PV-battery system can generate annual revenue unlike the diesel generator, since the proposed system is connected to the power plant house load system, so it is able to supply excess electricity to compensate house loads. The simulation was performed using PVsyst software to determine the 5.95 kWp PV-without-battery system electricity production for a year. The simulation was performed in Darajat Pad S1 location, with Global Horizontal Irradiation (GHI) of 1546 kWh/m2/year. The roof-mounted PV modules plane orientation was adjusted in accordance with the S4-SS substation roof construction. PV module degradation, module losses, inverter losses, and wiring losses are also included in the calculation. According to the simulation result portrayed in the loss diagram, the PV itself can be expected to produce electricity up to 7.3 MWh per year.

If the battery is assumed to operate and discharge 85% of its power capacity each day, it can be obtained that the energy storage system itself can produce electricity up to 1.5 MWh per year. In total, the proposed PV-Battery system can be expected to produce electricity and increase Darajat net generation up to 8.8 MWh per year, with assumed 0.6% degradation per year based on the manufacturer's claim. Based on Peraturan Presiden Republik Indonesia No. 112 Tahun 2022, electricity price of a 95 MW geothermal power plant which has neem operated for more than 10 years such as DRJ U2 is assumed as 0.0735 kWh/year. Hence, the expected amount of produced electricity can increase the revenue up to 645 USD each year.

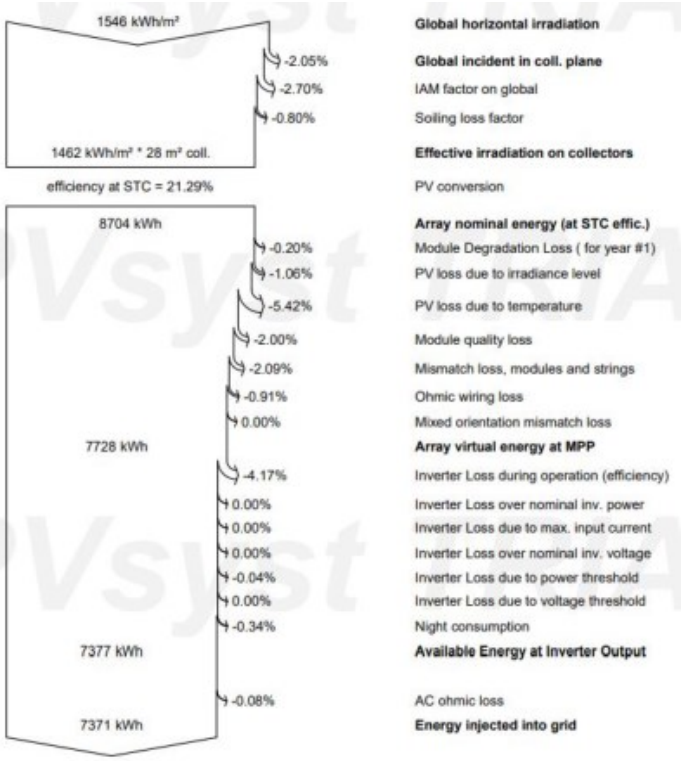


Figure 8: Loss Diagram of PV System.

4.2 Installation Time

The estimated installation time of the proposed PV-Battery system is 500 minutes longer than the installation time of the diesel generator set. The installation time estimation of the proposed PV-Battery system is conducted by assuming that all equipment and materials had arrived at the warehouse in the basecamp area, which is located 3.7 km away from the designated installation location (Pad S1). Detail of installation time estimation between two alternatives can be seen in Table 9.

4.3 Operability

4.3.1 Diesel Generator Set

the diesel generator set is not equipped with auto-start ability because it is designed to be portable and can be moved to different locations as needed. Hence it must be installed and started manually. Furthermore, if the diesel generator set is running out of fuel, it must be stopped first manually through the local switch and push button. The diesel generator set must be cooled down for about 5 minutes before it is fueled up. After the generator set is fueled up, it has to be started again and warmed up for about 5 minutes before it is loaded and operated again. The diesel generator set can only be used to supply power for loads under the S4-SS substation in loss of power plant supply worse condition such as power maneuver failure during SDTA or line fault. Since the power demand will be continuous, so the diesel generator set has to be operated continuously, which requires a quite large amount of fuels.

Table 9: Installation Time Estimation.

Diesel Generator Set		PV-Battery System	
Actions	**Estimated Time (Minutes)**	**Actions**	**Estimated Time (Minutes)**
3 km delivery from MTCE Tool Room to Pad S1 (including lifting and rigging)	40	3.7 km delivery from warehouse to Pad S1(including loading and unloading)	50
Connecting power cables	15	Mounting system installation	90
Fueling up	5	Equipment installation	180
Warming up	5	Cable connection	120
		System inspection, testing, and commissioning	120
Total	**70**	**Total**	**560**

4.3.2 PV-Battery System

The proposed PV-Battery system will utilize a hybrid inverter which makes the system can operate with (on-grid) or without (off-grid) power plant house load system connection. The proposed system also has several features which makes the system can operate under several conditions such as normal condition, loss of power plant supply during sunlight, and loss of power plant supply during no sunlight. During normal condition, the proposed system can operate to supply power to Pad S4 under S4-SS substation.

During normal condition where the connection or power supply from power plant is available, the excess power generated from PV is utilized to charge the battery module in energy storage system, and to supply the new condensate reinjection pump on the new switchgear 6.3 kV. The energy storage system (battery) can be operated in two operating modes, time-based and kWh-based. In time-based operation mode, the energy storage system will only supply power during specified time of the day. Meanwhile in kWh-based operation mode, the energy storage system will adjust its power supply according to the energy reading from the smart energy meter. When the PV is unable to generate required power due to the absence of sunlight, the energy storage system will cover the battery will cover the lack of power required by Pad S4. After the battery has been fully discharged or has been discharged below its designated State-of-Charge (SOC) percentage, the power plant house load system will take over the energy storage system to supply power to Pad S4. The operation schematic of the proposed PV-battery system during normal condition can be seen in Figure 9.

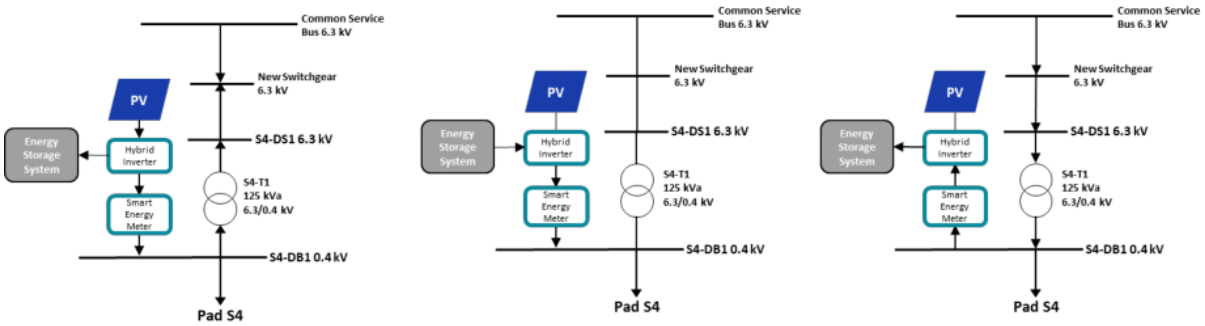

Figure 9: PV-Battey System Operation During Normal Condition.

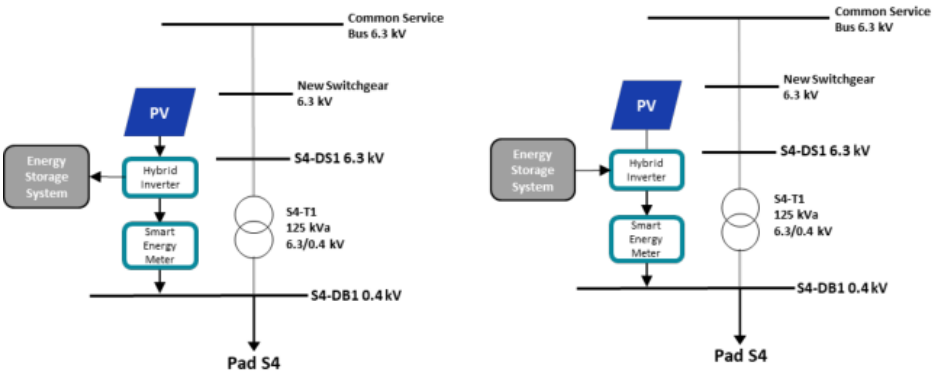

Figure 10: PV-Battery System During loss of Power Plant Supply Condition.

During loss of power plant supply condition such as manual power maneuver activity, power maneuver failure, or even worse line fault, PV will generate and supply power to Pad S4 where the excess power is utilized to charge the battery module in energy storage system. When there is not enough sunlight to generate enough power required by Pad S4, the electrical loads in Pad S4 will fully rely on the energy storage system until it runs out. The operation schematic of the proposed PV-battery system during loss of power plant supply condition can be seen in Figure 10.

In worse condition such as power maneuver failure during SDTA or line fault, where electrical loads in Pad S4 demand continuous power supply for much longer period, the energy storage system will supply power to loads under the S4-SS substation load. In this situation, the power will also be used to charge the battery in ADP's UPS DC system, which consists of 2x12V 38 Ah Valve Regulated Lead Acid (VRLA) battery, in order to substitute the role of PV-battery system as ADP power supply when there is absence of sunlight and the battery in energy storage system runs out.

4.4 Maintainability

In Darajat, several maintenance activities are performed on the diesel generator set every month. The PM activities includes equipment cleaning and checking on several parameters and equipment such as oil engine level, radiator water coolant level, air filter condition, v-belt condition, battery electrolyte, hose and tubing clamp condition, bolts mounting engine, oil engine pressure, engine temperature, engine rpm, pump pressure, abnormal noise, and leaks of oil or clamp hose or tubing. The engine oil, fuel filter, and oil filter also have to be changed or replaced every year.

Meanwhile, according to the manufacturer manual, the proposed PV-Battery system requires less maintenance activities compared to a diesel generator set. the maintenance activities requirement only includes monthly visual equipment and parameter inspection, monthly PV module cleaning, and annual electrical testing such as grounding resistance, PV open circuit voltage, DC cable insulation resistance, AC cable insulation resistance.

4.5 Reliability

Both diesel generator set and PV-Battery system possess high reliability value of 99%. However, the reliability of a diesel generator set is expected to be decreasing over outage and storing period.

4.5.1 Diesel Generator Set

Since the reliability of portable diesel generator set has not been assessed due its limited operating hours, reliability assessment of the diesel generator set in this paper utilized a study by (Marqusee, Ericson and Jenket, 2021) that assessed the impact and reliability of a emergency diesel generator on supplying critical loads. From the study, it can be summarized that a well-maintained EDG has a reliability between 92% and 96% for providing backup power for four days of outage, between 90% and 95% for one-week outage, and between 75% and 87% for a two weeks outage. In addition, long-term storage of diesel has a risk of microbial growth due to its limited shelf life, so diesel generators may experience a system failure if the fuel is not replaced every 6–12 months to maintain quality (Hwang, Tongsopit and Kittner, 2023).

4.5.2 PV-Battery System

High reliable operation is demanded in this proposed PV-Battery system. Inverter is identified as one of the most critical components in the system, whose failures can lead to a total loss of electricity production of the system. The manufacturer, Huawei, claims that the SUN2000-5KTL-M1 has high reliability number up to 99.9%. Furthermore, a study by (Sangwongwanich et al., 2018) reveals that the reliability of an inverter can be improved by battery utilization.

4.6 Environmental Impact During Operation

Increasing trend of renewable energy has never been separated from the environmental issues posed by conventional energy sources such as fossil fuels. Global warming has been the biggest environmental issue which caused by greenhouse gas emissions released from fossil-fueled engines, such as diesel generators, to the atmosphere. It is widely known that diesel generator emits greenhouse gases, such as carbon dioxide (CO2), due to the utilization of fossil fuels as its source of energy. The consumption of 1 liter diesel fuels (solar) emits around 2.4—2.8 kgCO2 (Jakhrani et al., 2012), which means that the existing diesel generator will emit around 59 kgCO2 per day if it is being utilized as a backup power supply for Pad S1 and S4, which is equal to 0.8 kgCO2 per kWh. Besides CO2, diesel generator also emits air pollutants such as sulfur dioxide (SO2), Carbon Monoxide (CO), and particulate matter (PM) (Hwang, Tongsopit and Kittner, 2023; Ahmed et al., 2020) which have negative impacts on human health. Meanwhile, The carbon footprint and pollutants of PV-battery solar systems that is emitted during operation is negligible (Bošnjaković et al., 2023). Meanwhile, about 98% of greenhouse gases and pollutant from non-renewable energy generator are emitted during the operation phase (Bošnjaković et al., 2023).

4.7 Levelized Cost of Energy (LCOE)

With 15 years of project lifetime, the expected LCOE of diesel generator set and PV-battery system is 0.439 USD/kWh and 0.296 USD/kWh, respectively. The detail calculation of diesel generator set and proposed PV-battery system LCOE can be seen in Eq. 7 and Eq. 8, respectively.

$$LCOE = \frac{7437 + \sum_{t=1}^{15} \frac{1124+8367}{(1+0.1)^{15}}}{\sum_{t=1}^{15} \frac{26280}{(1+0.1)^{15}}} = 0.439\ USD/kWh \quad (7)$$

$$LCOE = \frac{8500 + \sum_{t=1}^{15} \frac{238}{(1+0.1)^{15}}}{\sum_{t=1}^{15} \frac{8800}{(1+0.1)^{15}}} = 0.296\ USD/kWh \quad (8)$$

4.8 Cash Flow Analysis

Cash flow analysis was conducted by assuming the inflation rate for revenue, O&M cost, and fuel cost is 3%, geothermal income tax is assumed as 34% (based on Peraturan Menteri Keuangan Republik Indonesia No. 179/PMK.011 Tahun 2013), and DRJ U2 SDTA is assumed to be held once every 3 years with 30 period of days. The cash flow analysis is also conducted with assumption that the funds used for this project's investment come without any loans from external sources. Hence, the interest rate on loans is assumed as zero. The cash flow analysis calculation result shows that the proposed PV-battery system project possesses a positive NPV value of 652.49 USD, IRR value of 11.2%, and payback period of 14 years which is less than the project's expected lifetime.

5. RESULTS AND DISCUSSIONS

5.1 Strategy Table Result

The filled-up strategy table, which can be seen in Table 10, shows that even though the PV-battery system requires longer installation time than the existing portable diesel generator set, it proposes a better operability, more maintainable, more reliable, and greener stand-by power supply alternatives for Pad S1 and S4, which can also compensate power plant house loads to increase asset's revenue.

Table 10: Strategy Table Result.

	Portable Diesel Generator Set	PV-Battery	Remarks (+/Δ)
System Design	Medium	High	+
Installation Time	High	Medium	Δ
Operability	Low	High	+
Maintainability	Medium	High	+
Reliability	Medium	High	+
Environmental Impact During Operation	Low	High	+

5.2 LCOE and Cash Flow Analysis Result

From the LCOE calculation results, it can be identified that the proposed PV-Battery system still possesses smaller LCOE than diesel generator set, despite its higher investment cost and lower energy production. Meanwhile, cash flow analysis results show that the utilization of PV-battery system as a stand-by power supply for Pad S1 and S4 will not provide much benefits if compared to a diesel generator set from an economical point of view. This lack of benefits occur due to Indonesia's high geothermal income tax, which leads to decrease in project's annual net income. Changes in regulations related to renewable energy, especially geothermal energy, may increase interests from companies or investors to enhance the integration of renewable energy sources to replace fossil fuel-based energy sources. However, economical benefits from this project, may vary in different geothermal power plant locations, since higher electricity price will result in better NPV, IRR, and Payback Period.

6. CONCLUSION

In providing a stand-by power supply for Pad S1 and S4 to prevent unplanned trip during DRJ U2 and DRJ U3 power maneuver, PV-battery system is considered to be a doable stand-by power supply alternative other than diesel generator set. Despite its longer installation time and insignificant economic benefits if compared to the diesel generator set, proposed PV-battery system can offer a stand-by power supply alternative with better operability, maintainability, reliability, and less environmental impact during its operation which can lead to a better company image. However, the economical benefits from PV-battery system can be improved by change in regulation, such as tax reduction or renewable energy integration obligatory, or by executing the project in a geothermal power plant with higher electricity price.

ABSTRACT

Star Energy Geothermal Darajat Power Plant Unit 2 is a geothermal power plant located in Garut Area, 40 km south of Bandung, West Java Indonesia which operated by Star Energy Geothermal Darajat II, Limited. This geothermal power plant consists of turbine and generator as main equipment to produce the electricity. Generator equipment has nominal capacity 100.76 MVA and has been operated for more than 20 years. A comprehensive Lifetime Assessment (LTA) was conducted in 2022 to evaluate the generator current condition, estimate its remaining operational lifetime, and inform maintenance strategies. The LTA adhered to the K5.007.2020 SPLN "Pedoman Asessmen Generator" standard. Electrical tests of the rotor and stator were a primary focus in assessing the generator's health. Condition Indicators (CI) and Data Indicators (DI) were also evaluated to estimate the remaining useful life of the generator. The assessment determined lifetime of 24 years for the generator. Importantly, the LTA identified the potential to extend this lifetime through targeted repairs to the circuit ring brazing and cooling system. The results of this LTA will be instrumental in guiding Star Energy Geothermal Darajat II, Limited, in planning maintenance and repair activities. This proactive approach will help ensure the generator continued reliable operation and maximize its contribution to the power plant's output.

1. INTRODUCTION

Unit 2 Darajat Generator has been operated more than 20 years with capacity 100.76MVA. The subsequent data outlines its technical specifications.

Table 1: Darajat Unit 2 Generator Specification.

Generator Synchronous	
Type	FTLRI 524/60-2
Output	100706 kVA
Frequency	50Hz
Voltage	13800V
Current	4213A
Speed	3000rpm
Ex. Voltage	415V
Phase	3
Ex. Current	784A
Standard	IEC34-3(1988)

Darajat Unit 2 Generator functionality relies on the seamless interaction of its rotor, stator, and various accessories. Over time, all these components are susceptible to performance degradation. Since these components are critical and their failure can lead to reduced output, unplanned outage and loss production opportunity consequences. A proactive Lifetime Assessment (LTA) strategy is necessary to avoid such risks. The LTA is also helps determine the most appropriate maintenance steps for continued generator health. The LTA is expected to be determined a lifetime and a guideline for determine appropriateness operation on intervals inspection, repair decision nor replacement. Moreover, LTA is employed to increase the service life of equipment nearing the end of its design specified as mandated by ESDM Regulation No. 33 of 2021, Appendix V (J)(6).

2. METHODOLOGY

The condition assessment of Darajat Unit 2 Generator follows the guidelines established in the SPLN standard K5.007.2020, titled "Generator Assessment Guidelines." This standardized approach ensures a consistent and comprehensive evaluation of the generator health. The standard utilizes a comprehensive assessment Table 2 that evaluates various generator components based on specific criteria.

Figure 1: Darajat Unit 2 Generator.

Table 2: Overall Assessment Criteria for Generator Components.

Generator Components	Visual Inspection [a]	Age [b]	Technology Level [c]	Operation Limit [d]	Stator Electrical Test [e]	Rotor Electrical Test [f]	Stator Core Test [g]	Maintenance [h]	Data Quality [i]	Weighting Factor

Weighting for Condition Parameters	1.0	2.0	1.0	1.0	3.0	2.5	1.0	1.5	Data Quality (DI)	
Condition Indicator (CI)										

[a] Visual inspection value (see Table 2.), [b] Age value (see Table 3.)
[c] Technology level value (see Table 4.), [d] Operation limit value (see Table 5.)
[e] Stator electrical test value (see Table 6.), [f] Rotor electrical test value (see Table 7.)
[g] Stator core test value (see Table 8.), [h] Maintenance value (see Table 9.)
[i] Data quality value (see Table 10.)

Generator health is assessed by evaluating each component. This includes the stator, stator core, rotor, cooling system, neutral grounding system, bearings, stator casing, generator shaft, brush rigging and oil system. The assessment considers several factors: visual inspection, age, technology level, operating limit, maintenance history. Electrical testing is only performed on the stator and rotor to get more detailed health data. All this information is then used in a formula to calculate a Condition Indicator (CI) for the entire generator. This CI value provides a single score that reflects the overall health and lifetime of the generator.

$$CI = \frac{\sum_{K=1,M}^{J=1,N} SC(K,J)xF(K)xF(J)}{\sum_{K=1,M}^{J=1,N} F(K)x(F(J)} \quad (1)$$

The system assigns a quality score to each component. This score is then combined with a weighting factor specific to that component. The resulting value, called the Data Indicator (DI), is calculated by multiplying the quality score by the weighting factor.

$$DI = \frac{\sum_{K=1,M} SD(K)xF(K)}{\sum_{K=1,M} F(K)} \quad (2)$$

where M, K, J, SC(K, J), F(J), SD(K), F(K) are total part which related on generators, identification part no. generator (from 1 until M), no. identify condition parameters (from 1 to 8, depending on condition physical, age, and etc), weighted values for parameter conditions, value weighting parameters condition, data quality score for each part given by the assessor based on the rating quality data each component, weighting factor for part / item defined by level interest to overall component condition, respectively.

The lifetime of the generator is calculated by comparing its current health indicator (CI) with its condition maximum condition value of assessment of all 10 (5.28). The difference between these values is then multiplied by the generator's design specifications (30 years) to determine how much longer it can operate effectively.

$$\text{Lifetime} = \left[\frac{CI}{5.28} \text{ x } 100\%\right] \text{x Design Life Specification} \quad (3)$$

These tables offer a breakdown of various factors affecting generator condition. The information within them is then consolidated into Table 1.

The visual condition of a generator, assessed through a thorough inspection, offers valuable insights into its overall health and reliability. Stator winding insulation, a critical factor in generator performance, can be indirectly evaluated through visual inspection. Signs like loose components, corona discharge (often appearing as a faint glow), and adherence of dust, dirt, or grease can indicate potential overheating and warrant further investigation. These visual observations, when combined with other diagnostic techniques, can help establish the generator's health and predict potential problems before they escalate.

Table 3: Visual inspection value.

Visual Rating of Generator Condition (rotor pull out condition)		**Effect**	**Score**
Very clean	All conditions look clean, both stator and rotor	No real defects	9 – 10
Clean	An inspection revealed clean stator end windings, wedges, and core despite the presence of oil seepage within the generator stator	Some defects are obvious and do not affect function	7 – 8
Fairly Clean	The condition of one of the stator end windings looks dirty, there is oil seepage on the inside of the stator, several areas show corona, there is looseness in the wedges and spacers and medium dust air filters	Moderate damage with adequate function and several operational indicators can show more than limited values, an influence on reduced operation, checking seals related to cooling air, and replacing filters	4 – 6
Dirty	The condition of the end winding, wedges, brush holder, diode rectifier looks dirty and there is seepage of lubricating oil on the inside of the stator and the air filter has thick dust	Serious damage, at least in the seal section, has a large clearance, extensive corona, looseness in the wedges and spacers, several operating indicators show values that are more than the limit, thus affecting the decrease. operation, generator conditioning for testing	1-3
Very Dirty	The end winding, wedges, brush holder, diode rectifier, and generator body are covered in thick dust as well as the condition of the lubricating oil leaking on the inside of the stator, filter. thick dusty air	Serious damage, there is dirt that resembles grease on the winding insulation, extensive corona, the generator cannot be tested, the generator does not function long	0

Table 4: Age value.

Generator Life Rating				Score
Age of generator stator/insulation	**Generator stator core age**	**Age of generator rotor/insulation**	**Age of generator components (bearings, coolant)**	
< 5 years	< 5 years	< 5 years	< 5 years	10
5 – 10 years	5 – 15 years	5 – 10 years	5 – 8 years	9
10 – 15 years	15 – 30 years	10 – 15 years	8 – 12 years	7-8
15 – 20 years	> 30 years	15 – 20 years	12 – 15 years	5-6
20 – 25 years		20 – 25 years	15 – 20 years	3-4
25 – 30 years		25 – 30 years	20 – 25 years	2
> 30 years		> 30 years	> 25 years	1

Table 5: Technology level value.

Level of insulation technology used	Score
Class H	10
Class F	7 - 9
Class B	4 - 6
Class A	1 - 3

Table 6: Operation limit value.

Operation limit	Score
The design standards have not changed, and the original plant design has no operational constraints	8 - 10
Minimum restrictions: temperature, vibration, and coolant leaks	5 – 7
Moderate limitations: shorts between windings, changes in structural defects and rotor ground faults	3 – 4
Severe limitations: the generator can no longer operate, has significant degradation, limiting performance and reliability if operated	0 – 2

Table 7: Stator electrical test value.

Stator electrical test	Score
All measurement results are within the applicable limits (commissioning, manual book, standard reference) and are low partial with an increase in measurement results of <2% to the design value	9 - 10
All measurement results are within the applicable limits (commissioning, manual book, standard reference) and are low partial with an increase in measurement results of <5% to the design value	7 - 8
Some measurement results exceed the applicable limits, such as: IR, PI and PD	5 - 6
The limits for the IR, PI, PD and Tan Delta measurement results exceed the applicable limits	1 - 4
All measurement result value limits have passed	0

Table 8: Rotor electrical test value.

Rotor electrical test	Score
All measurement results are within the applicable limits (commissioning, manual book, standard reference) with an increase in measurement results of <2% to the design value	8 - 10
All measurement results are within the applicable limits (commissioning, manual book, standard reference) and with an increase in measurement results of <5% to the design value	5 – 7
The measurement result value exceeds the applicable limits	1 – 4
Rotor short between turns	0

Table 9: Stator core test value.

Operating with a defective condition	Score
ELCID testing with low flux did not show any anomalies	10
ELCID testing with low flux shows small abnormal area values	5 – 9
ELCID testing with low flux shows large areas of abnormal values,	1 – 4
Operating with a defective condition	0

Table 10: Maintenance value.

Number of corrective maintenances	Score
Minimum level (normal conditions): routine preventive maintenance with minor work, routine cleaning and testing carried out on recommended frequency.	9 – 10
Low level: routine corrective maintenance with light work, for example: repairs that can be completed during a unit outage, preventive maintenance that is scheduled periodically basic (e.g., cleaning cooling tubes, cooling system maintenance)	5 – 7
Medium level: some unit maintenance that requires time for the unit to be turned off as a preventative maintenance measure, for example tightening bolt connection on winding, cleaning cooling system)	3 – 4
Significant level: additional and corrective maintenance work is required, resulting in a forced shutdown, such as: oil leaks in bearings, coolant gas leaks, overheating temperature	0 – 2

Table 11: Data quality value.

Data Availability and Data Accuracy	Score
High. Generator maintenance policies and procedures are followed by operation, routine checks, tests, and measurements are carried out at a normal frequency. Required data and information are available for team assessment through all available means, possible and visual inspection interviews with experienced generating units.	8 - 10
Medium. One or more of the routine examinations, tests and measurements completed within the normal 6–24-month frequency, or a fraction of the required data information and documents not available to the assessment team.	5 – 7
Low. One or more of the routine examinations, tests and measurements completed in the past 24-36 months is normal frequency, or several results not available.	3 – 4
Low. One or more required inspection tests and measurements completed >36 months past normal frequency, as of results not available.	0 – 2

3. RESULTS AND DISCUSSION

The generator began Commercial Operation Date (COD) on June 1, 2000, resulting in an approximate age of 22 years at the time of LTA implementation in 2022. A major overhaul, including stator and core rewinding, was necessary in 2013 due to equipment failure. The generator rotor was subsequently replaced in 2016 to address excessive vibration. For the purpose of lifetime assessment calculations in the "Age" column Table 13, replaced components like stators and rotors are considered to have been restored to a 'new' condition.Table 12 outlines the age criteria evaluation. Table 13 are observations that were made during the Darajat Unit 2 Generator condition assessment.

Table 12: Generator component Age criteria evaluation.

No	Part	Note	Age (Years)	Score
1	Stator	Rewinding = 2013	10	9
2	Stator Core	Rewinding = 2013	10	9
3	Rotor	New Rotor = 2016	7	9
4	Cooling System	1998	25	5
5	Neutral Grounding	1998	25	5
6	Bearing	2016	7	9
7	Casing Stator	1998	25	5
8	Generator Shaft	New Rotor = 2016	7	9
9	Brush Rigging	Maintained Annually	x	9
10	Oil System	Maintained Annually	x	9

Table 13 highlights several key observations regarding the generator condition that warrant further investigation:

1. Neutral Grounding (Circuit Ring) Visual Inspection

The visual inspection of the neutral grounding system, particularly the circuit ring area, resulted in a score of 6, which is lower than the scores assigned to other generator components. This discrepancy is attributed to discoloration observed on the circuit ring. Discoloration may indicate brazing neutral bar issue, potentially impacting component lifetime.

2. Stator Operation Limit

Data analysis indicates elevated temperatures in the windings of the Darajat Unit 2 Generator. Notably, the winding temperature rises to 120°C under full load conditions. The operational temperature of the circuit ring falls within a range of 140°C to 150°C. Given the observed winding temperature and the typical operating range of the circuit ring (140°C – 150°C), the current operating limit for the stator is assigned a value of 6. This value likely signifies a cause for concern, as it suggests potential proximity to the stator safe operating limits.

Table 13: Result of Darajat Unit 2 Generator evaluation.

Generator Components	Visual Inspection	Age	Technology Level	Operation Limit	Stator Electrical Test	Rotor Electrical Test	Stator Core Test	Maintenance	Data Quality SD(K)	Weighting Factor
Stator	9	9	8	6	8			8	8	**3.0**
Stator core	9	9	8	8			10	8	8	**1.5**
Rotor	9	9	8	8		10		8	8	**2.5**
Cooling System	9	5	8	8				7	8	**2.0**

									Condition Indicator (CI)	**4.82**

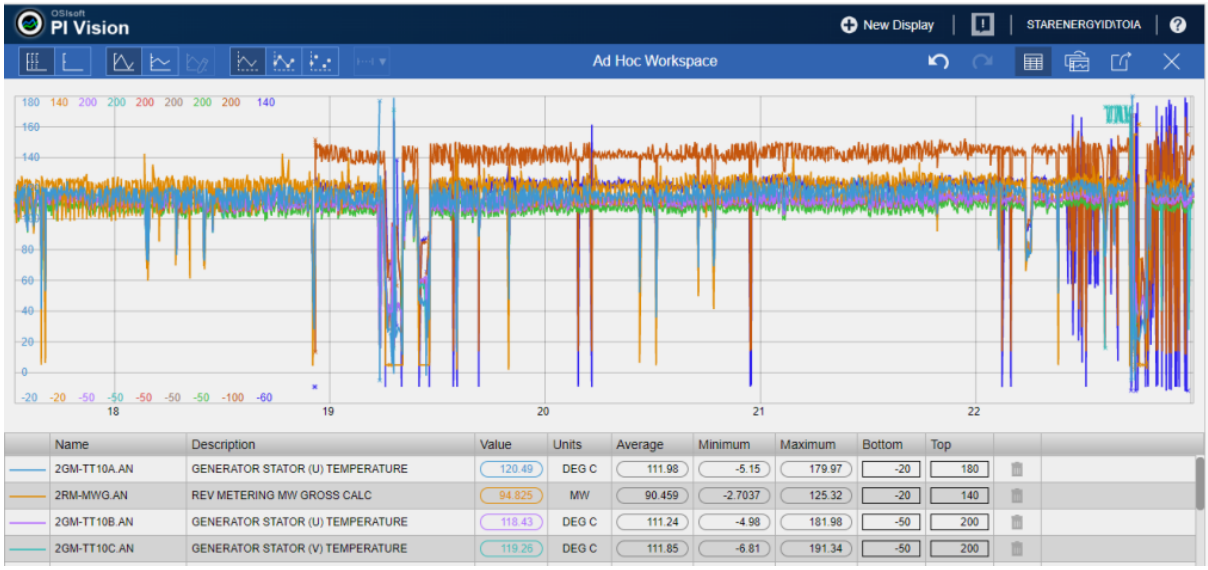

Figure 2: Operation data of Darajat Unit 2 Generator.

4. CONCLUSION AND RECOMMENDATION

4.1 Conclusion

While the initial lifetime estimate suggests the Darajat Unit 2 Generator could potentially function for another 27 years based on its design age (refer to previous sections for details on calculation method), certain observations necessitate further attention to ensure it reaches its full lifetime potential.

As highlighted in Table 13. (or mention the specific section if different), the visual inspection of the neutral grounding system, particularly the circuit ring area, revealed a concerning condition (discoloration). These observations suggest potential with brazing neutral bar issue. Additionally, data analysis indicates elevated temperatures in the windings, particularly under full load conditions. These observations suggest potential issues with the winding insulation degradation and dust accumulation.

4.2 Recommendations

Therefore, to achieve generation with Reliability Factor (RF) 99.59% and Availability Factor (AF) 99.09% and to maximize the generator lifetime estimated 27 years of operation since the last assessment, it is recommended to:

1. Prioritize maintenance of the neutral bar and circuit ring brazing. This could involve further visual inspection, x-ray testing, and potential repairs or replacements as needed.
2. Prioritize maintenance of the winding insulation. This could involve further visual inspection, partial discharge camera corona, partial discharge probe and potential repair for insulation degradation as needed.
3. Inspection during overhaul included a comprehensive evaluation of generator components, employing tests such as insulation resistance, winding resistance, tan delta, ELCID, bump, wedge analysis, core flux test, repetitive surge oscilloscope (RSO), and AC impedance/pole drop.
4. Predictive maintenance activities included continuous monitoring and analysis of winding and circuit ring temperatures using PI Vision, online partial discharge (PD) analysis, end winding vibration analysis, and flux probe measurements.

ABSTRACT

Vapor-dominated geothermal systems have their benefits and drawbacks when it comes to the power plant and steam above ground system (SAGS) facilities. SAGS of vapor-dominated geothermal systems are known to be less complicated due to the lack of brine production. But due to this very condition, plus the large amount of cooling fluid being wasted in the cooling tower to the air, one of the problems in dry steam power plants is the lack of fluid being injected back into the reservoir. The reservoir will continuously produce steam but with no addition of fluid from reinjection, the volume of fluid in the reservoir will be reduced. This can cause a rapid decline in well production, and can also result in the production of superheated steam. Superheated steam carries two major threats regarding the reliability of the power plant, which are chlorine carry over from reservoir that can cause corrosion along the pipeline, and impurities being carried into the turbine as the result of no steam condensation along the pipeline or scrubber, in which the condensed steam and impurities are supposed to be ejected from the system through condensate traps. The impurities then will be deposited on the high pressure stages of the turbine which have the highest pressure drop along the steam path. Deposition of impurities on the high pressure stages of the turbine can be indicated by the increase of wheel chamber pressure (WCP) at certain flowrate.

In this research, steam wash system was designed as an effort to prevent deposition in geothermal turbines. In the steam wash system, the temperature of superheated steam at a pressure of 7.7 bar abs with a mass flow rate of 80 kg/s is reduced from 173.835°C to saturation temperature using injection water with a temperature of 25°C and a pressure of 8.7 bar abs with a flow rate of 0.3757-0.3814 kg/s, or around 0.5% of the mass flow rate of superheated steam. This design can decrease impurities consentration from 2.86 ppm to 2.33 ppm. Water treatment plant is also designed to fulfill the required specification of injection water, which requires 2,923.07 W of electricity to operate. Apart from that, the economics of the steam wash system have been compared with the Business as Usual (BAU) scheme, where until 2045 the implementation of the steam wash system has a profit value of IDR 116,421,802,990.63 greater than the BAU scheme.

1. INTRODUCTION

In a dry steam geothermal power plant system, impurities such as silica and chloride carried by steam from the reservoir will be removed through the condensate trap or scrubber when the steam undergoes condensation. In cases which the steam condition is superheated, there is a chance that steam condensation will not occur along the pipeline or scrubber. When the largest pressure drop occurs in the first stage of the turbine, the steam will begin to condense so there is a chance that impurities will be deposited on the first stage of the turbine. Deposit buildup in the first stage of the turbine can be indicated through the deviation of wheel chamber pressure (WCP) from the design pressure according to the steam flow rate.

In geothermal fields with superheated steam, it is necessary to carry out wet scrubbing so that the steam can become a mixture of two phases, so that impurities can be removed through condensate that forms along the pipeline and disposed of through steam traps and scrubbers (Chauhan, 2019). Several methods of wet scrubbing can be used to improve steam purity, such as the application of a scrubbing line and steam wash. Scrubbing lines are segments of pipe that have a large diameter to reduce speed and promote condensation by reducing the thickness of the insulation (Mubarok and Zarrouk, 2016). The length of the scrubbing line is an important parameter because the condensate that is formed takes time to fall to the bottom of the pipe (Arifien, et al., 2015). Steam washing increases steam purity through two stages. The first stage is injecting water to reduce the temperature of the superheated steam. The second stage is the removal of impurities through condensate which is formed and removed through a steam trap and scrubber. In this case, the injected water has two roles, namely helping to separate the liquid phase from the vapor, which causes heavier droplets so that they can be removed from the vapor stream, and by capturing semi-volatile material with the liquid phase, so that it can be removed

via degreasing equipment. water (Richardson, et al., 2014). The mass flow rate of the injection water is approximately 0.5-2% of the mass flow rate of steam (Morris, et al., 2019). The amount of injection water should not be too much, because it can cause the steam to be too wet after the injection water is injected, thus increasing the risk of wear on the turbine components (Sakai, 2022). In addition, injection water must not contain oxygen so as not to cause pitting corrosion in production facilities (Villa Jr, et al., 2005). Between the scrubbing line and steam wash methods, the steam wash method is superior because its operation is more flexible, it can follow the conditions of the steam that will enter the turbine. The objective of this paper is to design a steam wash system that can remove impurities from superheated geothermal fluid, so that it can improve the reliability of the geothermal power plant.

2. METHODS

The design of a steam wash system is divided into several stages, including calculating the heat loss to the environment, calculating the injection water flow rate requirement, calculating the condensate formed, and calculating the water treatment plant specification. Apart from that, flow simulations and economic analysis were also carried out. The data used in the calculation is obtained from one of the dry steam geothermal power plant in Indonesia.

2.1 Calculation of Heat Loss to the Environment

To be able to calculate the amount of condensate formed after superheated steam becomes saturated steam after mixing with injection water, it is necessary to calculate the heat transfer from the steam in the pipe to the ambient air. The illustration can be seen in Figure 1, and the thermal circuit can be seen in Figure 2.

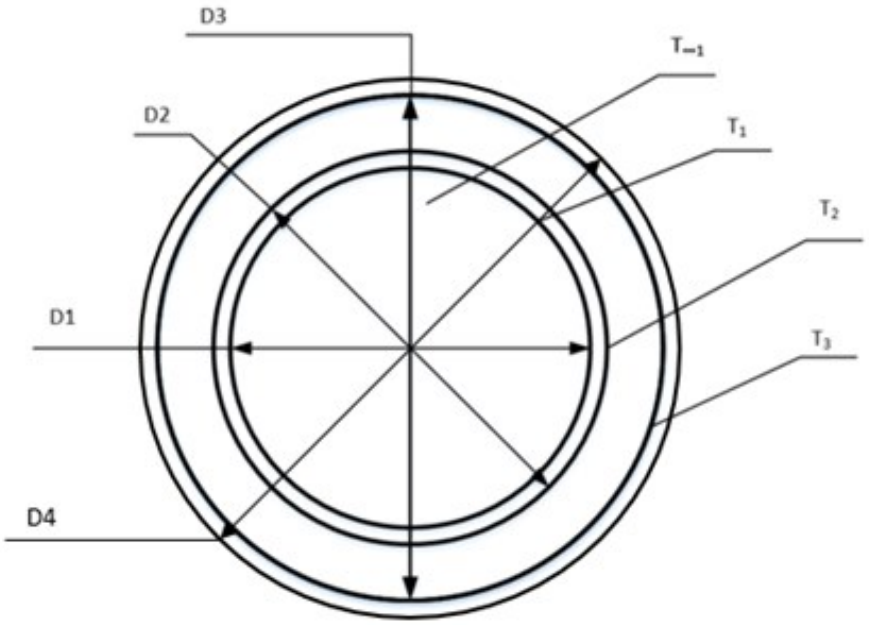

Figure 1: Heat transfer from steam to environment.

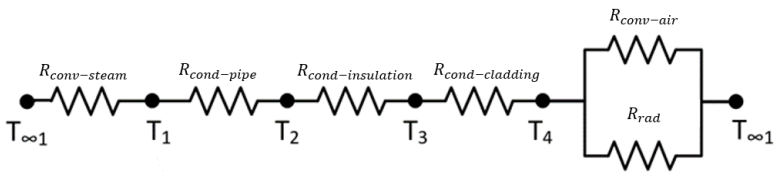

Figure 2: Thermal resistance circuit.

With the temperature on the outside of the cladding determined for safety reasons in operation and in accordance with the thermal resistance series above, the following equation is obtained (Bergman, 2011):

$$Q_{loss} = \frac{T_{\infty 1} - T_4}{R_{konv-uap} + R_{kond-pipa} + R_{kond-insulasi} + R_{kond-cladding}} \quad (1)$$

$$Q_{loss} = \frac{T_{\infty 1} - T_3}{\frac{1}{h_{uap}.A_1} + \frac{ln\,(R_2/R_1)}{2.\pi.k_{pipa}.L} + \frac{ln\,(R_3/R_2)}{2.\pi.k_{insulasi}.L} + \frac{ln\,(R_3/R_2)}{2.\pi.k_{cladding}.L}} \quad (2)$$

The value of h_{steam} is obtained from the following equation:

$$h_{uap} = \frac{Nu_{D_{uap}}.k_{uap}}{D_1} \quad (3)$$

$$Nu_{D_{uap}} = 0{,}023\ .\ {Re_D}^{4/5}.Pr^n \quad (4)$$

$$Re_D = \frac{\rho.VD_1}{\mu} \quad (5)$$

Equation 4 which is used to obtain the Nusselts Number has conditions including flow in a round pipe, turbulent flow, fully developed, $0.6 \leq Pr \leq 160$, $Re \geq 10{,}000$, $(L/D) \geq 10$, and $n = 0.3$ for $Ts < Tm$ (Bergman, 2011). The data used in this calculation can be seen in Table 1.

Table 1: Material and steam data as a basis for calculating heat loss to the environment.

	Prandtl Number	Pr	1.0955

2.2 Calculation of the Injection Water Flow Rate Requirement

After the heat loss to the environment is calculated, the need for injection water to reduce the temperature of superheated steam can be calculated using the energy and mass balance equation with the assumptions that the condition is in steady state, no work to or from the system, and kinetic and potential energy are ignored. from those assumptions, these equations are obtained (Moran, et al., 2010):

$$\dot{Q}_{loss} + (\dot{m}_1 h_1 + \dot{m}_2 h_2) = \dot{m}_3 h_3 \quad (6)$$

$$\dot{m}_1 + \dot{m}_2 = \dot{m}_3 \quad (7)$$

The value of $\dot{Q}_{loss}$ varies with the distance which is assumed to be the distance required until mixing between superheated steam and injection water has been completed. The longer the mixing distance, the less the injection water needed. Calculations are carried out using the data in Tables 2 and 3 to find the mass flow rate of injection water and steam downstream of the injection point using Equations 6 and 7 according to variations in the selected mixing distance.

2.3 Calculation of the Formed Condensate Flow Rate

The schematic of the steam wash system can be seen in Figure 3.

X in the figure describes the distance from the injection point to the point where mixing is complete. The criteria for mixing to be completed are where there is no difference in temperature, speed and density between the steam

and the injected water. Calculation of the mass flow rate of condensate formed can be done by dividing the heat value loss to the environment by the vaporization enthalpy of the steam. Apart from that, a simulation was also carried out using Aspen Plus software to calculate the amount of condensate formed in the steam trap and scrubber. The parameters entered in the model created in Aspen Plus software can be seen in Table 4. The mass flow rate of the condensate formed is calculated using equation 8.

$$\dot{m}_{condensate} = \frac{Distance\ of\ Pipie.\ Q_{loss}}{h_{vaporization}} \quad (8)$$

Tabel 2: Known parameters.

Known Parameters	Value	Unit
Superheated Steam Pressure (Upstream)	7.7	bar a

Table 4: Input parameter for steam condensation simulation.

Component	Parameter	Value	Unit
Superheated Steam	Mass Flow Rate	80	kg/s
	Temperature	173.835	°C
	Pressure	7.7	Bar a
Injection Water	Mass Flow Rate	According to calculation results	
	Temperature	25	°C
	Pressure	8.7	Bar a
Pipe	Distance from Injection Point to the First Steam Trap	40	m
	Distance from the First Steam Trap to the Second Steam Trap	40	m
	Distance from the Second Steam Trap to Scrubber	38	m
	Heat Loss	According to calculation results	

Table 5: Concentration and solubility of materials contained in the steam.

Ion	ppm	Solubility (PubChem, 2024)
Chloride Ion	0.05	6.3 mg/ml steam
Sulfate Ion	0.88	28.1 g/g steam
Sodium Ion	0.03	36 g/100g steam
Kalium Ion	0.08	100 mg/ml steam
Calcium Ion	0.04	74.5 g/100ml steam
Magnesium Ion	0.02	73.8 g/100ml steam
Lithium Ion	0.01	76.9 g/100ml steam
Total Iron	0.02	-
Fluoride Ion	0.05	0.00169 mg/ml steam

Ion	ppm	Solubility (PubChem, 2024)
Boron	1.66	-
Silica	0.02	-

The approach taken to calculate the amount of material content that can be carried away by the condensate is divided into two stages. The first stage is to calculate the solubility of the material contained in the condensate. The second stage is to calculate the minimum horizontal distance required for condensate droplets to descend from the highest point in the pipe to the bottom of the pipe. The assumption used in this approach is that the impurity material contained in the steam will dissolve completely in the condensate that has formed, in accordance with the limited solubility value of the material. Therefore, it can be assumed that condensate droplets that will fall from the highest point in the pipe to the bottom of the pipe will contain all dissolved material. The concentration and solubility value of each material contained in the steam can be seen in Table 5.

Single droplet model is used for calculating the minimum distance required for condensate droplets to descend from the highest point in the pipe to the bottom of the pipe (Arifien, et al., 2015). The schematic of the model can be seen in Figure 4. The equations used in this model are as follows (Mubarok and Zarrouk, 2016 & Arnold and Stewart, 2008):

$$V_t = 0{,}0036\sqrt{\frac{d_p(\rho_l-\rho_g)}{C_d\rho_g}} \quad (9)$$

$$C_d = \frac{24}{Re} + \frac{3}{Re^{0,5}} + 0{,}34 \quad (10)$$

$$Re = 0{,}001\frac{\rho_g d_p V_t}{\mu} \quad (11)$$

$$t_s = \frac{h}{V_t} = \frac{L}{V_s} \quad (12)$$

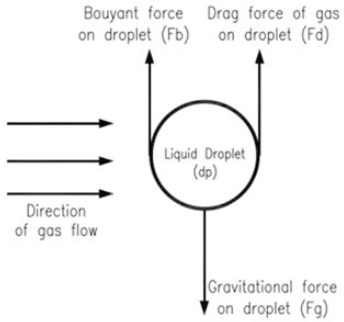

Figure 4: Single droplet model (Arifien, et al., 2015).

2.4 Calculation of Water Treatment Plant Specification

After the injection system is designed, the water treatment plant is designed. Because of the injection water is sourced from the cooling tower basin, the quality of which can be seen in Table 6, has lots impuries that does not meet the recommended values or limits for injection water determined from the turbine Operation & Maintenance Manual, a water treatment plant is needed so that The injection water quality can meet the recommended values and limits.

Table 6: Recommended Values, Limit Values, and Water Quality Data

Parameter	Recommended Values	Limit Values	Water Quality from Cooling Tower Basin
pH	≥ 5.0 ≤ 10.0	≥ 4.0 ≤ 10.0	6.5
TDS	≤ 0.5 ppm	≤ 5 ppm	96.42 ppm
SS	≤ 0.1 ppm	≤ 1 ppm	N/A
Chloride Ion	≤ 0.1 ppm	≤ 1 ppm	0.546 ppm
Sulfate Ion	≤ 0.1 ppm	≤ 1 ppm	4.207 ppm
Sodium Ion	≤ 0.1 ppm	≤ 1 ppm	5.217 ppm
Kalium Ion	≤ 0.1 ppm	≤ 1 ppm	4.275 ppm
Calcium Ion	≤ 0.1 ppm	≤ 1 ppm	40.241 ppm
Fluoride Ion	≤ 0.1 ppm	≤ 1 ppm	0
Arsenic	≤ 0.1 ppm	≤ 1 ppm	N/A

Parameter	Recommended Values	Limit Values	Water Quality from Cooling Tower Basin
Boron	≤ 0.5 ppm	≤ 5 ppm	N/A
Silica	≤ 0.1 ppm	≤ 1 ppm	N/A
Total Iron	≤ 0.1 ppm	≤ 1 ppm	N/A
Oxygen	≤ 0.01 ppm	≤ 0.1 ppm	9.09 ppm

Design of the water treatment plant for the reverse osmosis membrane section is using Water Application Value Engine (WAVE) software. In order to provide storage reserves in the tank before entering the injection system, the mass flow rate of water that needs to be produced from the water treatment plant is determined to be greater than the injection water requirement. The size of the tank is arranged in such a way that it can retain water for a certain time interval.

The oxygen content value in the cooling tower basin water exceeds the recommended limit value, so treatment is carried out by mixing hydrazine to reduce the oxygen content of the water to be injected, which meets the following chemical equation:

$$N_2H_4 + O_2 \rightarrow N_2 + 2H_2O$$

From this equation, the amount of hydrazine needed to reduce the oxygen level in the water to be injected can be calculated. The schematic of the water treatment plant can be seen in Figure 5.

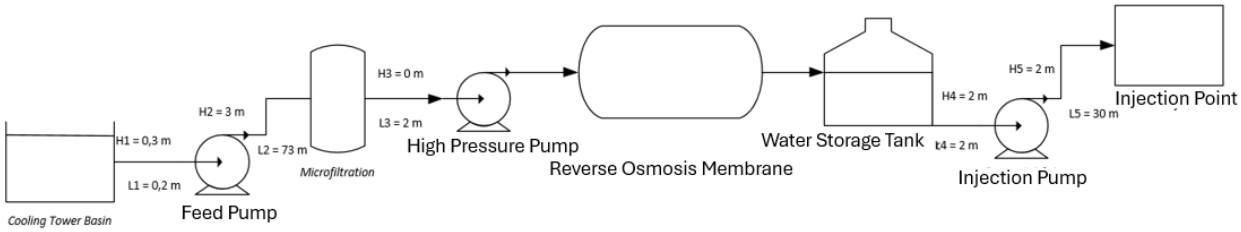

Figure 5: Schematic of Water Treatment Plant.

The input data and assumptions used to calculate pump specifications are as follows:

- Injection water temperature: 25°C
- Atmospheric pressure: 850 mBar
- Density of water: 995.7 kg/m^3
- Gravitational Acceleration: 9.81 m/s^2
- Microfiltration works at a pressure of 1 barg (Van Der Bruggen, 2018)
- The pressure drop across the microfiltration filter is 0.5 barg (Gao, 2022)

The equations used to calculate pump specifications are as follows:

$$P = \rho . g . Q . H \quad (13)$$

$$H = \frac{(P_{Discharge} - P_{Suction})}{\rho . g} \quad (14)$$

$$P_{Suction} = P_{surface\_suction} + P_{static\_suction} - \Delta P_{friction\_suction} \quad (15)$$

$$P_{Discharge} = P_{surface\_discharge} + P_{static\_discharge} + \Delta P_{friction\_discharge} \quad (16)$$

$$P_{static\_suction/discharge} = \rho . g . h_{static\_suction/discharge} \quad (17)$$

$$\Delta P_{friction\_suction/discharge} = f . \left(\frac{L}{D}\right) . \left(\rho \frac{V^2}{2}\right) \quad (18)$$

$$\frac{1}{\sqrt{f}} = -2 \log_{10} \left(\frac{\varepsilon}{3{,}7D} + \frac{2{,}51}{Re\sqrt{f}}\right) \text{ for } Re > 4000 \quad (19)$$

2.5 Flow Simulation

As a visualization of the calculation results, a flow simulation is carried out by entering input parameters from the calculation results of the heat heat loss and the required mass flow rate of the injected water. Flow simulations were carried out using Ansys Fluent software. The boundary conditions specified as input are the speed and temperature of the superheated steam, the speed and temperature of the injection water, and the pipe wall temperature.

2.6 Economic Analysis

An economic analysis was carried out on the installation of a steam wash system over the remaining life of the available generator, which was then compared to the Business as Usual (BAU) scheme. In the BAU scheme, there is no intervention in the deposition process in the turbine, resulting in suboptimal generation over time, which can then be returned to optimal conditions by cleaning at a Major Overhaul every two years. The data and assumptions used in economic analysis are as follows:

- Power plant production capacity is 35 MW.
- For schemes using steam wash it is assumed to be produced at full load throughout the year.
- The price of electricity is 8.25 US cents per kWh.
- The USD to IDR exchange rate is IDR 15,500.00 for 1 USD.
- Power plant will be operated until 2045.
- Operational costs incurred come from the use of hydrazine as an oxygen scavenger.
- Maintenance Outage is carried out every 2 years for 14 days for both schemes.
- In the Business as Usual (BAU) scheme, if an increase in wheel chamber pressure occurs because it exceeds certain limits, the steam mass flow rate must be reduced so that the wheel chamber pressure is within the permitted limits in accordance with the applicable operating guidelines.

3. RESULTS AND DISCUSSION

3.1 Heat Loss to the Environment

The results of the calculation of heat wasted on the environment can be seen in Table 7. It can be seen that the heat loss per meter of pipe length is 379.63 W. This value can then be used as a basis for calculating injection water requirements based on the distance required until mixing is complete. Apart from that, this value is used as input data in the Aspen Plus simulation to simulate condensation that occurs in pipes.

Table 7: Heat Loss to the Environment.

Parameter	Symbol	Value
Diameter	D1	0.813 m
Area	A	0.519 m^2
Fluid Velocity	V	38.404 m/s
Reynolds Number	Re_D	8557219.192
Nusselts Number	$Nu_{D_{steam}}$	12280.88985
Heat Transfer Coefficient	h_1	521.972 $W/m^2 . K$
Contact Surface Area	A_1	2474.318 m^2 per meter
Convection Thermal Resistance	$R_{conv-steam}$	7.743 x 10^{-7} $W/m . K$
Pipe Conduction Thermal Resistance	$R_{cond-pipe}$	9.355 x 10^{-5} $W/m . K$
Insulation Conduction Thermal Resistance	$R_{cond-insulation}$	0.3239 $W/m . K$
Cladding Conduction Thermal Resistance	$R_{cond-cladding}$	1.75 x 10^{-6} $W/m . K$
Heat Loss	Q_{loss}	379.63 W per meter

3.2 Injection Water Flow Rate

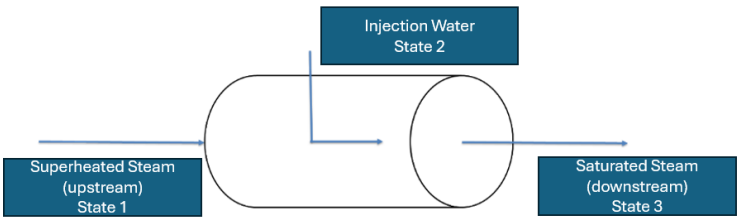

Figure 6: Schematic of Steam Wash Injection.

The scheme for water injection into superheated steam can be seen in Figure 6. The calculation results for injection water mass flow rate requirements are shown in Table 8.

It can be seen that to reduce the temperature of superheated steam at a rate of 80 kg/s from 173.835°C to the saturation temperature at 168.835°C at a pressure of 7.7 bar a requires water injection with a temperature of 25°C and a pressure of 8.7 bar a varying between 0 .3757-0.3814 kg/s according to the distance between the injection point until the mixing is complete, which is varied between 0-40 meters. The range of ratios of the value of the

mass flow rate of injection water to the mass flow rate of steam is between 0.470-0.477%, which is a very small difference, so a precise control system is needed to be able to produce steam with the appropriate values for each parameter.

Table 8: Results of Injection Water Mass Flow Rate Requirement Calculation.

		Parameter	Unit	State		
				1	2	3
		Temperature	°C	173.835	25	168.835
		Pressure	bar a	7.7	8.7	7.7
		Enthalpy	kJ/kg	2777.83	126.53	2766.73
Mixing Distance (m)	0				0.3814	80.3814
	1				0.3812	80.3812
	5				0.3807	80.3807
	10	Mass Flow Rate	kg/s	80	0.3799	80.3799
	20				0.3785	80.3785
	30				0.3771	80.3771
	40				0.3757	80.3757

3.3 Condensate Flow Rate

The steam wash system model has been created using Aspen Plus as can be seen in Figure 7.

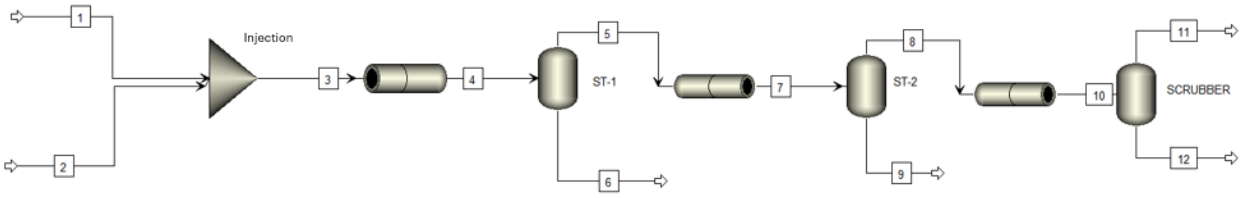

Figure 7: Model of Steam Wash Model.

The state of each flow are obtained using the model in Figure 7. In this model the input parameters are included as in Table 4 as well as the mass flow rate of injected water and heat loss to the environment which have been calculated previously. The simulation results can be seen in Table 9. It can be seen that the total condensate formed is 0.0096 kg/s or 34.72 kg/h, with details of 0.0032 kg/s in the first steam trap, 0.0033 kg /s on the second steam trap, and 0.0031 kg/s on the scrubber. From these results, the mass flow rate of the condensate formed is much less than the mass flow rate of the incoming injection water, so it can be concluded that there is an increase in the mass flow rate of fluid entering the turbine. Therefore, an approach was taken using the solubility of the contained material to ensure that the impurity material contained in the superheated steam could be carried out by the condensate formed through the steam trap and scrubber.

The mass flow rate limit of each contained material that can be dissolved in condensate water is obtained using the solubility data of the contained material from Table 5 and the calculation results of the condensate formed, the value of which can be seen in Table 10. Then, this value is compared with the flow rate the mass of each material contained, so that it can be concluded that almost all of the material contained can be dissolved in the condensate, except for sulfate ions and fluoride ions of which the remaining 102.64 g/h and 10.09 g/h respectively will be carried away. to the turbine. In addition, materials such as total iron, boron, and silica cannot be dissolved in the condensate.

The next stage is to calculate the distance required for the condensate droplets at the highest position in the pipe to be able to descend to the bottom of the pipe. This aims to illustrate the possibility of condensate formed along the pipe being able to descend to the bottom of the pipe and be removed through steam traps and scrubbers located at several points on the pipe route as in Figure 3. The minimum distance required for condensate droplets at the highest position in the pipe to be able to descend to the bottom of the pipe is greatly influenced by the diameter of the droplet formed as written in Equations 9 to 12. The calculation results can be seen in the graph in Figure 8. With the distance between the points injection and the first steam trap and the distance between the first steam trap and the second steam trap is 40 meters, the minimum diameter of the condensate droplet is 272 μm. Meanwhile, for condensation formed after the second steam trap, the minimum diameter of the condensate droplets is 282 μm so that all the condensate droplets formed can fall to the bottom of the pipe and be removed through a scrubber which is 38 meters from the second steam trap.

Table 9: Results of Process Simulation.

Parameter		Temperature (°C)	Pressure (Bar)	Mass Flow Rate(kg/s)
State	1	173.835	7.7	80
	2	25	8.7	0.3814
	3	168.83	7.7	80.3814
	4	168.72	7.68	80.3814
	5	168.72	7.68	80.3782
	6	168.72	7.68	0.0032
	7	168.62	7.66	80.3732
	8	168.62	7.66	80.3749
	9	168.62	7.66	0.0033
	10	168.52	7.64	80.3749

	12	168.52	7.64	0.0031

Tabel 10: Results of Material Solubility on Steam Flow After Steam Wash Injection.

Ion	Mass flow rate limit in which the ion is dissolvable	Mass Flow Rate after Injection	Details
Chloride Ion	81,13 g/h	10,15 g/h	Completely dissolved
Sulfate Ion	25,76 g/h	179,91 g/h	102,64 g/h left
Sodium Ion	4166,68 g/h	14,91 g/h	Completely dissolved
Kalium Ion	1287,80 g/h	40,33 g/h	Completely dissolved
Calcium Ion	9594,11 g/h	20,04 g/h	Completely dissolved
Magnesium Ion	9503,96 g/h	9,92 g/h	Completely dissolved
Lithium Ion	9903,18 g/h	4,96 g/h	Completely dissolved
Total Iron	-	9,92 g/h	Not dissolved
Fluoride Ion	0,02 g/h	10,15 g/h	10,09 g/h left
Boron	-	478,08 g/h	Not dissolved
Silica	-	5,76 g/h	Not dissolved

3.4 Water Treatment Plant Specification

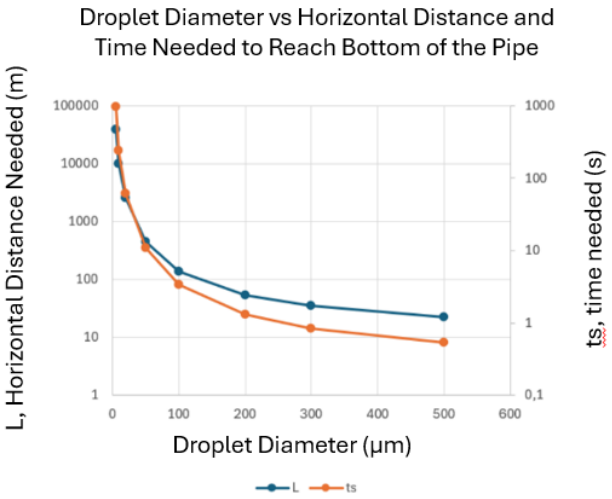
From the calculation results of the mass flow rate requirement for injection water of 0.3814 kg/s, or 1.38 m^3/h, it is determined that the volume flow rate of water entering the water storage tank is 4.5 m^3/h so that injection water can be stored, so the water treatment plant does not need to operate all the time. Assuming the RO membrane has a recovery rate of 75%, the volume flow rate of water entering the water treatment plant is 6 m^3/h. These values along with the water quality from the cooling tower basin as in Table 6 were entered into the WAVE software so that results were obtained as can be seen in Table 11.

Then, to calculate the size of the water storage tank, a minimum retention time of 8 hours is determined, so the minimum tank size is 11.03 m^3. Therefore, the water storage tank specifications are determined as follows:

- Tank diameter: 3 meters
- Tank height: 2 meters
- Tank volume: 14.14 m^3

With this volume of water storage tank, the water retention time in the tank during use of the injection system is 10.25 hours. After the water volume in the tank decreases and approaches empty because the water is used for steam wash injection, the water conditioning system operates again and refills the tank for 4.53 hours with the injection process continuing.

With an oxygen content in the injection water of 9.09 ppm, 0.935 kg of 35% hydrazine is needed per day to evacuate all the oxygen in the injection water so as not to cause corrosion in the system.



dp (μm)	5	10	20	50	100	200	300	500
L (m)	39422,1	9931,43	2537,11	446,98	138,17	53,67	34,7	22,07

Figure 8: The Effect of Droplet Size on the Horizontal Distance and the Time Required for the Droplet to Descend to the Bottom of the Pipe.

Table 11: Calculation Result of Water Treatment Plant Specification.

Parameter	Value	Unit
TDS of Source Water	96.39	Ppm
Volumetric Flow Rate of Source Water	6	m^3/h
TDS of Permeate Water	4.94	Ppm
Volumetric Flow Rate of Permeate Water	4.5	m^3/h
TDS of Concentrate Water	371.8	Ppm
Volumetric Flow Rate of Concentrate Water	1.5	m^3/h
Discharge Pressure of High Pressure Pump	7	Bar
Chloride Ion	0.0	ppm
Sulfate Ion	0.02	ppm
Sodium Ion	0.04	ppm
Kalium Ion	0.96	ppm
Calcium Ion	0.29	ppm

The calculation results regarding pump specifications can be seen in Table 12. In a water treatment plant, the greatest power requirement comes from the pump. In this system the total power requirement is 2,923.07 W.

Table 12: Calculation Result of Pump Specification.

No	Pump	Differential Pressure (m)	Hydraulic Power (W)
1	Feed Pump	14.52	236.87
2	High Pressure Pump	75.09	1,225.33
3	Injection Pump	89.53	1,460.87

3.5 Results of Flow Simulation

In carrying out flow simulations, a mesh of the flow in the pipe has been created covering the flow in the pipe along 30 meters from the injection point to find the point where mixing between the injected water and superheated steam has been completed. The criterion for mixing to be complete is where there is no difference in temperature, speed and density between the steam and the injected water. In this simulation, the number of elements used was 239,397, and the number of spots was 241,292.

The flow simulation results in the form of velocity contours can be seen in Figures 9 and 10. It can be seen in Figures 9 that the velocity contours in the area around the injection point are slower up to a distance of around 4

meters, after which the flow has the same velocity profile. Apart from that, it can be seen in Figure 10 that the water volume fraction has reached 0 percent at a distance of around 0.3 meters from the injection point, which illustrates that all of the injected water has changed phase to steam.

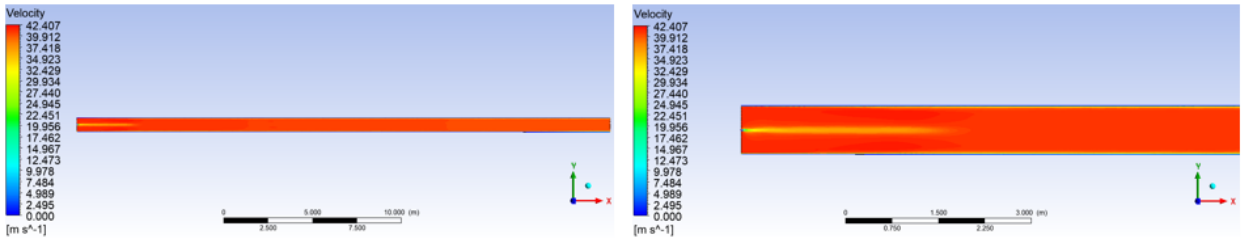

Figure 9: (a) Velocity Profile on 0-30 Meter from Injection Point and (b) Velocity Profile on Injection Point.

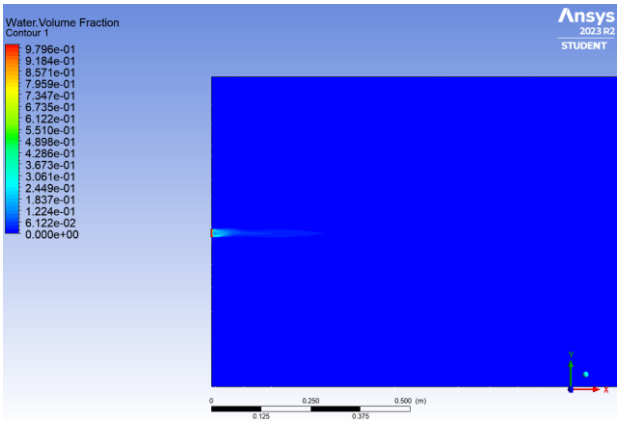

Figure 10: Volume Fraction Profile of Steam on Injection Point.

3.6 Results of Economic Analysis

The capital costs of a steam wash system consist of the capital costs of components consisting of a nozzle and a water treatment plant which includes a water storage tank, feed pump, high pressure pump, injection pump, RO membrane, and oxygen scavenger system. The capital costs of each component were obtained from offers from various companies which were then compared to obtain an estimated capital cost of the steam wash system of IDR 1,820,862,507.00. Operational costs for the steam wash system are related to the use of 35% hydrazine as an oxygen scavenger which requires an amount of 0.935 kg per day or 341.415 kg per year, which is estimated to cost IDR 47,798,061.90 per year.

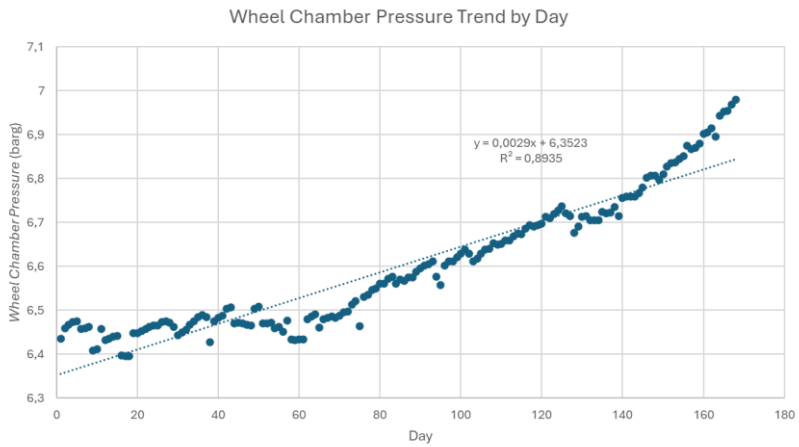

Figure 11: Wheel Chamber Pressure Trend By Day.

In the Business as Usual (BAU) scheme, the plant operation is modeled in accordance with the wheel chamber pressure increase modeling. From previous operational data, a graph of the increase in wheel chamber pressure is obtained as in Figure 11. From this graph, an equation is obtained that describes the increase in wheel chamber pressure per day, where the increase will continue until the maximum value that can be operated. In this condition, according to the turbine operation & maintenance manual, the steam mass flow rate entering the turbine must be reduced so that the wheel chamber pressure value is at the maximum value at the upper limit of the steam mass flow rate. Reducing the steam mass flow rate causes a decrease in generation. This decline in generation occurred until periodic maintenance outages were carried out every 2 years. Figure 12 explains the operational modeling results of the BAU scheme.

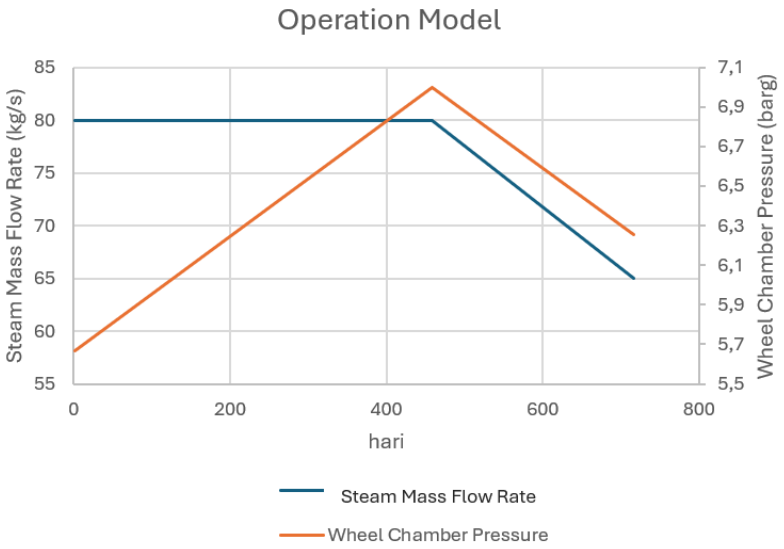

Figure 12: Operation Model Results of BAU Scheme.

Until 2045, the steam wash scheme gets a Net Present Value (NPV) of IDR 3,711,527,813,835.86, while the BAU scheme gets an NPV of IDR 3,595,106,010,845.23, so that using the steam wash system provides a profit of IDR 116. 421,802,990.63 compared to if the deposition problem was only resolved by mechanical cleaning every maintenance outage every 2 years.

4. CONCLUSIONS

The steam wash system has been designed to prevent deposition on the turbine caused by impurities contained in the steam. In a system where the steam is in a superheated condition, the steam temperature needs to be lowered to the saturated steam temperature so that the steam can then be condensed. To reduce the temperature of superheated steam at a pressure of 7.7 bar abs with a mass flow rate of 80 kg/s, injection water with a temperature of 25°C and a pressure of 8.7 bar abs is required as much as 0.3757-0.3814 kg/s, or about 0.5% of the mass of superheated steam. Variations in the mass flow rate of injection water are caused by differences in distance from the injection point to the point of complete mixing. The total power required for the water conditioning system that supplies injection water is 2923.07 W, where this system can produce injection water with Total Dissolved Solids of 4.94 ppm. In addition, there is a conditioned water storage tank that can retain water for 10.25 hours during operation of the steam wash system, and can be fully filled in 4.53 hours with the injection process still running.

Using the steam wash system until 2045 provides a profit of IDR 116,421,802,990.63 compared to if the deposition problem was only resolved by mechanical cleaning every maintenance outage every 2 years, during which period derating would occur due to the buildup of deposition on the turbine.

ABSTRACT

PT Geo Dipa Energi GDE (Persero) has embarked on the expansion of Patuha Geothermal Field in West Java, Indonesia in January 2022 based on the updated resource assessment and reservoir modelling of greater Patuha resource, follow on geoscientific studies and feasibility update of Patuha project. The expansion program called for drilling of twelve (12) production wells to support the 55 MWe Patuha-2 power plant. The drilling campaign was successfully completed in March 2024, but the programmed production well testing activities encountered a few challenges that presented some difficulties in proving the capacity of the wells.

Well testing of Patuha-2 steam wells has been programmed to generally meet the prescribed environmental, safety and social standards related to H_2S gas emissions, Brine Carry-Over (BCO) and Nosie levels that could potentially affect the nearby households/vegetation. The discharge of the wells could also potentially present some level of mineral (calcite) deposition like calcite scaling in a Patuha-1 production well. This paper discusses the modifications made to the current Atmospheric well test facility component with the application of Rock Muffler concept in addressing the BCO and Noise level issues. Additional modification using Palm Fibers to further control the BCO were successfully implemented. Discharge testing of the wells using the abovementioned novel solutions successfully addressed the BCO and noise level issues.

1. INTRODUCTION

The steam dominated Patuha Geothermal Field is in West Java province of Indonesia and about 50 kilometers southwest from Bandung city. The Indonesian government assigned PT Geo Dipa Energi (GDE) in 2002 to continue development of Patuha after the financial crisis in 1998. GDE constructed the surface gathering system in 2011 and commissioned the first 55 MWe Patuha-1 power plant in September 2014. GDE has lately embarked on the 55 MWe Patuha-2 expansion and started the drilling campaign in December 2021.

Discharge testing of Patuha-2 production wells is expected to produce single phase/dry steam fluid at the wellhead that requires measurement of enthalpy of the fluid mixture as well as the total mass flow. Here, the James Lip pressure method is initially planned to be employed in calculating the discharge enthalpy and flows using the Low-Emission Compact Muffler (LECM) unit. The programmed well testing activities encountered some challenges in addressing noise levels and Brine Carry-Over (BCO). The performance of LECM was found to be less effective in managing these issues that made GDE examine the application of portable rock muffler technology.

1.1 Low Emission Compact Muffler (LECM)

The LECM well testing unit developed by Thermochem has proven to be a robust system that provides good flow rate and enthalpy measurements for geothermal production well flow tests. The LECM units have been verified to yield good enthalpy and brine flow measurements from Mag Flow Meters on the outlet of the LECM, as well as the internal LECM unit design with baffles in the lower container and mist eliminator pads on the upper stack to improve separation efficiency and reduce brine carryover out of the top of the LECM unit.

In Patuha, a 20 ft LECM was employed as atmospheric separator for well flow testing with some modifications, where the James tube is then replaced by an orifice plate and Mag Flow Meters with the expected small amount of brine component in the discharge fluid. Figure 1 shows the schematic layout of the LECM while Figure 2 shows the modified schematic of the LECM.

1.2 Low Emission Rock Muffler Container (LERMC)

The Low Emission Rock Muffler Container is normally used to vent steam to atmosphere under pressure control for well testing purposes. Here, the bottom part of the LECM was modified where the inlet pipe into the LERMC is connected to a header pipe with several perforated pipes attached to the header to uniformly distribute the discharge fluid and flow separation is achieved. Several layers of rocks are placed on top of the discharge pipes inside the bottom rock muffler container. This configuration will ensure the steam will pass through the rock layers and exit to the atmosphere.

The upper component of the LECM was also modified with the installation of Palm fibers to reinforce the Mist Pads that were damaged during initial flow tests of Patuha wells. Figure 3 shows the schematic layout of the Low Emission Rock Muffler Container while Figure 4 shows the modified schematic layout of LECM.

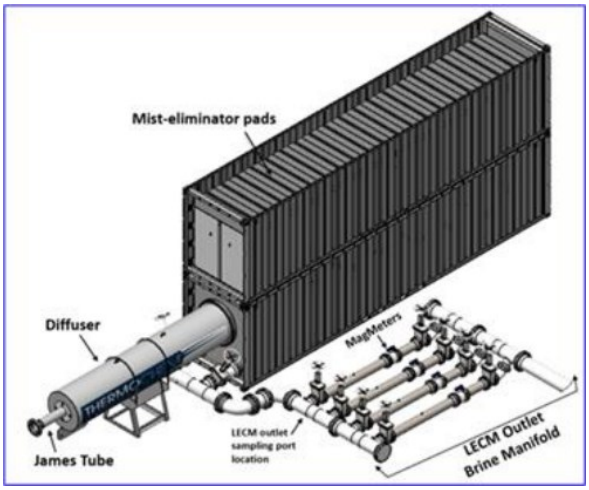

Figure 1: Schematic of the LECM components, including James tube, diffuser, mist eliminator pads, LECM outlet brine manifold, location of LECM brine outlet sampling port, and Mag Flow Meters.

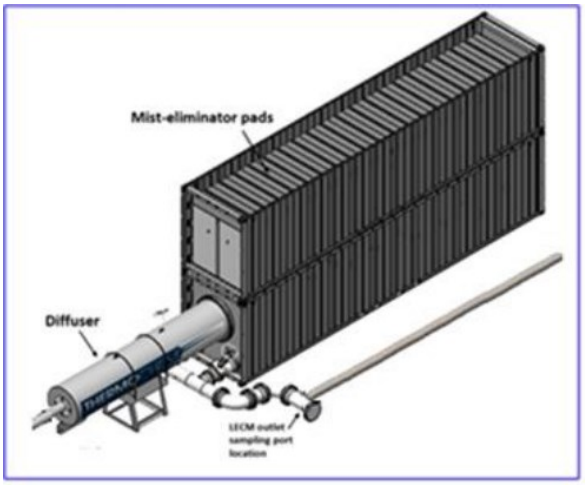

Figure 2: Schematic of the LECM components, dummy James-tube, diffuser, mist eliminator pads, LECM outlet brine outlet sampling port.

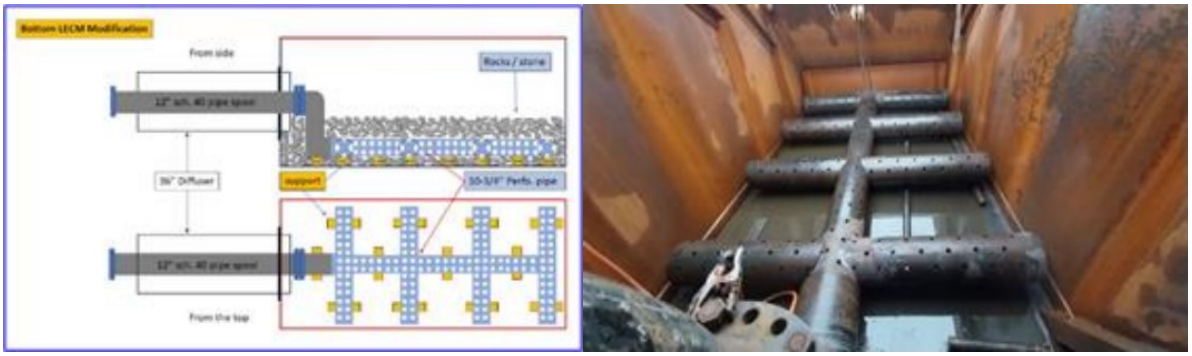

Figure 3: Schematic of the modified bottom part of LECM with the installation of rock muffler components.

1.3 Low Emission Rock Muffler Container Design Criteria

There are some engineering and environmental criteria to be considered in designing the Low Emission Rock Muffler Container (LERMC). The engineering criteria are as follows:

a. Flow capacity should be considered to avoid erosion effect and choke effect (covered by flow velocity analysis study).
b. Proper material selection for long term operation (covered by mechanical strength analysis study).
c. The foundation of rock muffler unit must be able to withstand weight load of rocks.
d. The pipe should be easy to maintain due to corrosion and erosion effect.

The environmental criteria are as follows:

a. Noise emission and proximity to inhabited areas.

b. The potential for accumulation of Non-Condensable Gas (NCG) including hazardous concentrations of H2S in the system.
c. The need to avoid steam clouds drifting over access roads, transmission lines, and local communities.

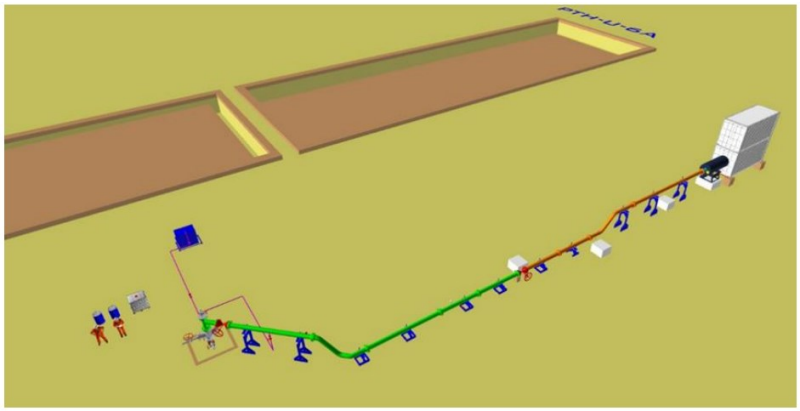

Figure 4: Well Testing Schematic using Rock Muffler.

2. PATUHA WELL TESTING PROGRAM

Horizontal discharge testing is conducted on Patuha-2 production wells to measure the discharge fluid characteristic and fluid chemistry with the aim of establishing their production characteristics. The atmospheric silencer testing method is generally the acceptable and preferable technique of testing production wells because of its low cost and simple installation. Separating the water and steam phases in a cyclone separator (pressurized) and measuring the two phases (while contained within pipelines) separately is generally considered an accurate method of testing the output of a production well.

More recently, the Low Emission Compact Muffler (LECM) is being used to replace the cyclone separator and address brine carryover during discharge test. The application of tracer flow testing (TFT) method can also be an option in establishing well flows during horizontal discharge test. The TFT method was initially developed for the on-line measurement of brine and steam flows and total enthalpy within a pipeline carrying two-phase geothermal fluid.

The well testing process at Patuha was initially designed for single phase/dry steam wells. The Patuha-2 wells are tested using a Low Emission Compact Muffler unit that allows the anticipated brine component to be separated from the steam and collected in a well site disposal pond while the steam is discharged directly into the atmospheric separator. The initial discharge of the Patuha-2 wells contained some drilling debris and good amount of brine that presented some challenges in addressing Brine Carry Over (BCO). Noise emission is generally acceptable for the single-phase discharge, but the noise levels become a concern after dry steam discharge follows, which also becomes an issue to the surrounding community.

The application of a Low Emission Rock Muffler Container was then evaluated to address the above issues especially the increased noise emission levels. The inlet pipe, complete with the header and perforated pipes, were fabricated and installed inside the container. The tank was then filled with porous rocks to reduce the produced noise level. This work can be conducted in short time using available materials in the field and can meet the standard criteria of environmental aspects.

3. ENGINEERING CALCULATIONS

The process design of Rock Muffler Container considers two methods of analyses namely:

3.1 Fluid Velocity Analysis

For pipe sizing, velocity analysis is conducted to ensure fluid velocity will not cause pipeline erosion which will shorten operating life of the pipeline. For orifice hole/perforation sizing, velocity analysis is also conducted to obtain the required pressure for the steam to pass through the holes with specified mass flow rate. Another consideration is that the rock muffler will exhaust steam which has certain mass flow rate and velocity to drag/carry the rocks. Therefore, the drag force produced should not exceed the force exerted by the rocks due to gravity to make sure the rocks will not be blown away from the rock muffler container.

For Patuha well PTH-X-1 well testing case, by assuming the median pipe pressure rate during well testing line to be 18.6 bars in 12” Flowline Sch. 40 API 5L Gr. B pipe with mass flow rate is 20 kg/s, the calculated steam velocity is around 36.5 m/s. This fluid velocity is below the maximum velocity limit for dry steam of 60 m/s.

Hence, the calculated velocity is considered acceptable considering the short term well testing duration. Routine intensive pipe thickness monitoring was also conducted to assure the pipeline reliability.

Orifice hole sizing was performed iteratively. With upstream pressure of 3.56 bara at the header pipe and downstream pressure of 2.97 bara, the diameter of hole (perforations) is measured at 27 mm with total mass flow rate is 20 kg/s (or 72.27 ton/hr.) for estimated total of 600 holes. The velocity in each hole is estimated at about 62.68 m/s (see calculation in Table 1).

Assuming the surface area of rock muffler tank is 20% and using Coefficient of Drag (Cd) of 2 and rock density of 2,500 kg/m3 with diameter (sphere type) of 200 mm, the calculated drag force is 5.3 N. This drag force is still much lower than rock's gravity force of 102.7 N. Further calculation is conducted using smaller rock diameter of 20 mm; the calculated drag force is about 0.05 N. This drag force is still lower than rock's gravity force of 0.10 N (see calculation in Table 2). Thus, it is concluded that the rocks will not be blown away from the tank for diameter greater than 20 mm.

Table 1: Calculation results for velocity analysis.

Description		Unit
Beta	0.7	
C	0.61	
Upstream P	3.56	barg
Downstream P	2.97	barg
Delta P dP	0.59	barg

Gravity	9.81	m/s2	9.81	m/s2
Drag	5.32	N	0.05	N
Gravity Force	102.74	N	0.10	N

3.2 Strength Analysis

Strength analysis was also conducted to ensure a fluid pressure below the limit of design pressure to have a long operating life. Pipe bursting pressure of 10.3/4 inch Grade K 55, #40.5 ppf is 1580 psi or 108.93 bar, which is much higher than shut in pressure of well PTH-X-1 (18.6 bar).

4. LOW EMMISSION ROCK MUFFLER CONTAINER VS LOW EMMISION COMPACT MUFFLER

The main issue with the flow test of PTH-X-1 is its proximity to the nearby household community (areal distance ~1 km) that would likely present concern on elevated noise emission levels during discharge test. GDE has then

implemented the use of Rock Muffler Container to address the issue. The bottom part of the LECM was then modified where the 12" inlet pipe was connected to a header pipe with several perforated pipes attached to the header. Several layers of rocks are then placed on top of the discharge pipes inside the bottom rock muffler container.

The performance of LERMC was evaluated by comparing the following discharge parameters against the parameters obtained from the previous discharge test of well PTH-Z-1 using the 20 ft LECM:

a. Noise Measurement
b. Exposure of Brine Carry Over

The noise levels recorded during PTH-X-1 discharge using the rock muffler LERMC ranged from about 69 to 88 dBA within 10 meters radial distance as summarized in Table 3 below. The noise levels obtained during PTH-Z-1 discharge using LECM ranged from 98 to 109 dBA which were much higher than noise levels using LERMC.

Table 3: Comparison of noise level monitoring results.

Day No	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
LERMC noise (dB)	83.7	77.6	69.3	69.2	71.8	80.4	72.1	84.1	81.3	85.2	82.3	78.4	85.1	86.4	87.8	85.5	88.5
LECM noise (dB)	102.3	104.2	97.9	105.1	105.2	106.2	108.8	107.1	105.4	106.6	105.2	105.4	105.7	105.0	105.2	105.2	104.0

The noise level measurements in the nearby community during PTH-X-1 discharge was found to be below 60 dBA which is much lower than the prescribed WHO noise level threshold at around 85 dBA during daytime. Figure 5 below summarizes the noise level monitoring during PTH-X-1 (LERMC) and PTH-Z-1 (LECM) discharge test.

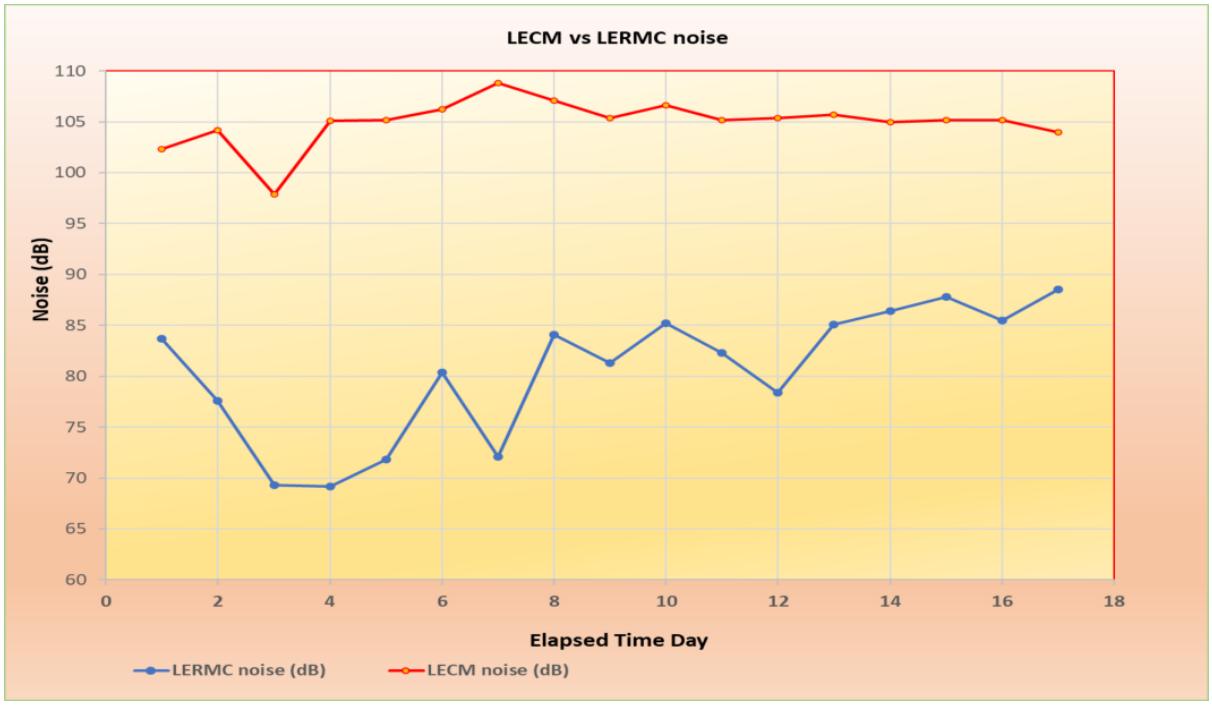

Figure 5: Noise level comparison plot.

Exposure of Brine Carry Over (BCO) was also evaluated, during PTH-Z-1 discharge test using LECM. BCO was observed within 20-to-30-meter radius of LECM. The BCO observed during PTH-X-1 flow test using LERMC is within 5 to 10 meters radial distance. The results obtained may not be conclusive since other factors such as wind speed and direction may likely affect the BCO evaluation.

5. PALM FIBER OPTION TO ADDRESS BCO

The upper component of LECM includes the Mist Pads to address the Brine Carry Over during the well discharge tests in Patuha. The Mist Pads become damaged, and its performance deteriorated after several Patuha wells tested that prompted GDE to examine other options to address BCO. The use of Palm fibers was tested and the upper LECM component was modified to accommodate the Palm fibers. Application of Palm fibers provided good control of BCO with succeeding discharge tests. Figure 6 below shows the typical Palm fiber installation undertaken during the Patuha well discharge tests.

Figure 6: Typical Palm fiber installation during Patuha well discharge test.

6. SUMMARY AND CONCLUSION

Discharge testing of Patuha-2 production wells using the abovementioned novel solutions successfully addressed the Brine Carry Over (BCO) and Noise level emission issues.

Some conclusions and recommendation are made for this study as follows:

a. The Rock Muffler Container (LERMC) can be used for well testing purposes in dry steam wells. The fluid velocity limits should be considered, which depends on well flow capacity. Further study of container rock muffler design is recommended.
b. The Rock Muffler Container (LERMC) can effectively reduce Noise emission levels and Brine carry over.
c. Application of Palm fibers to replace the Mist Pads was successfully implemented. The cost-effectiveness of using Palm fibers against the Mist Pads was successfully demonstrated apart from its single advantage to be ecofriendly.

ABSTRACT

Geothermal energy is an important renewable energy source in reducing dependence on fossil fuels. Based on the fluid phase in the reservoir, geothermal systems are divided into single phase systems (vapor dominated) and two phase systems (water dominated). In the Dieng field, it is included in the two phase fluid system (water dominated) which contains 60% liquid phase (brine) and 40% steam phase. The PLTP generation system is a generation system that utilizes geothermal energy in the form of steam. The steam used to rotate the turbine contains chemical elements that cause scale, corrosion and erosion on the turbine. This steam will experience a decrease in pressure, temperature, enthalpy and chemical content. Steam quality is defined as a physical aspect which includes temperature (superheat), dryness (water content in a liquid state), and non-condensable gas content. High levels of impurities in the steam will reduce the purity level of the steam. It is necessary to analyze the quality of steam to get good steam. Monitoring parameters starts when steam flows to the turbine and condenser. When steam is flowed to the turbine, parameters such as Wetness, Non-Condensable Gas (NCG), Cl and SiO_2 content, Na content, total dissolved solid (TDS) will be obtained. Total dissolved solids (TDS). Then a standard will be obtained to maintain the quality of geothermal steam. If the NCG value is below 2% then it can be said that the steam quality can be used well. If the steam has a small solids content below 300 then the TDS value is said to be safe and unlikely to cause corrosion. If the steam parameters contain Cl and SiO_2 which have values below 1 ppm, the steam quality is said to be good for society. Likewise, with a Na content that has a value below 0.1 ppm, if the steam has a small Na content, the steam is said to be good. If steam has a Wetness value of less than 1% then the steam is said to contain little water.

1. INTRODUCTION

Geothermal comes from the words Geo which means earth and Therm which means heat. Geothermal energy itself is an environmentally friendly energy source that comes from the heat contained in hot water, water vapor and rocks along with their associated minerals and other gases, all of which cannot be separated genetically in a geothermal system and to utilize them requires several stages. processing.

The hot fluid will press against the surrounding rock to find a gap or way out and release the pressure. Because the pressure is higher than the pressure at the surface, the fluid will move up through the cracks. The fluid will come out as a surface manifestation. Based on the fluid phase in the reservoir, geothermal systems are divided into single phase systems (vapor dominated) and two phase systems (water dominated). In the Dieng field, it is included in the two phase fluid system (water dominated) which contains a water dominated system which is 60% liquid phase (brine) and a vapor dominated system which is 40% steam phase.

Geothermal energy is an alternative energy that has great potential to be developed in the future, especially for use as electricity generation energy, replacing dependence on the use of hydrocarbon energy sources whose reserves are decreasing day by day. Indonesia has geothermal resources reaching 40% of the world's potential and is a renewable energy source and environmentally friendly energy in its production stage. The Dieng geothermal field began to be developed in 1990. The installed power plant with a capacity of 60 MW began operating in 1998. There are 3 prospect areas in the Dieng geothermal field, Sileri, Sikidang and Pakuwaja.

Steam field project owned by PT. Geo Dipa Energi, located in Dieng, is a geothermal company operated to produce electrical power. In the geothermal processing process, of course there are many installations and pipe networks used for various geothermal production activities, one of which is the distribution pipe as a medium for transporting steam and brine.

PLTP Unit I Dieng has 44 production wells including injection wells, however, due to limitations in some wells which are no longer able to produce steam or damage to the reservoir, only 8 wells are operated as steam suppliers with an installed production capacity of 60 MW, whereas for PLTP's own injection wells The Dieng unit has 8 injection wells. On average, these production wells have a depth of around 3000 m below the earth's surface.

Each well has a different wellhead pressure ranging from 20 - 45 bar, and is capable of producing steam with different capacities. To be able to drive the turbine driving the generator requires steam that is really clean and has the lowest possible humidity level so that it is not damaging to the turbine. Because the quality of the steam produced by the Dieng production well is very low, a very complex steam processing system is needed starting from the production well, steam separation, gathering system, to the power plant.

Basically, geothermal production equipment is very important in the ongoing geothermal production to be transported to the power plant to act as a generator and power plant driver.

2. THEORY REVIEW

2.1 Steam Production Components

The steam production components here are equipment or construction related to steam production from geothermal sources. The equipment and construction include:

a) Production Well

A production well is a well that produces geothermal steam at a depth of around 3000 m below the ground surface. This well produces wet steam which still contains water so it must be separated using a separator.

b) S-bend

The S-bend functions to flow two-phase fluid from the production well to the throttle valve.

c) Throttle Valve

The throttle valve functions to regulate the flow rate and at the same time to regulate the pressure at the wellhead. The purpose of regulating pressure through the throttle valve is to prevent scaling in the wellbore. Throttle valve opening is adjusted to SSI (Silica Saturated Index).

d) Two-Phase Flow Pipe

This pipe functions to convey two-phase fluid originating from the well to the separator. This pipe has various sizes, namely: 12", 16" and 18".

e) Rupture Disk

The rupture disk functions as a safety measure if excess pressure occurs in the pipe located before the separator and in the separator. The rupture disk will break if the pressure exceeds the set pressure and the fluid will flow directly to the AFT/free silencer so that the pipe is safe from damage.

f) By Pass Valve

The function of the by pass valve is to flow two-phase fluid directly to the AFT/silencer when the well is opened or when it is about to operate, namely to check the cleanliness of the fluid before it flows to the separator. Fluid is considered clean if the results of brine sampling analysis meet existing standards, especially chloride (Cl) analysis.

g) Separator

The separator functions to separate the two-phase fluid from the production well into a vapor phase and a liquid phase. When the 2-phase fluid enters the separator, the steam will rise to the top while the brine will fall to the bottom. The steam formed is used to drive the turbine through a gathering system. The brine will be pumped by a brine pump to be injected back into the earth. The type of separator used here is a cyclone separator with a working pressure ranging from 10-14 bar.

h) Dump Valve

The function of the dump valve is to maintain the brine level in the separator according to the set point. If the dump valve experiences problems, it will fail to close which will flow to the AFT/silencer.

i) Acid Pump

The acid pump functions to pump acid into the brine through a nozzle located downstream of the separator. The acid used is sulfuric acid (H_2SO_4). This acid functions to maintain the pH of the brine between 4.7-5.2, thereby slowing down the deposition of silica in the brine distribution pipe.

j) Seal Water Pump

The water pump seal functions to pump water into the flow pipe which is paired in series with the acid pump to dilute the acid and is used as a mechanical seal water pump.

k) Atmospheric Flash Tank (AFT)/Silencer

The Atmospheric Flash Tank (AFT) or silencer functions to reduce the level of noise resulting from the production process, to flash the brine so that low pressure brine is obtained and to control the flow of fluid to be discharged. On the inside of the AFT there is a plate which is useful as a sound dampener.

l) *Kanal*/Ditch

The canals or ditches in the pad function as a place to drain the brine originating from the AFT. The brine that comes out will experience a decrease in temperature and pressure, when the temperature and pressure decrease there will be a separation of silica and brine.

m) *Balong* (Pond)

Balong or pond is used to accommodate the brine that comes out of the AFT/silencer. Brine from each pad in the batang (pond) is distributed using a brine pump to be re-injected through the injection well.

n) Silica Holding Area

Silica from the *balong* (pond) in each pad is deposited and then taken and stored in a silica reservoir. The reservoir has a filter which functions to filter the brine that enters the silica. The filtered brine is pumped to pond 29 and then injected into DNG-10 and HCE 29-A.

o) Condensate Drop Port (CDP)

The condensate drop port (CDP) is a place to dispose of condensate formed along the steam distribution on the steam line to the power plant. CDP also functions to release condensate to keep the steam quality dry until it reaches the turbine. CDP has several components such as a chamber, 1.5" and 2" valves, and a steam trap. The chamber functions to collect the condensate that is formed. The steam trap functions to automatically release condensate as a place for water vapor (condensate) output.

p) Condenser

The condenser is a tube-shaped device filled with water which functions to cool the brine by using tubing which has a spiral shape to ensure cooling occurs during brine sampling.

2.2 Steam and Brine Distribution Components

The steam and brine distribution components here are equipment related to the distribution of the results of the separation separator. This equipment includes:

a) Injection Pump (Brine Pump)

The brine pump functions to flow the brine resulting from the separation from the separator to the pond.

b) Booster Pump

A booster pump is a pump used to increase brine pressure which is installed in series with the brine pump. This pump is only used if the discharge pressure from the brine pump is insufficient.

c) Steam Line

A steam line is a pipe-shaped medium for flowing steam from a production well to a turbine which is usually 36” in size.

2.3 Supporting Components

Supporting components here are equipment or construction related to the process of generating power from the steam produced. The equipment and construction include:

a) Wellhead

A wellhead or what is usually called a well head is surface well control equipment made of steel which forms a seal system which is useful for preventing bursts or leaks of well fluid to the surface. This wellhead functions to control the flow rate of the well, monitor well head pressure, and act as a support for the casing string. In this well head there are several parts as follows:

1) Annulus Valve

The function of the annulus valve is to determine whether the production casing is leaking or not. In this component, a manometer is installed which functions to see the pressure in the valve annulus.

2) Wing Valve/Side Valve

The wing valve or side valve functions for well bleeding, which means that when the well is not producing, it does not emit steam from the top. This wing valve is used to release steam so that it does not die, because if it dies it will experience steam condensation which causes the steam to decrease in temperature so that the bowels of the earth will not reach the perfect boiling point. Apart from that, the wing valve also functions as a wellhead pressure indicator.

3) Angle Valve

The angle valve functions as a way for injection fluid to enter when well logging is carried out. When logging, the production well needs to be killed first so that no fluid will flow to the surface. Apart from that, this angle valve also functions as a wellhead pressure indicator.

4) Master Valve

The master valve is composed of an upper master valve and a lower master valve. This master valve functions to open and close the well fluid flow. The master valve is a type of gate valve, so the master valve is always 100% open (fully open) or 100% closed (fully closed). The master valve must not be left half open because there will be turbulence in the flow which can cause erosion at the corners of the gate.

5) Flow-T

Flow-T is a component that functions to direct fluid flow from the master valve to the s-bend.

6) Crown/Top Valve

The crown/top valve functions as a well survey route. Used for well maintenance, pressure and temperature measurements, and well logging.

b) Mixing Tee

Mixing Tee functions as a mixture of acid and clean water (seal water).

c) Weirbox

The Weirbox functions to roughly determine the flow rate of the production fluid and the quality of the fluid. There are 3 types of weirboxes that are often used, namely: rectangular, suppressed, triangular. The type often used in Dieng Unit I is the rectangular weirbox type. Currently the weirbox is no longer used because of the large amount of silica that has deposited.

d) Valves

A valve is a component that functions to control flow and pressure in a system. In general, the types of valves used, especially at PLTP Dieng, are gate valves, ball valves and check valves.

e) Sumur Injeksi

Injection wells function to inject cooled brine into the bowels of the earth. This is done by keeping the cycle in the bowels of the earth running, so that the Dieng PLTP process can continue to produce.

2.4 Electric Power Plant Component

Power generation components here are equipment or construction related to the process of generating power from the steam produced. The equipment and construction include:

a) Rock Muffler

A rock muffler is a block-shaped structure containing rocks which functions as a safeguard for steam from excessive pressure before it enters the power plant, as well as reducing noise that occurs when steam is emitted.

b) Scrubber

A scrubber is a tool that has the same function as a separator, namely as a final separator before the steam enters the turbine, as well as as a steam purifier. The purpose of this separation in the scrubber is to separate the steam from the water that is still carried during the distribution of steam in the steam line. By using a scrubber, it is hoped that the steam entering the turbine is truly dry steam that is free from the liquid phase.

c) Demister

A demister is a tool in the form of a cylindrical tube and inside it there is a grid to eliminate water droplets and solid particles contained in the steam. This component functions as a filter for particles that are still carried by the steam, so that the steam entering the turbine is completely dry. This is done as an effort to avoid vibration, erosion and scale formation processes on the turbine.

d) Turbin

The turbine functions to drive a generator using steam power from a production well that has been processed first.

e) Governor

The governor functions to control the steam entering the turbine. By controlling the amount of steam entering the turbine, the turbine rotation can also be adjusted to either increase or decrease. The governor consists of two components, the first to measure or detect speed, the second to translate this measurement into movement at the governor output to control equipment that regulates the amount of steam entering the turbine.

f) Generator

The generator functions to produce electricity from the rotation of the turbine. The generator used has an installed capacity of 60 MW, frequency of 50-60 Hz and rotation speed of 3000 rpm.

g) Transformator

A transformer is equipment used to increase or decrease voltage. 15kV/150kV step up transformer and 150kV/15kV step down transformer. This transformer has two functions, when the generator is on, the transformer functions to step up or increase the voltage from 15kV to 150kV. If the generator is being overhauled or is not operating, the transformer functions to step down or reduce the voltage obtained from PLN by 150kV to 15kV.

h) Main Condenser

The steam that has been used to drive the turbine is fed into the condenser which functions to condense the steam that has been used to rotate the turbine. The condensation process is carried out by mixing the steam coming out of the turbine with cooling water directly. Cooling water is obtained from the cooling tower which is sprayed at the top of the main condenser.

i) Steam Ejector

This component functions to maintain vacuum conditions in the condenser by sucking in non-condensable gas (NCG) or gas that cannot be condensed in the main condenser and expelling it through the cooling tower by being sucked in by the fan and expelled into the open air.

j) Hot Well Pump

This pump is very vital for use in power plants. This pump is directly connected to the main condenser, namely to drain condensate with a temperature of 33°C to be cooled to the cooling tower. The amount of condensate with a volume of around ±5,400,000 liters requires a pump with a very large capacity to move it, especially since the steam supply from the turbine runs continuously so that to keep the main condenser vacuum (with a water level of around 40% of the total volume), the condensate must be moved , this is done because the condensed steam will increase the volume of the condensate.

k) Cooling Tower

The type of cooling tower used is a mechanical draft cooling tower. In a mechanical draft cooling tower, hot water from the condenser is sprayed on a wooden structure in layers called fill. When passing through the fil, heat transfer occurs from the hot water to the air (at the top of the cooling tower there is a fan). The cooling tower used has 9 pairs of fans.

2.5 Geothermal Power Plants

The electricity generation process at the Dieng PLTP has several stages, namely separating steam and brine in the separator, removing moisture from the steam (moisture remover) in the scrubber, then the steam is passed to the turbine and produces electricity in the generator. Steam quality plays an important role in geothermal power plants. High levels of impurities in the steam will reduce the level of purity of the steam. If the steam used to rotate the turbine contains impurities, it is likely that the turbine will experience corrosion so that the rotation of the turbine rotor connected to the generator does not work optimally, which will result in the generator's output power not being optimal. Therefore, it is necessary to analyze the quality of steam to get good steam.

In geothermal power plants (PLTP), various types of fluids such as hot water, hot steam, salt solutions, organic fluids, supercritical CO2, and hydrocarbon fluids are used based on the geological characteristics and temperature of the PLTP location to produce electrical energy.

PLTP Dieng is a Geothermal Power Plant located in the tourist area of Dieng, Central Java. Dieng PLTP is one of several PLTPs owned by PT Geo Dipa Energi (Persero), a company operating in the geothermal energy sector in Indonesia. PLTP Dieng has a capacity of 60 MW and consists of two units, namely Unit 1 and Unit 2. Unit 1 has been operating since 2011, while Unit 2 is currently under construction and is expected to be operational in 2024.

In an effort to increase the use of geothermal energy in Indonesia, the government is targeting increasing the role of geothermal energy in the energy mix for electricity generation from 5% to 11% by 2025. This is in line with the vision of PT Geo Dipa Energi (Persero) to become a thermal energy company leading earth in Indonesia and contributing to national energy security.

The type of PLTP development in Dieng uses the flash PLTP type. PLTP Flash Steam uses hot water mixed with steam from a geothermal reservoir as a working fluid. This hot water has a temperature higher than its boiling point at atmospheric pressure. When this hot water is drawn to the surface and the pressure is reduced, it boils and turns into steam. The steam produced is used to drive turbines and electric generators.

Flash PLTP is more flexible than dry PLTP. The advantage is that it can be used in areas with geothermal sources that contain hot fluids, even in areas with lower geothermal temperatures.

The steam that flows into the turbine then moves the turbine rotor and spins the generator. The electric charge is also generated from the rotation of the magnet in the generator and the electricity flows through copper cables to the transformer where the voltage is increased before being distributed to homes. After the steam works in the turbine, the remaining steam from the turbine (exhaust steam) which has lowered pressure and temperature will flow to the condenser to be condensed (water steam). Main steam comes out of the turbine along with the NCG (Non Condensable Gas) contained in it. The condensation process is assisted by cooling water to speed up the phase change process. Meanwhile, NCG from the condenser is pulled by the ejector towards the intercondensor and then cooled using cooling water by spray which is pumped by the ACWP (Auxiliary Cooling Water Pump) from the cooling tower.

The condensate from the condenser is then pumped by the HWP (Hot Well Pump) to the cooling tower. If the water level in the cooling tower is excessive, it will be channeled to the injection well to increase natural filling of the reservoir to maintain reservoir pressure and extract more heat from the hot reservoir.

2.6 Steam Quality

The PLTP generation system is a generation system that utilizes geothermal energy in the form of steam. The steam is obtained from wells that have been made by Pertamina. Steam from the well is channeled to the steam receiving header, which functions to ensure that the steam supply does not experience disruption even if there is a change in supply from the production well. The steam is channeled to a separator to separate solid substances, silica and water spots carried in it. This is to avoid vibration, erosion and scale formation on the turbine which will rotate the generator.

The quality of geothermal steam is no less than boiler steam. Under the same pressure conditions, geothermal steam is usually drier than boiler steam due to its superheated nature. General parameters of steam quality are Wetness, Non-Condensable Gas (NCG), Cl and SiO2 content, Na content, total dissolved solid (TDS). Total dissolved solid (TDS) is the total amount of substances dissolved in water. The dissolved solids or salt content of water present as ions increases the electrical conductivity of water. The higher the conductivity, the greater the potential for corrosion. A higher value of total dissolved solids will reduce the rate of heat transfer, increase scale deposits and will increase heat loss (Kamal, 2019).

Steam quality is defined as a physical aspect which includes temperature (saturated), dryness (water content in liquid condition), and non-condensable gas content. High levels of impurities in the steam will reduce the purity level of the steam (<1). Taking into account the decrease in pressure and temperature which will have an impact on reducing the MW produced and allow condensation to occur in the steam flow pipe which will result in corrosion of the turbine which will endanger the continued operation of the geothermal plant.

The steam used to rotate the turbine contains chemical elements that cause scale, corrosion and erosion on the turbine. This steam will experience a decrease in pressure, temperature, enthalpy and chemical content. Steam quality is defined as a physical aspect which includes temperature (superheat), dryness (water content in a liquid state), and non-condensable gas content. High levels of impurities in the steam will reduce the purity level of the steam. Geothermal steam contains many minerals such as salt, silica, sodium and other minerals. Most of the decline that occurs in steam is behind the decline in steam quality (Triyana, 2016).

To calculate steam quality, use the equation (Muharrir & Hajar, 2019):

$$x = \frac{s1 - sf}{sg - sf} \quad (1$$

Where :

x = Steam Quality, S1 = Entropy Value Steam Pressure Entry of turbin, sf = Entropy values saturated liquid Steam pressure out Turbine, SG = Entropy values saturated vapor vapor vapor pressure out of turbine.

Entropy is a thermodynamic quantity that functions to measure energy in units of temperature that cannot be used to do work. The entropy of a closed system will always increase and in heat transfer conditions the heat energy will move from components at high temperature to components at low temperature. To determine the enthalpy and entropy values of the steam used in the generating system in this research, you can use a saturated steam table. If the pressure or temperature data is inaccurate, it is necessary to interpolate the data. In this research, data interpolation can be used, which is intended to determine a value that is between two known values. This interpolation is based on comparative theory. In this study, comparisons were made between the steam pressure value entering the turbine and the enthalpy of saturated vapor (h1), the value of the steam pressure entering the turbine with the entropy of saturated vapor (s1), the value of the steam pressure leaving the turbine with the enthalpy of saturated liquid (hf), the steam exiting pressure. turbine with saturated vapor enthalpy (hg), turbine exit steam pressure with saturated liquid entropy (sf), and turbine exit steam pressure with saturated vapor entropy (sg).

3. RESEARCH METHODOLOGY

3.1 Introduction

By reviewing related and relevant literature, both literature from the company and outside the company, interviews and field observations at the company.

3.2 Data Collection

The data required is standard parameter monitoring data from the fluid laboratory.

3.3 Data Analysis

To maintain steam quality, it is also necessary to analyze the parameters that are monitored. One way to maintain steam quality can be seen from measuring the efficiency of the separator which can be done by comparing the chloride (Cl) content between steam and brine. Checking chloride levels in steam and brine is carried out using the Mohr argentometric titration method and analysis of chloride (Cl) content is carried out in the laboratory. The smaller the concentration of chloride that dissolves or is carried away by the steam, the better the working efficiency of the separator as a separation tool to produce good quality steam. Table 1 is the standards for monitoring steam quality parameters. Optimizing and maintaining steam quality can be seen based on standards set by the laboratory.

Table 1: Steam Quality Standards.

Parameter	Geothermal Steam
Non-Condensable Gas (NSG)	Less than 2%
Steam Wetness	Less than 1%
Cl Content	Less than 1 ppm
SiO2 Content	Less than 1 ppm
Na Content	Less than 0,1 ppm
Total Dissolved Solid (TDS)	Less than 300

4. DISCUSSION

As can be seen in the picture, monitoring parameters starts when steam flows to the turbine and condenser. When steam is flowed to the turbine, parameters such as Wetness, Non-Condensable Gas (NCG), Cl and SiO_2 content, Na content, total dissolved solid (TDS) will be obtained. Total dissolved solids (TDS). Then a standard will be obtained to maintain the quality of geothermal steam. If the NCG value is below 2% then it can be said that the steam quality can be used well. If the steam has a small solids content below 300 then the TDS value is said to be safe and unlikely to cause corrosion. If the steam parameters contain Cl and SiO_2 which have values below 1 ppm, the steam quality is said to be good for society. Likewise, with a Na content that has a value below 0.1 ppm, if the steam has a small Na content, the steam is said to be good. If steam has a Wetness value of less than 1% then the steam is said to contain little water. Steam temperature is also an important factor the quality of a geothermal well.

The higher the steam temperature, the better the quality. From the observation results, the steam temperature was quite stable for each well. Laboratory analysis of well condensate samples (SCS) shows that the anion and cation content is relatively stable. The concentration of silica in well fluid is still far below the solubility of silica at temperatures above 100oC, but developments must still be monitored. An increase in the Sulphate/Chloride ratio can indicate the entry of water resulting from steam heating into the reservoir.

ABSTRACT

In the dynamic landscape of geothermal energy production, Karaha Bodas stands as a significant asset within the portfolio of PGE. Despite its importance, the power plant at Karaha Bodas has faced challenges, notably a high reservoir decline rate of 24% since 2019. The PGE drilling campaign of 2023-2024 initially targeted the drilling of only a single well in the Talaga Area, namely the TLG-3.4 well. Well TLG–3.4 aimed towards the western side, where the fracture network is predominantly composed of pyroclastic rocks, fault models, and lateral permeability, with a planned total depth (TD) of 2400 mMD. However, the drilling operation encountered significant challenges, including a stuck pipe and Lost in Hole (LIH) at a depth of 2189 mMD within the 12-1/4" hole section. Despite these challenges, the well managed to recover three out of four drilling targets. Encouraged by the promising results from logging surveys, PGE Management decided to expedite the drilling campaign by adding the TLG-3.5 well to the schedule. Targeting a similar direction as TLG-3.4, the TLG-3.5 well aimed to leverage on the potential identified in its predecessor while striving for optimal outcomes and embracing the challenge of reaching the planned target depth. With approximately only one month of preparation, the PGE Drilling Team conducted a thorough internal evaluation to address operational and engineering concerns from the stuck pipe incident in TLG-3.4. This paper presents the success story of the PGE Drilling Team in the drilling of the TLG-3.5 well, achieving the target total depth without encountering a stuck pipe and minimizing Non-Productive Time (NPT) to a remarkable 0.35%, compared to TLG-3.4's NPT of 15.74%. It underscores the resilience, adaptability, and technical prowess demonstrated in overcoming obstacles and advancing geothermal exploration in Karaha Bodas.

1. INTRODUCTION

In the GWA (Geothermal Working Area) Karaha-Cakrabuana located in West Java, Indonesia, there is a geothermal prospect known as Karaha-Talaga Bodas. Within this prospect, GGGR (Geological, Geophysical, Geochemical, and Reservoir) studies and drilling have been conducted. Based on the GGGR study, the reservoir is divided into three areas, each with different characteristics. The southern part (Talaga) is a reservoir area with acidic reservoir fluid. The central part (Karaha) is a reservoir area with neutral pH fluid. The northern part (G. Putri) is a reservoir area with medium temperature and low permeability. Based on the reserve calculations using the volumetric heat stored method, it is concluded that the proven reserves of the Karaha geothermal prospect are 30 MW. Geothermal system of Karaha–Talaga Bodas is partially vapor-dominated and fracture-controlled, situated in the northern area of the Galunggung Volcano.

Currently, there is only one power plant unit in this region, commissioned in 2018. The Karaha Power Plant, operated by PT Pertamina Geothermal Energy Tbk, has installed capacity of 30 MW, contributing substantially to the region's energy needs. Despite its importance, the power plant at Karaha Bodas has faced challenges, notably a high reservoir decline rate of 24% since 2019 due to several subsurface issues such as very acidic reservoir fluid, scalling problem, well integrity concerns, and other complications.

Despite these intricate challenges, PGE perseveres in continuously seeking strategic solutions to restore the Karaha Power Plant to its original production capacity. As part of the solution, initially a single make–up well, named TLG–3.4 will be drilled in the Karaha area during PGE 2023 – 2024 drilling campaign. TLG–3.4 well aimed towards the western side, where the fracture network is predominantly composed of pyroclastic rocks, fault models, and lateral permeability, with a planned total depth (TD) of 2400 mMD. Unfortunately, it didn't turn out smoothly according to plan. During the drilling operation, challenges such as rig equipment problem, water supply shortage, slow rate of penetration (ROP), and pipe stuck were encountered. The Non-Productive Time (NPT) for this well amounted to 170 hours, with 100 hours due to pipe stuck incidents, 46 hours due to shortage of water supply, 20 hours due to rig equipment failure, and 3.5 hours due to aerated drilling equipment failure. The financial loss due to the pipe stuck incidents is estimated to be around 1.1 million USD for compensating the BHA equipment left in the wellbore, along with an additional 500,000 USD in daily operational costs for the efforts to

free the stuck pipe. With an NPT of 170 hours, or approximately 15.7% of the total drilling duration and the final total depth (TD) that could be reached only 1940 mMD due to pipe stuck and lost in hole event, there are many aspects that need to be mitigated and improved to ensure that future well drilling in the Karaha-Talaga Bodas area can be conducted more effectively and efficiently.

Despite these incidents, the well managed to recover three out of four reservoir targets with promising logging surveys results. With this good news, PGE Management decided to expedite the drilling campaign by adding the TLG–3.5 well to the schedule. Targeting a similar direction as TLG–3.4, the TLG–3.5 well aimed to leverage on the potential identified in its predecessor and enhance steam supply to Karaha Power Plant Unit 1. With approximately only one month of preparation, the PGE Drilling Team conducted a thorough internal evaluation to address operational and engineering concerns from the stuck pipe incident in TLG-3.5.

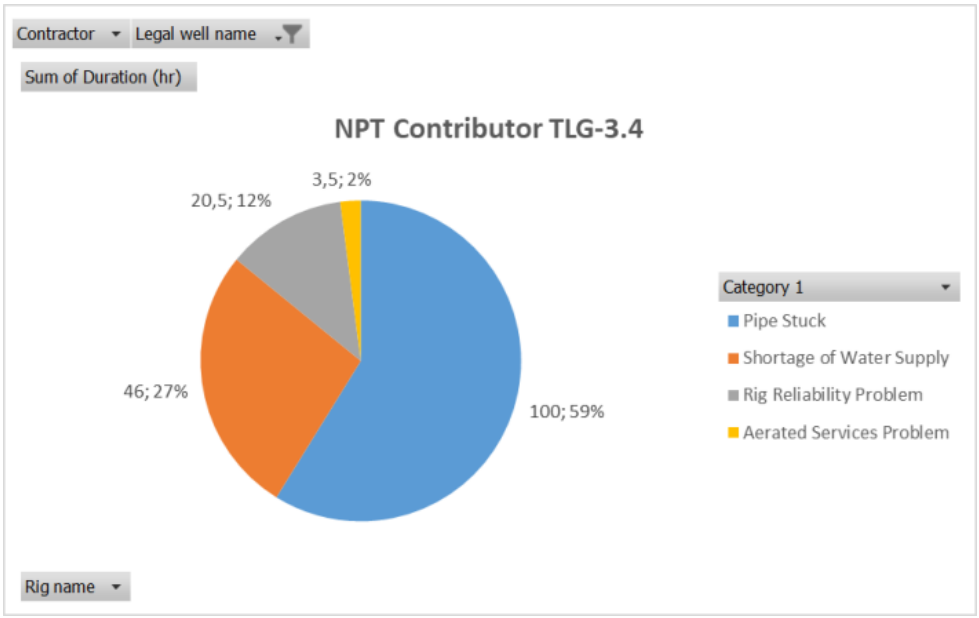

Figure 3: NPT Contributor TLG-3.4 Well.

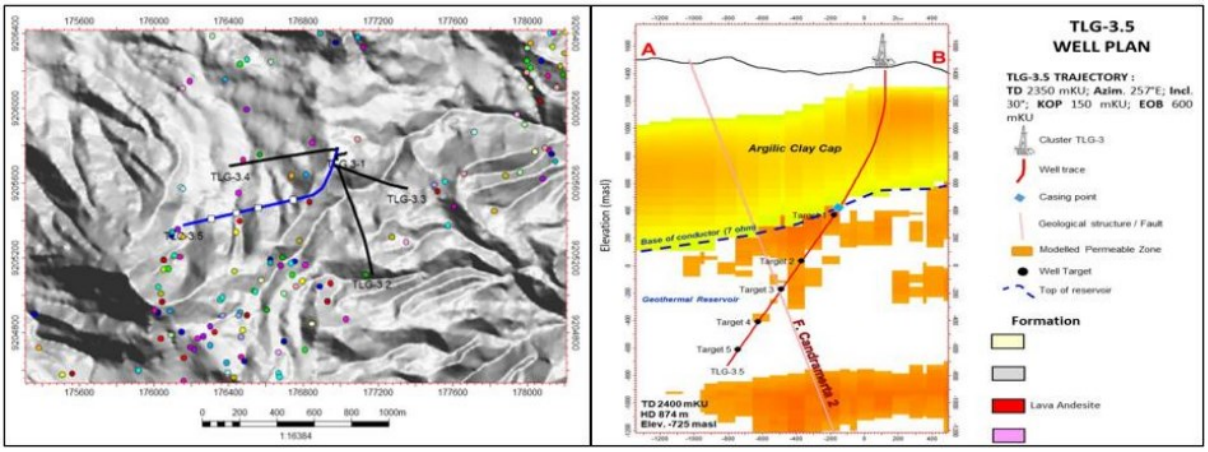

Figure 4: Target Map of Drilling TLG-3.5 Well.

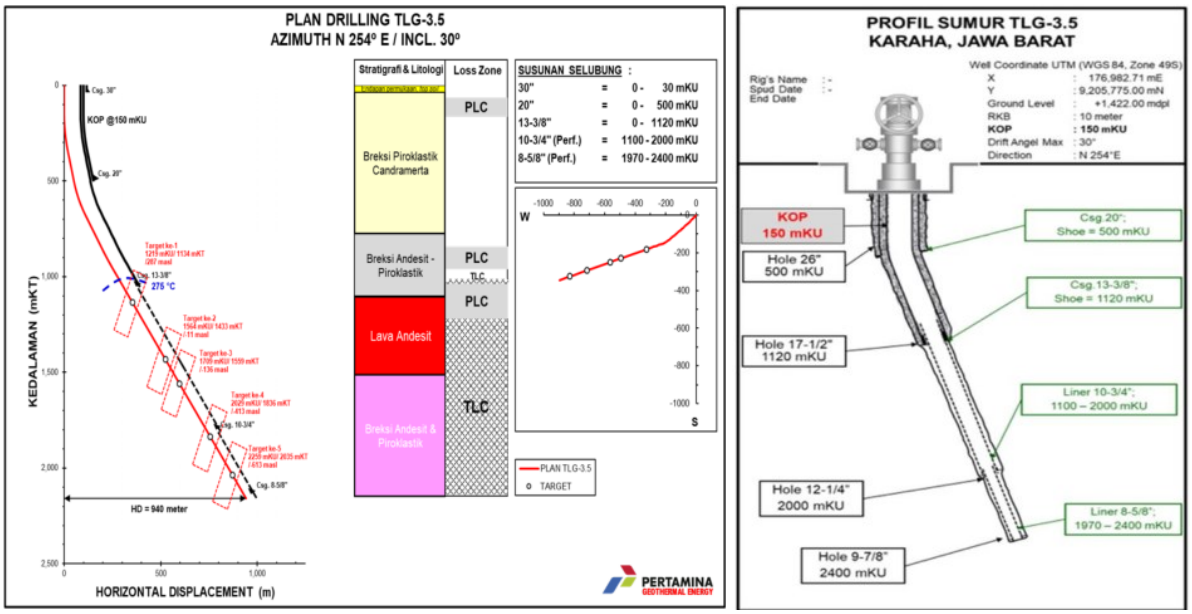

Figure 5: Directional Drilling & Well Profile Plan TLG-3.5 Well.

With well budget allocation and planned drilling time similar to TLG-3.4, the TLG-3.5 well is designed as big hole well type with 5 hole sections (36", 26", 17-1/2", 12-1/4", 9-7/8") and total depth (TD) of 2400 mMD.

2. KARAHA BODAS KEY CHALLENGES

2.1 Short Preparation Time For Materials And Documents

Originally there were no plans to drill the TLG-3.5 well during the 2023-2024 drilling campaign which made this a significant shift in strategy. The decision to drill the TLG-3.5 well was made on short notice due to the promising steam potential discovered in the TLG-3.4 well. PGE management recognized the opportunity to optimize mobilization costs and accelerate the fulfillment of steam supply needs, so they decided to move forward with the TLG-3.5 well immediately after the completion of TLG-3.4. As a result, the PGE drilling team faced the challenge of preparing for this new well in a compressed timeline of approximately 1.5 months, starting from scratch. The compressed timeframe presented several challenges:

- **Budget Administration**: The allocation and approval of the budget for TLG-3.5 had to be fast-tracked. This required intense coordination between the drilling team and PGE's financial department to ensure that funds were made available without delay. Streamlining the budget administration process was crucial to prevent any bottlenecks that could hinder the timely commencement of drilling operations.
- **Prognosis & Drilling Program Development**: Developing a comprehensive drilling prognosis and program under such tight deadlines was another significant hurdle. The drilling team had to quickly analyze the data from TLG-3.4, incorporate lessons learned, and create an optimized drilling plan for TLG-3.5. This involved rapid decision-making and close collaboration between geologists, engineers, and operational planners to ensure that all potential risks were addressed and that the well design was both robust and efficient.
- **Procurement and Supply Chain Management of Drilling Materials**: Procuring drilling materials and equipment, which is usually a time-consuming process, needed to be expedited. The team had to quickly secure various items, from casing and accessories to bits, within a short timeframe. To address this, team decided to transfer several drilling materials from other PGE areas to speed up the process.

Despite these challenges, the PGE drilling team managed to spud the TLG-3.5 well on schedule. This achievement was made possible through intense collaboration across departments, the acceleration of key processes, and the team's ability to adapt quickly to changing circumstances.

2.2 Limited Water Supply

Due to its geographical location, the Karaha-Talaga Bodas area is situated in a mountainous region, which presents several challenges related to water availability. The region's limited water sources are heavily dependent on rainfall, making water supply unpredictable and variable. Additionally, local communities rely on these water sources for their daily needs, further straining the availability of water for industrial use. Given these constraints, drilling activities in the Karaha-Talaga Bodas area are typically scheduled only during the rainy season (November – January). Water supply is critical in geothermal drilling operations for several reasons. It is essential for lifting drilling cuttings, cooling various bottom hole assembly (BHA) tools, preventing well kicks, and maintaining overall drilling efficiency. Inadequate water supply can lead to significant operational issues, including delays in drilling, increased costs, higher risks of equipment failure, and other safety hazards.

In the existing water line system of the region, two operational water sources are available for drilling purposes: Pancuran 7 and Talaga-2. However, the water from these sources has certain limitations. Due to their proximity to the crater, the water is acidic and sulfuric. These properties can pose additional challenges, such as corrosive effects on equipment and potential complications in managing water quality during drilling operations.

2.3 Absrasive Formation

In geothermal drilling, abrasive formations refer to geological layers or rock formations that contain hard, abrasive minerals such as quartz, feldspar, or volcanic rocks. These minerals are particularly challenging for drilling operations due to their hardness and abrasive nature, which leads to significant wear and tear on drilling equipment. As a result, drilling through these formations often results in increased maintenance costs, slower drilling progress, and a higher likelihood of equipment failure. The TLG cluster, specifically within the 12-1/4" hole sections, is known to have abrasive formations. Based on drilling history and lithology studies, this section is predominantly composed of Lava Andesite formations that have undergone significant alteration, with silica and total mineral content ranging from 60% to 79%. This high level of alteration makes the rock even more challenging to drill through.

Given these difficulties, the type of drill bit used becomes critically important. Different type of bits can produce varying types of cuttings and result in different hole geometries, which can either facilitate or hinder the drilling process in such abrasive environments. Therefore, selecting the appropriate bit and precisely designing the Bottom

Hole Assembly (BHA) are essential to successfully navigating these challenging formations, so that the drilling operation can penetrate abrasive zones efficiently, minimizing downtime and reducing costs while maintaining the integrity of the wellbore and equipment.

2.4 Pipe Stuck TLG-3.4

During the drilling operation of the TLG-3.4 well, the team encountered significant challenges with two times of pipe stuck incidents. which occurred at depths of 1937 and 2195 mMD. The first pipe stuck incident occurred at a depth of 1937 mMD after the initial appearance of Total Loss Circulation (TLC) at 1915 mMD in the 12-1/4" hole section. Fortunately, the issue was resolved after several jarring jobs, allowing the drill string to be freed from the stuck point. The team then decided to pull the drill string to the surface and replace the Bottom Hole Assembly (BHA) with a new one. The second pipe stuck incident occurred at a depth of 2195 mMD in the 12-1/4" hole section. Unfortunately, this issue could not be resolved despite several jarring jobs, leading to the decision to perform a mechanical back-off. Multiple attempts were made to fish the BHA left in the wellbore, but these efforts were unsuccessful, resulting in the loss of the entire Bottom Hole Assembly (BHA) within the well. This incident not only caused considerable cost overruns but also significantly extended the drilling time, as the team had to manage the aftermath of the stuck pipe and replace the lost equipment. Due to this pipe stuck event, The Non-Productive Time (NPT) amounted to a total of 100 hours, severely impacting the overall efficiency of the drilling operation. The illustration of this pipe stuck incident is shown in Figure 6.

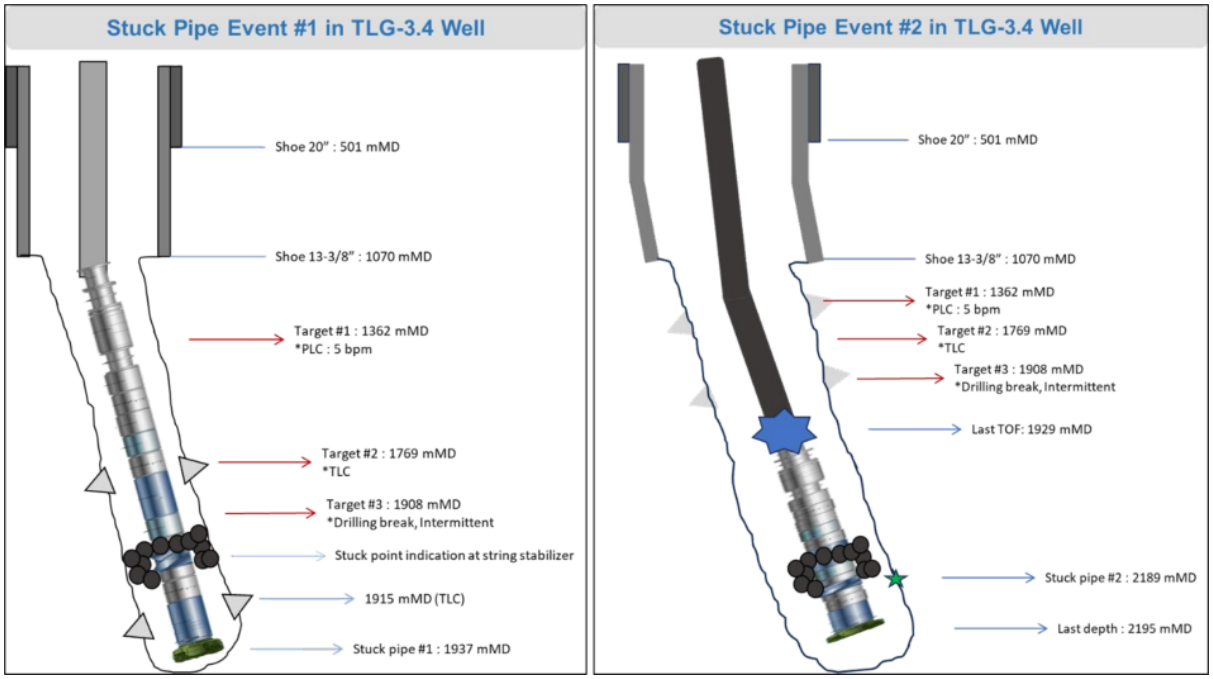

Figure 6: Pipe Stuck Ilustration of TLG-3.4 Well.

Several factors have been identified as root causes of the pipe stuck incidents in the TLG-3.4 well, particularly in the zone with total loss circulation. These issues include ineffective hole cleaning, excessive sliding drilling, and inadequate control of drilling parameters.

- **Ineffective Hole Cleaning**: The practice of hole cleaning in the TLG-3.4 well was insufficiently executed under total loss circulation condition, resulting in a significant build-up of cuttings and debris within the wellbore. As these materials gather, they can obstruct the path of the drill pipe, creating a situation where the pipe may become stuck in the wellbore. This issue was clearly shown by the Torque and Drag chart of TLG-3.4 well, which displayed anomalies and deviations from the expected simulation chart, as shown in Figure 7.
- **Excessive Sliding Drilling**: The frequent use of sliding drilling under total loss circulation conditions can contribute to pipe stuck event because the drill pipe moves along the wellbore without surface rotation, reducing the hurling effect on cuttings compared to rotating drilling mode.
- **Inadequate Control of Drilling Parameters**: Drilling parameters such as weight on bit (WOB), rotation speed (rpm), and rate of penetration (ROP) must be controlled, especially under total loss circulation conditions. This is to ensure that the volume of cuttings produced does not exceed the capacity for removing them from the wellbore. Failure to manage these parameters effectively can also lead to pipe stuck events.

With the root causes identified, the PGE drilling team will focus on improving hole cleaning practices, optimizing drilling techniques, and better controlling drilling parameters. These measures are intended to significantly reduce the risk of pipe sticking in future well drilling operations.

3. KARAHA BODAS KEY SUCCESS

3.1 Water Supply Strategic Improvement

In the case of the TLG-3.4 well, the PGE Drilling Team encountered a shortage of water supply when drilling under total circulation condition in 12-1/4" hole section. Even though it was the rainy season, the main water source can't supply the required minimum flow rate of 1200 GPM, which was essential for continuing drilling. The insufficient water supply posed a risk to the drilling operation, making it necessary to halt drilling until the water supply could be restored to adequate levels. As a result of this issue, Non-Productive Time (NPT) accumulated to 46 hours. This is the second largest contributor to NPT in this well after the pipe stuck issue. The water supply for the TLG-3.4 drilling operation depended to WPS Pancoran 7 and Talaga 2. However, these sources were inadequate for providing the necessary flow rate for effective drilling. Approximately 1 kilometer

from WPS Talaga 2, there is a large reservoir known as Talaga-Bodas Crater. Despite its proximity and potential, this water source had never been utilized, and a water line connecting it to the drilling site had not been installed. To address this challenge and prevent similar issues in future operations, the PGE Drilling Team came up with an idea to improve water supply reliability by tapping a new water line system that bypassed directly from Talaga Crater to Talaga 2 using 6" pipe. This improvement allows for a stable water flow rate of 1200 GPM into the wellbore because the Talaga-2 water source has larger capacity to accommodate larger volumes compared to Pancuran 7. However, the water reaching the drilling site still had acidic and sulfuric properties, making it unsuitable for direct use. Therefore, the water was first collected in the rig's active tank, where it underwent treatment with KOH (potassium hydroxide) to neutralize the acidity and make it safe for equipments in drilling operations.

3.2 Trajectory & BHA Design Improvement

The TLG-3.5 was designed as a 3D well with a J-shaped trajectory, which had a maximum inclination of 30° and was oriented to an azimuth of 254°. The KOP (Kick-off Point) was designed to start at a depth of 150 mMD, and the End of Build (EOB) was expected to be completed before reaching the Total Loss Circulation (TLC) zone, thereby minimizing the need for corrections or sliding drilling in the TLC zone. Based on the root causes and lessons learned from the TLG-3.4 well, the following improvements have been made regarding trajectory and BHA design:

Casing Point Adjustment: Initially, TLG-3.4 well was designed with a casing point of 10-3/4" at a depth of 2400 mMD to maximize the steam potential from the existing feed zone. However, the appearance of erratic torque in the 12-1/4" section indicated that continuing drilling under these conditions posed a significant risk of pipe stuck. Thus, the casing point for the 10-3/4" casing of TLG-3.5 well was adjusted to 2100 mMD. After that, drilling continued with a 9-7/8" section to reach the total depth (TD).

TLG-3.4 Well Design

Figure 10: Bit Run for TLG-3.4 & TLG-3.5 Well.

- **Trajectory Tendency Management**: In TLG-3.4, drilling in the 12-1/4" hole section exhibited a tendency to drift left due to drilling through fracture zones. The main target for both TLG-3.4 and TLG-3.5 was directed to the main fault. When the well intersected the main fault, the direction was further affected by the fault's dip, causing a stronger leftward tendency. To address this challenge, the drilling engineer adjusted the strategy for drilling this section by aligning the directional work to the right side of the directional plan. This strategy aimed to minimize the need for corrections or sliding drilling in the reservoir section. Since it was identified that TLG-3.4 got stuck prior to correcting or sliding in the reservoir section.
- **Jar Setting Modification**: To accommodate a wider range of WOB (Weight on Bit) during drilling of the 12-1/4" section, the team decided to replace several 5" HWDP (Heavy Weight Drill Pipe) below the jar with severals 6-1/2" DC (Drill Collar), increasing the weight below the jar by 5 to 10 klbs. The additional WOB also improved efficiency for penetrating abrasive formations compared to TLG-3.4.
- **Bit Selection**: Because of bit stock availability, the bit selection for the TLG-3.4 well involved using two types: PDC (Polycrystalline Diamond Compact) and TCI (Tungsten Carbide Insert) Tri-Cone Bit. Both types of bits have different cutting mechanisms. The PDC bit uses a mechanism with a fixed, shear-cutting action that is effective in softer formations but can wear down more quickly in abrasive

conditions. On the other hand, the TCI bit employs a rotary, impact-cutting mechanism that is more durable and suited for harder, abrasive formations. In addition, this led to inconsistencies in the type of cuttings produced, variations in hole geometry, and the formation of ledges along the well trajectory. To address these issues in the TLG-3.5 well, the team decided to use a single bit type, TCI bit. This strategy helps ensure a more uniform and accurate hole shape, which is crucial for successful drilling operations and minimizing additional downhole challenges.

3.3 Drilling Parameter Gameplan

Offset wells data plays a pivotal role across design and execution phases. These datasets offer essential insights into parameters shaping drilling conditions. Analyzing past operational behaviors provides engineers with a clearer view of anticipated outcomes and potential challenges. When designing wells, several critical factors are considered to optimize performance and mitigate risks.

MD	SWOB MIN	SWOB MIN	SWOB MAX	SWOB MAX	SRPM MIN	SRPM MIN	SRPM MAX	SRPM MAX	FLWI MIN	FLWI MIN	FLWI MAX	FLWI MAX	DIFF PRESS MIN	DIFF PRESS MIN	DIFF PRESS MAX	DIFF PRESS MAX

Figure 11: Optimum Operating Window.

Foreseeing subsurface hazards is paramount, involving comprehensive geological and geophysical assessments to identify potential challenges such as unbalanced formation pressures, lost circulation, or hard, abrasive formations that can impact service quality. Through meticulous planning and strategic measures, all these risks were effectively managed, ensuring operations followed trajectory plans precisely, achieving targets safely and efficiently. As shown in Figure 12, optimum parameters were established based on this data and were implemented during the operation, demonstrating enhanced performance and successful drilling outcomes in the TLG-3.5 well. This improvisational effort aims to cultivate mutual understanding and commitment among stakeholders, paving the way for seamless implementation by the project team. By translating these strategies into actionable steps, these teams are poised to execute effective solutions that not only address current inefficiencies but also establish a pathway to sustainable operational excellence in drilling operations. During monitoring phases, this historical data becomes crucial as real-time metrics are continuously compared against established benchmarks from offset wells.

3.4 Hole Cleaning Practice

In this section, concerns and best practices related to hole cleaning under total loss circulation conditions (17-1/2", 12-1/4", & 9-7/8" Hole Section) will be described. These best practices has been applied in drilling the TGL-3.5 well, which is part of the lessons learned from TLG-3.4. Drilling under total loss circulation conditions is a tricky and challenging job because we can't be exactly sure whether the produced cuttings have been safely transported to secure zone or not. The objective of drilling under total loss conditions is not to bring the cuttings to the surface but to lift them to the disposal zone (fracture) or at least as high as possible away from the BHA area, which has the smallest clearance to the wellbore. Without good hole cleaning practices, drilling cannot proceed and may cause pipe stuck issue. In addition, total loss conditions can result in an insufficient hydrostatic column in the wellbore, potentially causing a well or steam kick. Therefore, here are some best practices to ensure effective hole cleaning in the wellbore:

- Perform wash and ream 3 times after reaching stand down depth or before making the next DP connection.
- Conduct air bypass before doing connection for the next string at depth of 1 jts off bottom.
- Execute two times Hi-Vis with sweeps per DP stands
- Apply 1 joints off-bottom during drilling in total loss conditions.
- Ensure connection time does not exceed 5 minutes.
- Maintain ROP within safe range to ensure that the cuttings we produce are balanced with our lifting capacity.
- Use two float subs in the DP assembly to avoid kick through the string.
- At the first occurrence of total loss circulation, observe the well's reaction. If a well kick occurs, begin preparations to pump water via the annulus. Pump water within safe range via annulus to mitigate the risk of well kick from the annulus.
- Apply adequate water flowrate (gpm) and air flowrate (scfm) according to the drilling program, ensuring the total mixture flowrate does not exceed an equivalent of 900 gpm (limitation of 8" mud motor).

- Use foam and corrosion inhibitors (with formula as per drilling program) during aerated drilling to assist with cuttings lifting and prevent corrosion on the tubular string.
- If sliding drilling is unavoidable during total loss conditions, polish the hole along the slide interval (raise the string 1-2 m above the initial slide interval without rotation, then continue rotating the string until the last drilling depth).
- After TD is reached, do wiper trip drill string until the last casing point depth.

3.5 Drilling Parameter Real Time Monitoring

Real-time monitoring of drilling parameters refers to the continuous and immediate observation of various indicators during the drilling operation such as WOB, ROP, RPM, and torque. The real-time monitoring system must be accessible and monitored directly both of personnels in the field and engineer at the head office so that immediate adjustments can be made in case of operational changes and anomalies, enhancing operational efficiency, enabling data-driven decision-making, ensuring compliance with regulations, and facilitating continuous improvement across department in the future. For instance, during the drilling of the 12-1/4" and 9-7/8" hole sections under challenging total loss circulation conditions, real-time monitoring provided immediate feedback on the effectiveness of hole cleaning practices. Any deviations in the expected performance, such as a drop in ROP or an unexpected increase in torque, could be quickly addressed by adjusting drilling parameters or implementing corrective actions like additional wash and ream cycles, additional sweep Hi-Vis, or lowering drilling parameter. Additionally, the data collected in real-time served as a valuable resource for post-drilling analysis, contributing to continuous improvement in drilling practices and strategies.

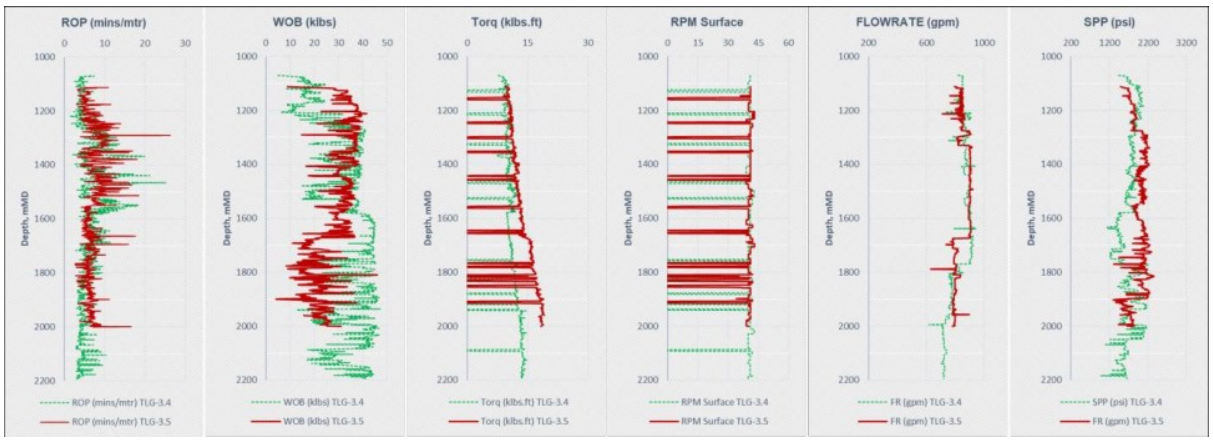

Figure 12: Drilling Parameter Real Time Monitoring TLG-3.5.

Another parameter that needs to be monitored is the Torque and Drag Chart. Torque refers to the rotational force required to turn the drill string and bit, while drag refers to the frictional resistance that the drill string encounters as it moves through the wellbore. Both parameters are crucial for assessing wellbore conditions and understanding whether the drill string is experiencing excessive torque or if cuttings are not being effectively removed. If the torque values exceed expected levels, it describes that the drill string is encountering more resistance than anticipated. This could be due to inadequate hole cleaning, leading to the accumulation of cuttings or other debris that causes friction. By monitoring the torque values in real time, the drilling team can identify if the drill string is experiencing excessive torque and take corrective actions to mitigate the issue. This can be seen in Figure 14, marked in red circle. Starting at a depth of 1800 mMD, the values for pick up, slack off, rotating weight, on-bottom, and off-bottom torque showed excessive increases. Then, drilling was halted to normalize parameters and consider continuing drilling until the casing point at 2100 mMD with close monitoring.

4. RESULTS AND DISCUSSIONS

As a result of implementing the various lessons learned and best practices from previous operations, the TLG-3.5 well was successfully completed in both a timely and cost-effective manner. The well reached its target depth of 2403 mMD as planned, with no incidents of pipe stuck, steam kicks, or other significant downhole issues. This successful execution led to substantial cost savings, amounting to approximately 30% of the planned budget, and the project was finished 29% ahead of the scheduled timeline. The non-productive time (NPT) for this project was exceptionally low, totaling only 3.5 hours, which constitutes just 0.35% of the total drilling days. This NPT was due to the overheating of check valves from aerated drilling equipment, but the issue was quickly troubleshooted. In comparison to other wells drilled within the TLG cluster, the TLG-3.5 well has the best NPT and drilling time performance to date. In addition, all of 5 reservoir targets were hit within the center-to-center distance coverage.

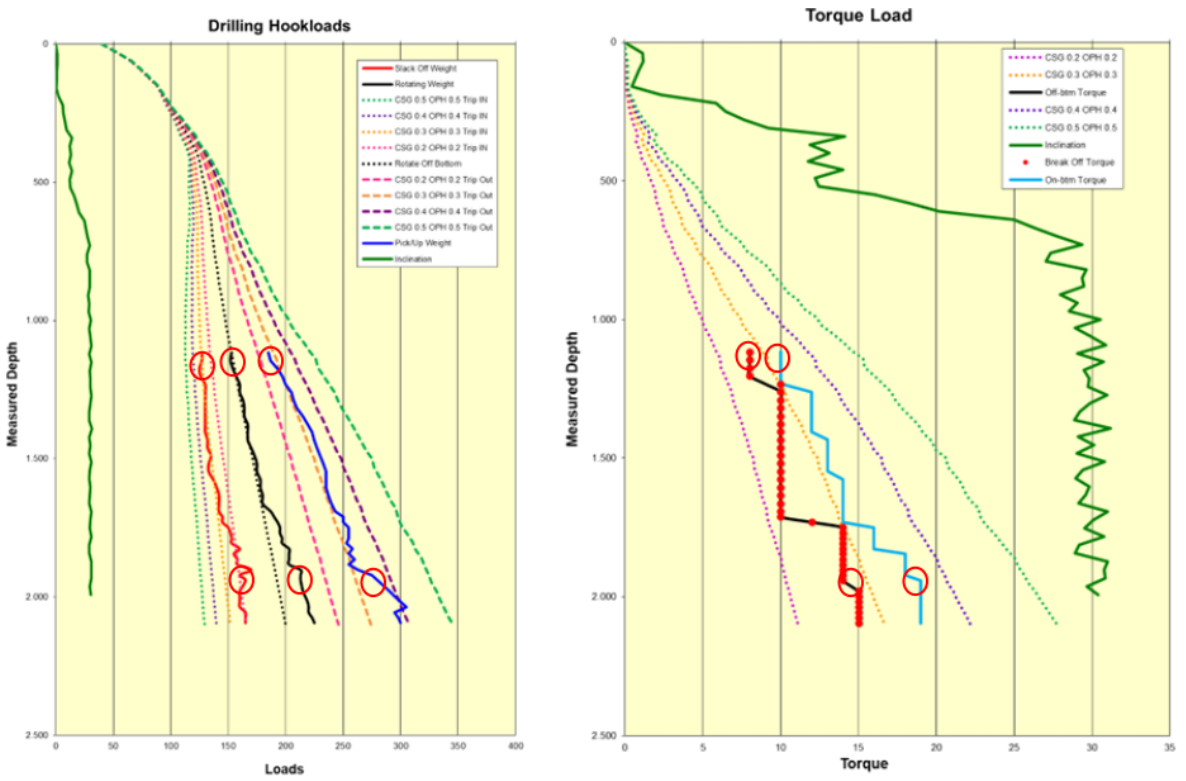

Figure 13: Torque and Drag Chart TLG-3.5.

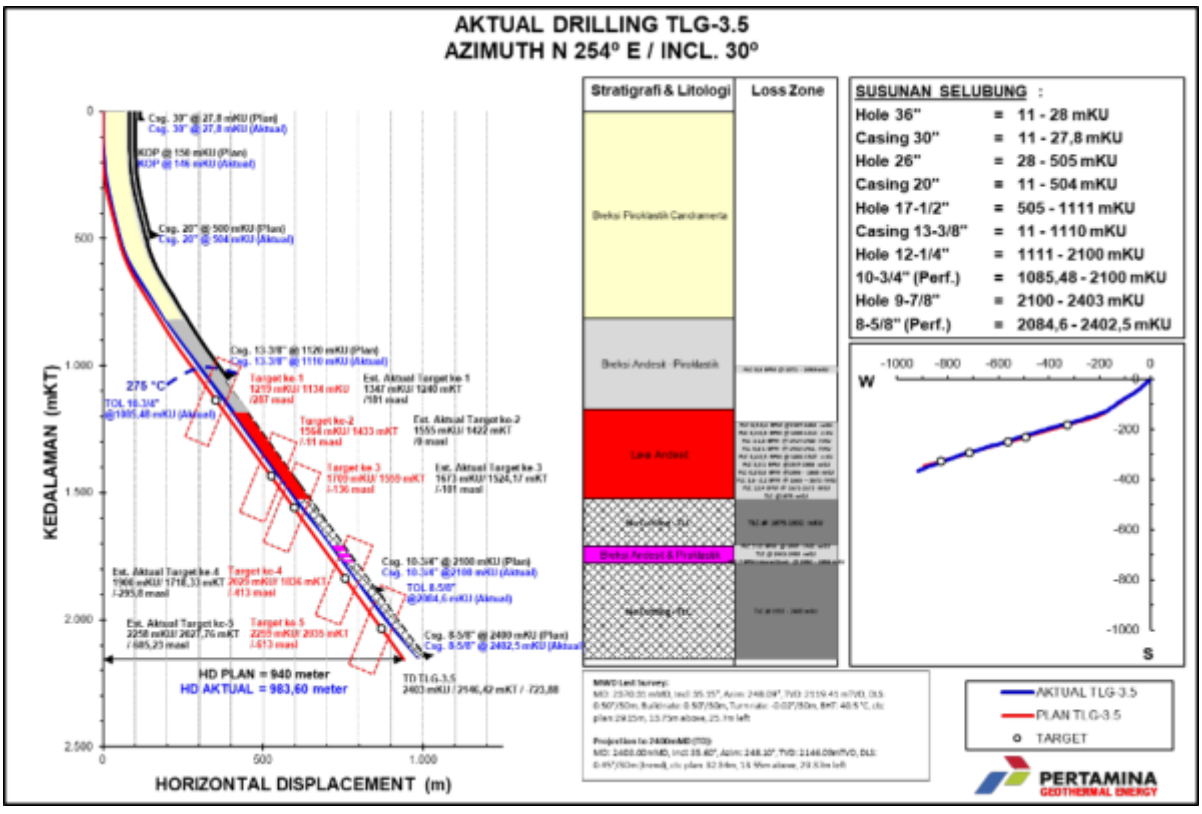

Figure 14: Actual Well Profile & Lithology - TLG-3.5.

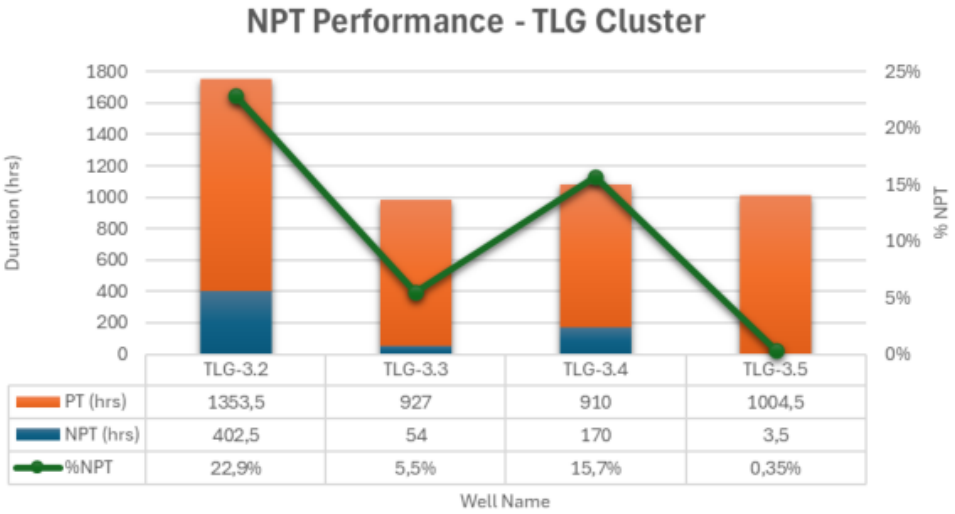

Figure 15: NPT Performance - TLG Cluster.

Based on logging surveys and reservoir simulation, the TLG-3.5 well has the potential to supply steam in line with the P50 target. With this potential addition, it is hoped that the TLG-3.5 well can be a key to the puzzle for restoring the Karaha Power Plant to its original production capacity

5. CONCLUSIONS

The success story of drilling the TLG–3.5 well is a result of comprehensive and in-depth collaboration between drilling engineering and drilling operations, as well as the lessons learned from the TLG–3.4 well. The unconformities encountered during the drilling of the TLG–3.4 well were not viewed as setbacks but rather as valuable experiences for drilling better wells in the future. From a drilling engineering perspective, the factors that contributed for preparing a comprehensive drilling program for TLG–3.5 drilling are as follows:

- Detecting and mitigating all drilling hazards to anticipate and prevent undesired problems during the operation
- Redesigning the wellbore trajectory and BHA tally to accommodate the existing limitations in the reservoir
- Determining the most optimal drilling parameters for each section to achieve the best drilling performance

On the other hand, drilling operations play an important role in ensuring that the actual drilling sequences proceeds according to the plan determined by all stakeholders, as follows:

- Ensure the reliability and suitability of all rig equipment and service companies before drilling operations commence to minimize unnecessary non-productive time (NPT).
- Review hole cleaning practices and ensure they are executed as planned to ensure the cuttings produced during drilling are lifted to safe area in order to prevent pipe stuck issues.
- Close monitor drilling parameters in real-time to immediately intervene and rectify any anomalies during drilling operations.

The drilling design and best practices used at the TLG–3.5 well will serve as a reference for the TLG-3.6 well, the next makeup well in the cluster. For the geothermal industry, the author hopes that the success story of drilling the TLG-3.5 well will serve as an inspiration and milestone in geothermal well drilling and reservoir development.

Keywords: thermal expansion, PSV

ABSTRACT

This paper presents a rigorous analysis of the adequacy of Pressure Safety Valve (PSV) capacity for thermal expansion scenarios in the cooling water service of an inter condenser within a geothermal operation. Conventional calculations for PSV capacity were reviewed and found to lack consideration of critical factors such as variable heat transfer rates, temperature-dependent fluid properties, and manufacturer-specific empirical formulas. To address these limitations, a rigorous calculation approach was employed, incorporating dynamic simulations and detailed heat transfer reduction phenomena. The results indicate that while conventional calculations suggest the current PSV is inadequate, rigorous calculations demonstrate that the PSV capacity is sufficient to handle the required relief rates. The study concludes that the existing PSV does not require upgrading and recommends further Hazard and Operability (HAZOP) studies to assess the necessity and scenarios for PSV deployment. This analysis underscores the importance of considering real-world phenomena and manufacturer-specific data in PSV sizing and selection.

1. INTRODUCTION

Pressure Safety Valves (PSVs) are critical components in geothermal operations, ensuring the safe release of excess pressure to prevent equipment damage and potential hazards. This study focuses on the adequacy of PSV-YYY, which protects the inter condenser in a geothermal cooling water system. The inter condenser, a key component in the geothermal process, transfers heat from non-condensable gases (NCG) and steam to cooling water. The PSV is designed to relieve pressure caused by thermal expansion of the cooling water, which can occur if the cooling water flow is blocked while the hot side remains active.

Conventional calculations for PSV capacity often rely on simplified assumptions, such as constant heat transfer rates and fixed fluid properties, which may not accurately reflect real-world conditions. This study revisits these calculations, incorporating a more rigorous approach that accounts for variable heat transfer rates, temperature-dependent fluid properties, and manufacturer-specific empirical formulas. The goal is to verify whether the current PSV capacity is adequate for the thermal expansion scenario and to identify any potential need for PSV upgrades.

Conventional calculations have been done to check the capacity adequacy of PSV-YYY. Review for that calculation is conducted to verify calculation result. From the review, there are some items that need to be considered for adequacy check of PSV. Those items are shown in Table 1.

Considering those items, further calculation was conducted. There are 2 types of calculation:

a. Rigorous calculation is conducted to get maximum and realistic result that match that real phenomenon.
b. Conventional calculation by applying maximum heat exchanger duty during operation and leakage factor is conducted as per discussion with Facility Engineering Team and Technical Authority Process.

Comparison of calculation results is summarized in Table 2.

Table 1: Required Items to be Considered for PSV Calculation.

Item	Consideration
Heat Transfer Rate	The heat transfer rate is not fixed. As the cold side fluid temperature is increasing and reach temperature of hot side, heat transfer rate will decrease accordingly since driving force for heat transfer is temperature difference
Cold Side Fluid Properties Changed	Cold side fluid (cooling water) has significant difference of properties at different temperatures. Therefore, calculation need to be conducted at any point temperature to achieve all possible highest required relief rate
Formula by Manufacturer	The manufacturer has its own empirical formula. As per API 520, it is recommended to conduct calculation by using valve manufacturer formula (Kd value by manufacturer)

Table 2: Calculation Result of Adequacy Check of PSV.

Item	PSV-YYY
Conventional Calculation	
Required Flowrate [USGPM]	22.6
Current PSV Flowrate Capacity [USGPM]	17.7
Current PSV Status	Not Adequate
Rigorous Calculation	
Required Flowrate [USGPM]	19.1
Current PSV Flowrate Capacity [USGPM]	20.1
Current PSV Status	Adequate

Therefore, the PSV is not required to be changed or upgraded for current usage. As per discussion, it is found that there is less likely PSV will pop due to thermal expansion scenario. Therefore, it is recommended to conduct further HAZOP study to assess the requirement and scenario of those PSV.

2. GENERAL INFORMATION

This report covers the review of adequacy check of current PSV capacity. Information regarding PSV and its protected equipment is shown in table 3 and table 4 below:

Table 3: Information of PSV.

PSV Item	Value / Remark
Protected Equipment	Inter Condenser
Set Pressure [barg]	5.85
Over Pressure [%]	10
Relief Pressure [barg]	6.44
Back Pressure [barg]	0 (to atmosphere)
Orifice Area [mm2]	47.74
Manufacturer	Crosby
Type	3990

Table 4: Information of Protected Equipment.

Protected Equipment	Inter Condenser
Maximum Heat Exchange [Watt]	15,852,654
Hot fluid	
Fluid name	NCG – Steam
Mass flow [kg/hr]	30,048
Inlet Temperature [C]	96.5
Outlet Temperature [C]	43.3
Inlet Pressure [barg]	-0.5445
Outlet Pressure [barg]	-0.5685
Protected Equipment	**Inter Condenser**
Cold fluid	
Fluid name	Cooling Water
Mass flow [kg/hr]	1,209,535
Inlet Temperature [C]	27.2
Outlet Temperature [C]	38.5
Inlet Pressure [barg]	4.15
Outlet Pressure [barg]	4.10
Shell (Hot side)	
OD [m]	1.092
Length [m]	7.315
Tube (Cold side)	
OD [mm]	19
ID [mm]	17.27
Length [m]	7.315
Quantity [ea]	1598

Protected Equipment	Inter Condenser
Volume [m3] (include margin 50%)	4.11
Design Pressure [barg]	6.86

All value is using SI unit. However, for convenience reason, flowrate calculation result is shown in field unit [USGPM] since value in SI unit [m3/s] shown is very small value.

2.1 Assumption

- Heat transfer is reduced with linear approximation as per equation for jacketed vessel with isothermal heating medium.
- No heat loss from system to environment vice versa.
- Perfect mixing of cooling water after heated by steam.
- Sudden relief once there is volume expansion.
- Atmospheric pressure is 0.85 bara.
- The volume of cooling water that is directly affected by heat transfer is the volume of cooling water at tubing plus 50% design margin.

2.2 General Calculation Procedure

The required relieving rate is not easy to determine. Since every application is for a relieving liquid, the required relieving rate is small; specifying an oversized device is, therefore, reasonable. A nominal diameter NPS 3/4 × NPS 1 relief valve is commonly used. If there is reason to believe that this size is not adequate, the procedure in API 521 section 4.4.12.3 can be applied.

If the fluid properties vary significantly with temperature, the worst-case temperature should be used. Alternatively, API-521 also recommends conducting more Rigorous calculation methods that include temperature-dependent fluid properties can be used to optimize the size of the relief device.

In this review, 2 types of calculation were conducted:

1. Rigorous calculation is conducted to get maximum and realistic result that match that real phenomenon.
2. Conventional calculation by applying maximum heat exchanger duty during operation and leakage factor is conducted as per discussion with Facility Engineering Team and Technical Authority Process.

2.3 Methodology for the Calculation

The methodology for the calculation was followed from API 521-2014 section 4.4.12 (Hydraulic Expansion) and API 520 section 5.8 (Sizing for Liquid Relief). All constants and factors must be evaluated in the standard which included Expansion rates for sizing of relief devices that protect against thermal expansion was calculated using equation from API 521, section 4.4.12.3 as below:

$$q = \frac{\alpha_v \cdot \phi}{1000 d \cdot c}$$

ASME allowable accumulation pressure of which 10% is chosen for the pressure relief device. The cross-sectional area of each pressure relief device was determined from the selected size orifice area in pressure safety valve specification.

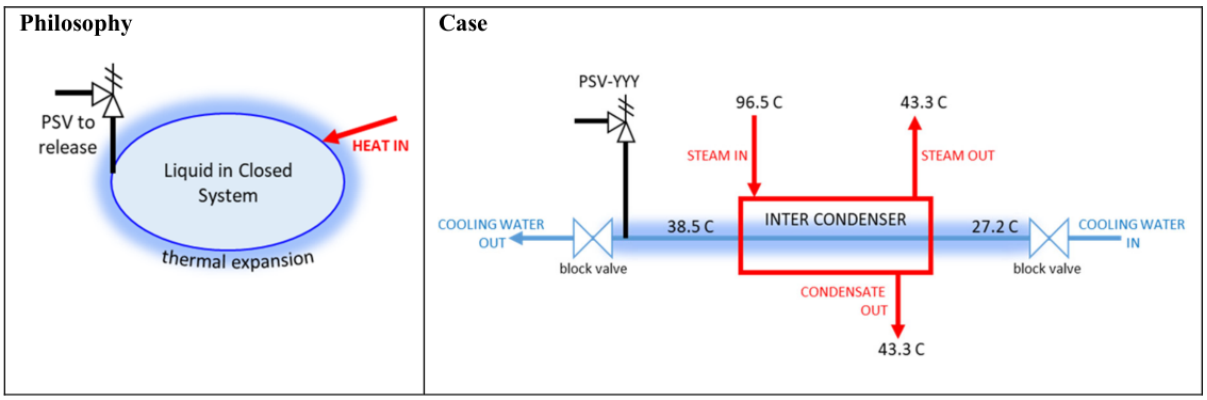

Figure 1: Simplified Diagram of Thermal Expansion Scenario.

3. DISCUSSION AND ANALYSIS

3.1 Relief scenario

As per API 521 there are 14 possible relief scenarios. However, there is only 1 possible relief scenario, thermal expansion, which could occur in this system. Other relief scenarios such as blocked outlet, for instance, will not occur since tube side design pressure 6.86 barg, while maximum service water pump (AWP) discharge pressure is only 4.34 barg. (Muskan, 2015). Thermal expansion could occur due to an exchanger is blocked in on the cold side with flow in the hot side as described in figure 1. Blocked cold side is described in yellow highlight.

3.2 Heat Transfer

In the heat exchanger, heat is transferred from hot fluid (steam) to cold fluid (cooling water). When cooling water is blocked, the temperature of cooling water will increase until reach the inlet steam temperature. Once the temperature of cooling water reaches the temperature of inlet steam, thermal equilibrium is established, and heat transfer will be stop since driving force of heat transfer is temperature difference. (Rates of Heat Transfer, n.d.) Since there is blocked cooling water, heat transfer profile is applying equation for batch heating process: jacketed vessel with isothermal heating medium as per Perry Chemical Engineering Handbook 8ed-(2008), equation 11-35.

$$\ln (T_1 - t_1)/(T_1 - t_2) = UA\Theta/Mc$$

Where:

T1 is temperature of incoming hot fluid (constant) [^oC]
t1 is temperature of cold fluid at beginning of period [^oC]
t2 is temperature of cold fluid at end of period [^{oC}]
U is coefficient of heat transfer [W/m^2 C]
A is heat-transfer surface [m^2]
Θ is time [s]
M is mass of fluid being heated [kg]
c is specific heats of cold fluids [J/kg C]

The heat transfer profile is shown in Figure 2 and Figure 3 for Inter Condenser A/B and After Condenser respectively.

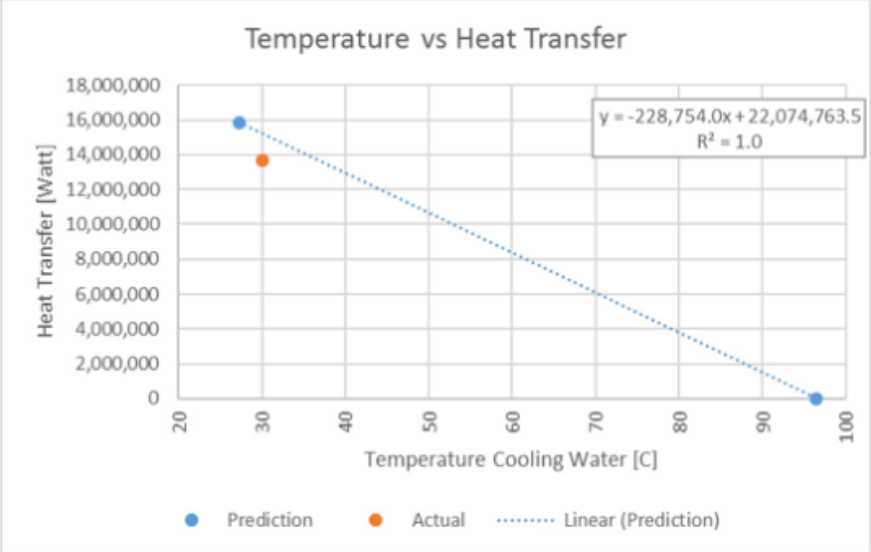

Figure 2: Profile of Temperature vs Heat Transfer for Inter Condenser (related to PSV-YYY).

By considering heat transfer reduction, the temperature profile of blocked cooling water (CW) that is heated by steam is shown in Figure 3 for Inter Condenser. Figure 3 also shows the comparison of temperature profile where there is constant heat transfer is applied.

Figure 3 shows that reduced heat rate is more representing real condition, where cooling water temperature will always below or maximum same with steam temperature. While constant heat rate shows something odd where at some point, cooling water temperature could reach higher than steam temperature.

Conventional calculation did not consider heat transfer reduction. Conventional calculation is applied constant heat transfer (design duty of heat exchanger) in all temperature and time. Heat Transfer reduction applied for Rigorous calculation as this condition is more match with real phenomena.

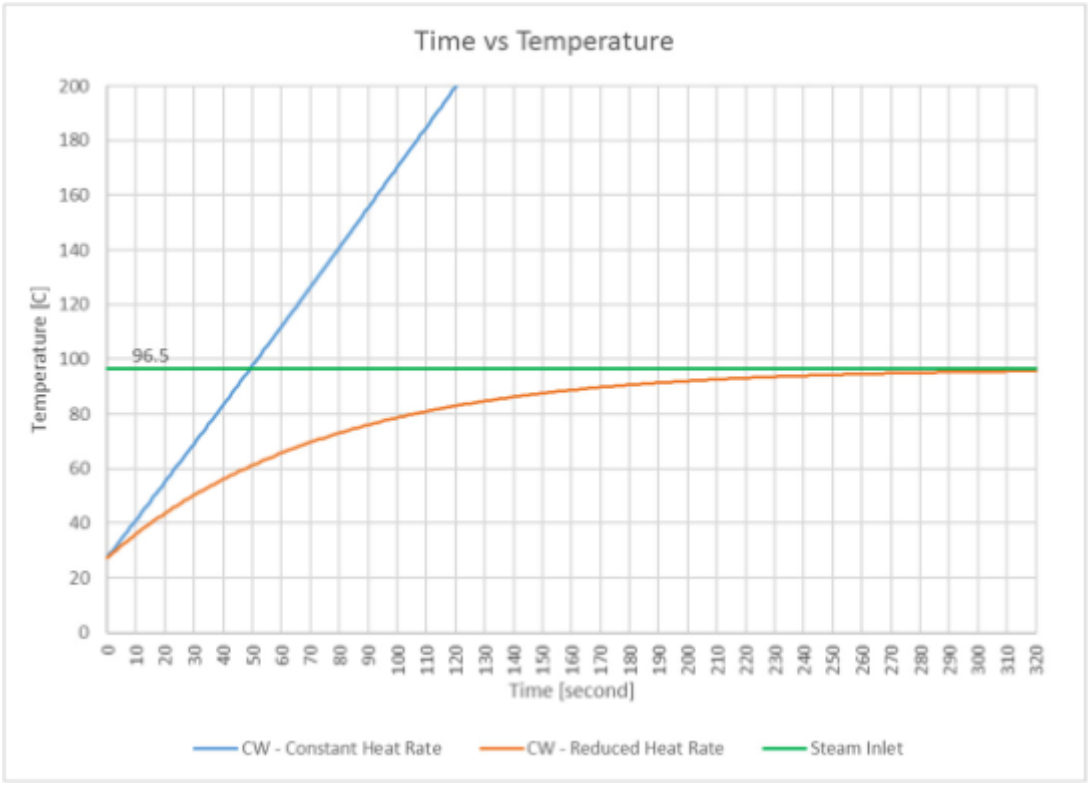

Figure 3: Profile of Time vs Cooling Water Temperature for Inter Condenser (related to PSV-YYY).

3.3 Cold Side Fluid Properties Changed

Cooling Water (Cold Side Fluid) has significant difference of properties at different temperatures. Specific gravity, cubic expansion coefficient, and heat capacity of water are shown in Figure 4, Figure 5, and Figure 6 respectively.

Conventional calculation was only conducted at 1 point which is in 38.5 ^{o}C for PSV YYY. In this review, Rigorous calculation is conducted in all possible temperature ranges, to get maximum and realistic value of relief rate.

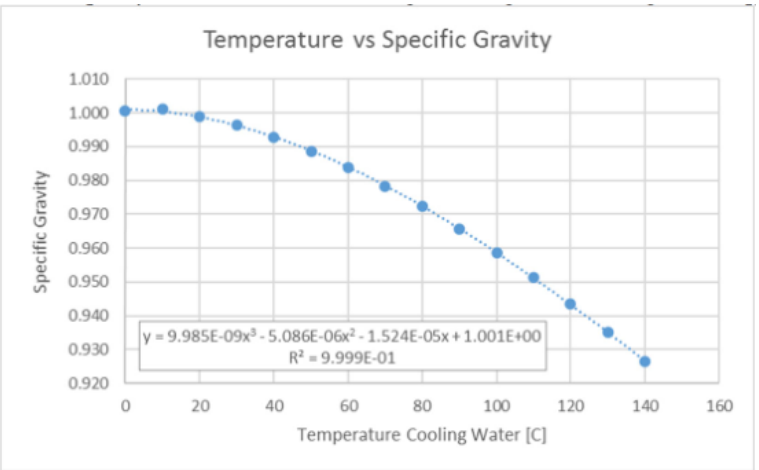

Figure 4: Profile of Temperature vs Density of Cooling Water.

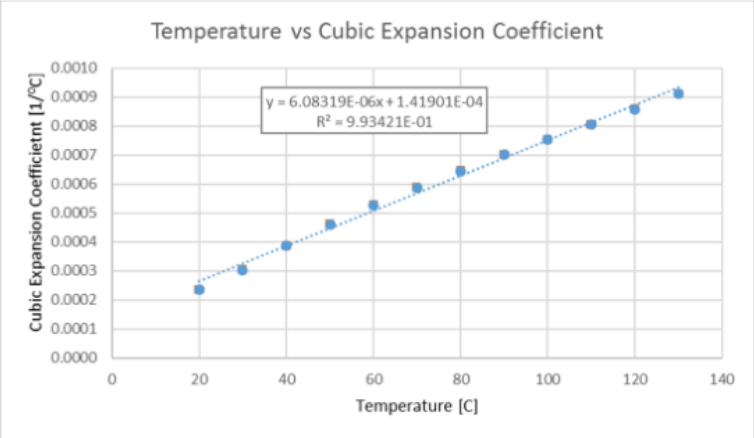

Figure 5: Profile of Temperature vs Cubic Expansion Coefficient of Cooling Water.

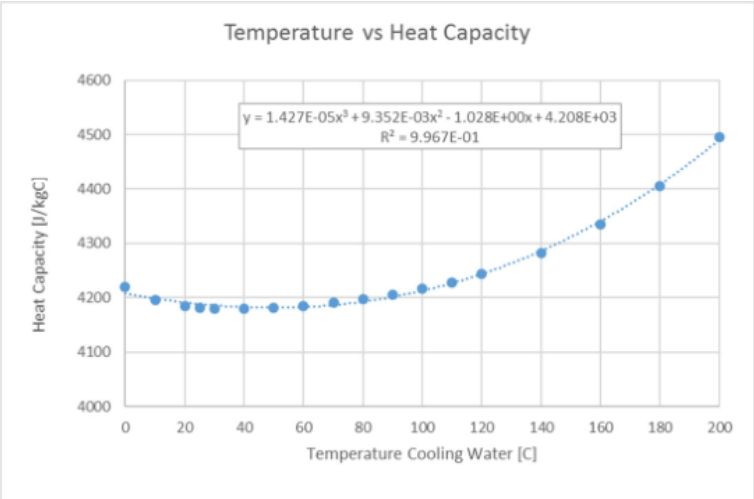

Figure 6: Profile of Temperature vs Heat Capacity of Cooling Water.

3.4 Formula by Manufacturer

General formula for PSV flowrate capacity per API 520 section 5.8.1.3 page 76 is defined as formula below:

$$Q = \frac{A \,.\, \boldsymbol{Kd} \,.\, Kw.Kc \,.\, Kv}{11.78} \sqrt{\frac{\Delta P}{G}}$$

Where:

Q is PSV flowrate capacity, L/min
A is effective discharge area, mm2
Kd is coefficient of discharge that should be obtained from valve manufacturer. For preliminary sizing, a value of 0.65 can be used.
Kw is correction due to backpressure
Kc is combination correction factor for installation with a rupture disk
Kv is correction factor due to viscosity
ΔP is differential pressure, kPa. Differential pressure = set pressure + over pressure – back pressure
G is specific gravity of the liquid

All coefficients are the same for both API and Vendor equation, except for Kd. API is recommending value Kd 0.65 for preliminary sizing, while CROSBY equation is applying value Kd 0.74 (Crosby® Pressure Relief Valve Engineering Handbook, 1997). However, API recommends using Kd value from valve manufacturer, while Conventional calculation is still using preliminary Kd value of 0.65.

3.5 Pressure and Temperature Rise

As the cold fluid is being heated by steam, the cold fluid temperature will increase. As the temperature rises, pressure will increase accordingly. Pressure will increase from operating temperature until reaches the set point of PSV, and PSV will start to open to release pressure. Pressure rise formula is defined in below equation:

$$p_2 = p_1 + \frac{(T_2 - T_1)(\alpha_v - 3\alpha_l) - \left(\frac{q_{ll} \cdot t}{V}\right)}{\chi + \left(\frac{d}{2E \cdot \delta_W}\right)(2.5 - 2\mu)}$$

Where

p_2 is the final gauge pressure of blocked-in, liquid-full equipment, expressed in kPa (psig);

p_1 is the initial gauge pressure of blocked-in, liquid-full equipment, expressed in kPa (psig);

T_2 is the final temperature of blocked-in, liquid-full equipment, expressed in °C (°F);

T_1 is the initial temperature of blocked-in, liquid-full equipment, expressed in °C (°F);

α_v is the cubic expansion coefficient of the liquid, expressed in 1/°C (1/°F);

α_l is the linear expansion coefficient of metal wall, expressed in 1/°C (1/°F);

χ is the isothermal compressibility coefficient of the liquid, expressed in 1/kPa (1/psi);

d is the internal pipe diameter, expressed in m (in.);

E is the modulus of elasticity for the metal wall at T_2, expressed in kPa (psi);

δ_W is the metal wall thickness, expressed in m (in.);

μ is Poisson's ratio, usually 0.3;

q_{ll} is the liquid leakage rate across the block valve seat (usually taken as 0), expressed in m^3/s ($in.^3/s$);

t is the elapsed time for leakage, expressed in seconds;

V is the pipe volume, expressed in m^3 ($in.^3$).

From the equation P1, P2, and T1 are known variables. By modification of the equation, T2 can be calculated.

3.6 Calculation Result

3.6.1 Conventional Calculation.

Calculation result conducted by Conventional is summarized in table 5 below:

Table 5: Result of Adequacy Check of PSV by Conventional Calculation.

Item	PSV-YYY
Initial Temperature Cooling Water start blocked in [C]	38.50
Temperature Cooling Water at Required Relief [C]	38.72
Heat Transfer at Required Relief Rate [Watt] (note 1)	15,852,654
Kd (note 2)	0.65
Required Flowrate [USGPM]	22.6
Current PSV Flowrate Capacity [USGPM]	17.7

Notes:

1. Apply design duty of heat exchanger
2. Apply preliminary Kd value

From the above calculation result, it is shown that current PSV capacity is lower than required flow rate which means current PSV is not enough to handle relieving scenario.

3.6.2 Rigorous Calculation

Rigorous calculation is applying dynamic simulation and rigorous calculation to achieve maximum relief rate by considering heat transfer reduction phenomenon and cold fluid properties change.

Calculation is conducted in all possible range of cooling water temperature (27.2 – 96.5 C for PSV-YYY) depending on how fast valve closing. Calculation result is summarized in Table 6,

Table 6: Result of Adequacy Check of PSV by Rigorous Calculation.

Item	Remark / Value
Initial Temperature Cooling Water start blocked in [C]	(note 1)
Temperature Cooling Water at Required Relief Rate [C]	37.53 (note 1)
Heat Transfer at Required Relief Rate [Watt] (note 2)	13,490,596
Kd (note 3)	0.74
Required Flowrate [USGPM]	19.1
Current PSV Flowrate Capacity [USGPM]	20.1

Notes:

1. Cooling water could be blocked at any possible range of cooling water temperature.
2. Apply heat transfer at maximum relief rate result of rigorous calculation as per Figure. 7 and Figure 8.
3. Apply Kd value from Manufacturer

Detail calculation result of relief rate for each PSV by applying Rigorous calculation is shown in Figure 7 and 8.

From the above calculation result, it is shown that relief rate is not fixed at all time. Relief rate increases until reaches maximum and then decreasing until reach zero. From the above calculation result, it is shown that relief rate reach maximum at some point of cooling temperature and reach zero at maximum cooling water temperature. At maximum temperature of cooling water, temperature of cooling water is same with temperature of steam where thermal equilibrium is reached so that there is no heat transfer and consequently no liquid expansion. From the above calculation result, it is shown that current PSV capacity is higher than required flow rate.

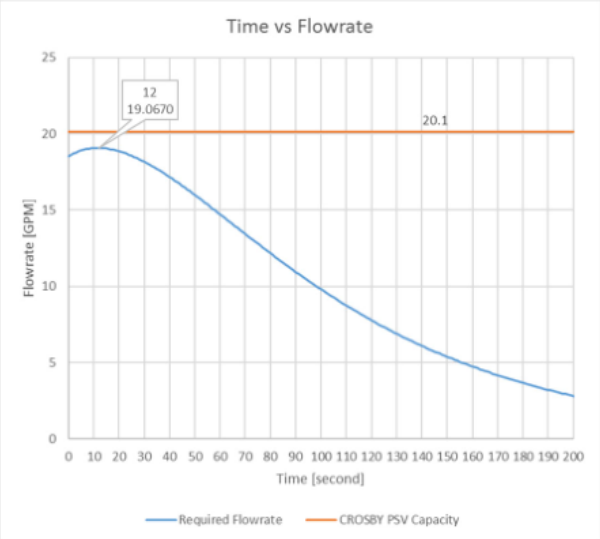

Figure 7: Profile of Time vs Required Flowrate and PSV Flowrate Capacity for PSV-YYY.

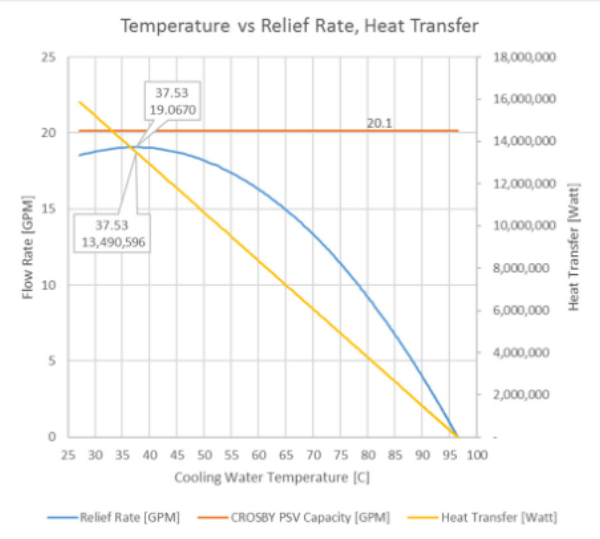

Figure 8: Profile of Temperature vs Required Flowrate and PSV Flowrate Capacity for PSV-YYY.

4. CONCLUSION AND RECOMMENDATION

4.1 Conclusion

As per the above analysis, there are some points that need to be considered for sizing PSV with thermal expansion case for an exchanger that blocked in on the cold side with flow in the hot side. Those consideration are summarized in table 7.

By considering those above aspects. Further calculation for PSV adequacy check was conducted. A comparison of calculation method and result is shown in Table 8 and 9 respectively.

From the calculation result, it is concluded that PSV-YYY is still adequate to accommodate thermal expansion of blocked cooling water at heat exchanger due to heated by steam.

4.2 Recommendation

PSV-YYY is still adequate to accommodate relief rate of protected equipment due to thermal expansion scenario. Therefore, this PSV is not required to be changed or upgraded for current usage. As per discussion, it is found that there is less likely PSV will pop due to thermal expansion scenario. Therefore, it is recommended to conduct further HAZOP study to assess the requirement and scenario of this PSV.

Table 7: Required Items to be Considered for PSV Calculation.

Item	Consideration
Heat Transfer Rate	The heat transfer rate is not fixed. As the cold side fluid temperature is increasing and reach temperature of hot side, heat transfer rate will decrease accordingly since driving force for heat transfer is temperature difference
Cold Side Fluid Properties Changed	Cold side fluid (cooling water) has significant difference of properties at different temperatures. Therefore, calculation need to be conducted at any point temperature to achieve all possible highest required relief rate
Formula by Manufacturer	The manufacturer has its own empirical formula. As per API 520, it is recommended to conduct calculation by using valve manufacturer formula (Kd value by manufacturer)

Table 8: Comparison of PSV Calculation Method.

Item	Conventional Calculation	Rigorous Calculation
Heat transfer	Constant heat transfer by applying heat exchanger design duty	Applying heat transfer reduction by assuming system as batch heating process for jacketed vessel with isothermal heating medium
Initial blocked temperature	Calculation conducted at 1 point temperature: 38.5 ºC	Calculation conducted at all possible temperature range: 27.2 – 96.5 ºC
Kd value	Apply preliminary value	Apply value from manufacturer

Table 9: Comparison of PSV Calculation Result.

Item	Remark
Conventional Calculation	
Required Flowrate [USGPM]	22.6
Current PSV Flowrate Capacity [USGPM]	17.7
Current PSV Status	Not Adequate
Rigorous Calculation	
Required Flowrate [USGPM]	19.1
Current PSV Flowrate Capacity [USGPM]	20.1
Current PSV Status	Adequate

Keywords: Geothermal Power Plant, Deep Learning, Cooling Tower Fan Motor, Data Analysis

ABSTRACT

Geothermal power plants represent a significant renewable energy source with considerable potential in Indonesia. One critical process within the geothermal industry involves the cooling of condensate water using cooling towers, which involve large rotating equipment comprising fans and motors, leading to high vibrations occurs in the cooling tower, which can affect the performance of the geothermal power plant generation. In the Wayang Windu power plant, occasional reductions in generation load occur due to cooling tower issues. This is attributed to the suboptimal functioning of the cooling tower. In Wayang Windu case, a decrease in load commonly occurs by approximately 0.5 – 2 MW per fan, but it will increase exponentially whenever more than one fan is affected. The loss of a fan reduces cooling capacity and efficiency of the condenser unit. Cooler water allows for more efficient condensation, which enhances the efficiency of the thermodynamic cycle. Those cases can lead to Loss of Production Opportunities (LPO). Therefore, motor measurement and analysis play a critical role in diagnosing cooling tower faults. In Wayang Windu, data analysis of motors on the cooling tower is conducted using internal resources without the assistance of third-party engineering services. As a result, Wayang Windu possesses raw data for motor analysis, comprising vibration data for each motor, along with analysis reports in managing motor conditions. Therefore, there is potential to enhance the existing system's efficiency by applying artificial intelligence through the development of deep learning that studies the existing trends and reports. The amount of data available for creating deep learning models includes cooling tower motor data from 2019 to 2024, with a sampling time of 500 milliseconds. This approach is expected to shorten data analysis and report generation time which usually takes minimum 2-4 days from data collecting to analysis, thereby achieving time efficiency, and increasing the reliability of the system due to continuous condition-based maintenance implementation. Deep learning techniques have gained popularity for condition-based maintenance applications due to the promulgation of industrial data globally, expediting the optimization of maintenance activities by monitoring assets. The utilization of Deep learning algorithms in developing anomaly detection model based on instrument data has been applied across various industries. This research discusses the application of deep learning algorithms to create auto-detection models for motor analysis on geothermal power plant cooling towers. Incorporating deep learning enables the transformation of condition-based maintenance, converting conventional reporting analysis, which is time-consuming, into an instant process. Deep learning enables swift and firsthand analysis of real-time sensor data, which can immediately provide text-based warnings to the PC workbench when undesirable occurrences arise. This research can provide comprehension of how deep learning application enhance instant analysis in geothermal power plant cooling tower, offering a solution to enhance the current safety measures with condition-based maintenance method, enabling prompt and direct actions when undesired conditions occur.

1. INTRODUCTION

One of the critical components of geothermal power plants is the cooling tower. Cooling towers are employed to condense steam on the low-pressure side of the turbine, optimizing electrical generation efficiency (Sarmago et al.,2001). Cooling towers utilize electric motors to drive fans that facilitate the heat exchange process, a crucial function in maintaining the operational stability and efficiency of the plant. The presence of large rotating equipment and their elevated placement within the tower structure, such as the wooden structure standing for about 24 years in one of the cooling towers at Wayang Windu, poses significant challenges, contributing to potentially high vibrations in the tower. As a result Over the past years, vibration levels in the Wayang Windu cooling tower were classified between Zone B (okay) & C (alert) in normal operation according to ISO 108613. This vibration environment is critical as it directly affects the equipment's condition and performance.

The performance of cooling towers directly influences the overall efficiency of geothermal power plants. For instance, in the Wayang Windu case, a failure in a single cooling tower cell can result in a load reduction of approximately 0.5 to 2 MW. This reduction becomes exponentially greater with multiple cell failures, leading to a substantial drop in overall load when up to eight cells are non-operational. This potential for load reduction underscores the importance of maintaining the optimal operation of cooling tower cells. Proper maintenance of

cooling towers is crucial not only for sustaining the power plant's output but also for ensuring its economic viability. The failure of multiple cells can lead to a cascade effect, where the plant's efficiency deteriorates rapidly, causing increased operational costs and reduced power availability.

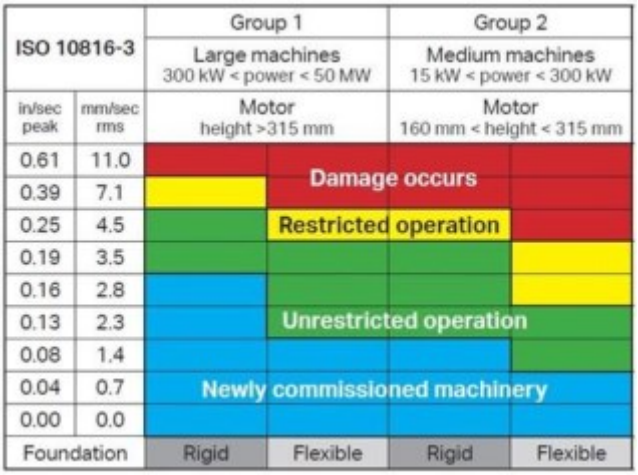

Figure 1: ISO 10816-3 Standard.

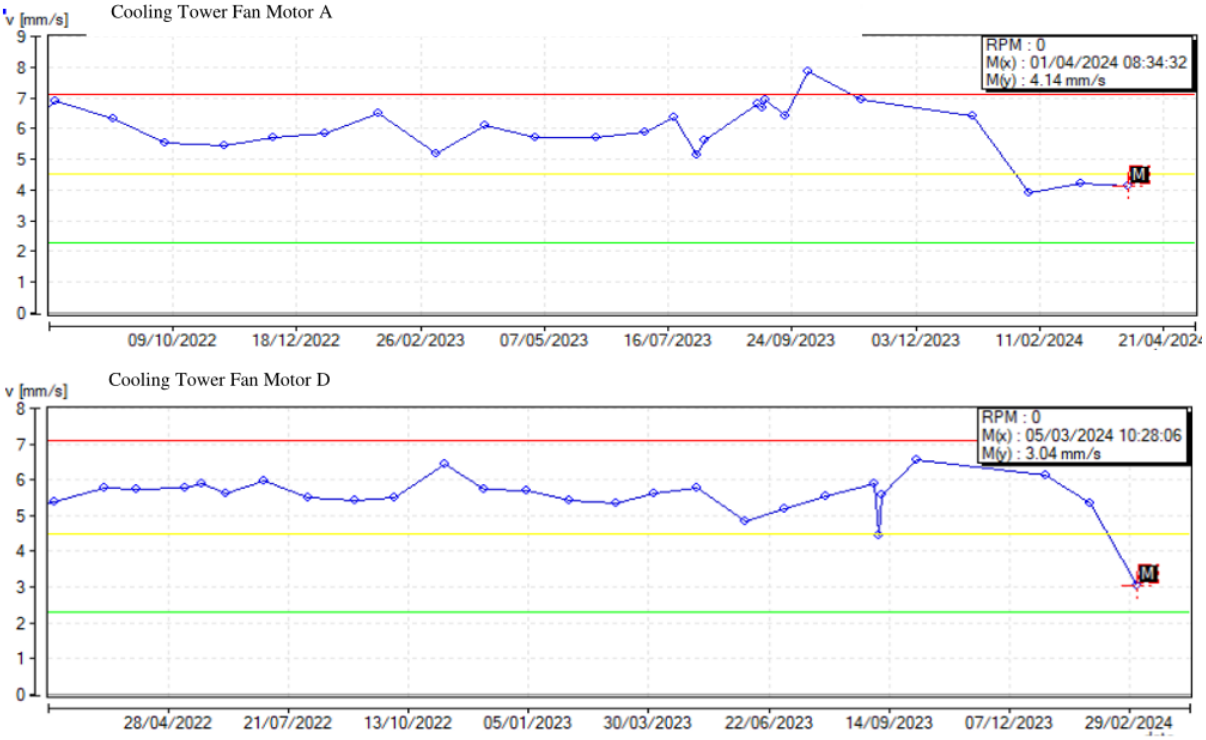

Figure 2: Overall Velocity Vibration of the Electric Motor Cooling Tower.

One method to maintain the performance of cooling towers involves preparing a monthly report for geothermal power plants to evaluate the condition of each piece of equipment. This report is known as the P2RM (Powerplant Performance Reliability and Maintainability). The report contains detailed analyses where the analyst looks for symptoms, behaviors, and patterns that recur over time. These details are compiled, outlined in the report, and published at the end of each month. This report explains all measurements, whether the equipment is operating under normal conditions or not. The analyst translates the measurement data to identify potential failures in the equipment being analyzed, highlighting parts that may fail. This process involves manual data collection, data entry into a work computer, performing manual analysis on the data and report generation to assess the condition of the motor or gearbox in the cooling tower.

In the 21st century, New Industry 4.0 is driven by the integration of cyber-physical systems and advanced computing infrastructures like AI, big data, data analytics, cloud computing, and IoT platforms (Lee et al., 2019). Various studies explore different Artificial Intelligence methods for predictive maintenance across diverse systems, aiming to optimize maintenance strategies in industrial applications (Nchekwube et al., 2022). These

technologies significantly enhance the precision and effectiveness of predictive maintenance systems, making them more autonomous and adaptable in complex operational environments (Ucar et al., 2024). Data-driven intelligent predictive maintenance (IPdM) addresses the pressing need to predict equipment failures and reduce unplanned downtime (Wang et al., 2023). Deep learning, a subset of AI, plays a crucial role by training algorithms to detect patterns in large datasets, improving the accuracy and timeliness of failure predictions. The application of deep learning in data analysis shows considerable potential to enhance maintenance processes, offering insights that can lead to more efficient operations (Mohammadi et al., 2018). The application of artificial intelligence in condition monitoring systems, specifically using deep learning (DL) algorithms for intelligent identification and prediction in industrial facilities, can significantly enhance productivity by reducing the required man-hours (Kraus et al., 2020). This results in a decreased time span in the analysis process, leading to better allocation of human resources. Moreover, if this process can be streamlined seamlessly, continuous predictive maintenance can be implemented, allowing for the constant prediction of equipment failures. This enables the early detection of potential issues, ensuring timely interventions and minimizing downtime.

The integration of deep learning into the maintenance procedures of cooling towers at geothermal power plants has the potential to transform condition-based maintenance practices. Prior to adopting deep learning, maintenance efforts were largely manual and time consuming. By Implementing deep learning, the maintenance process becomes more efficient. This paper aims to highlight the synergy between historical equipment data derived from reports compiled by capable people that have already observed the equipment for over several years and artificial intelligence in geothermal industry. By integrating these insights, the AI system aims to replicate the maintenance team's decisions that used to take time in reporting to be instantaneous, thereby increasing the productivity of manhours in operations at geothermal power plants.

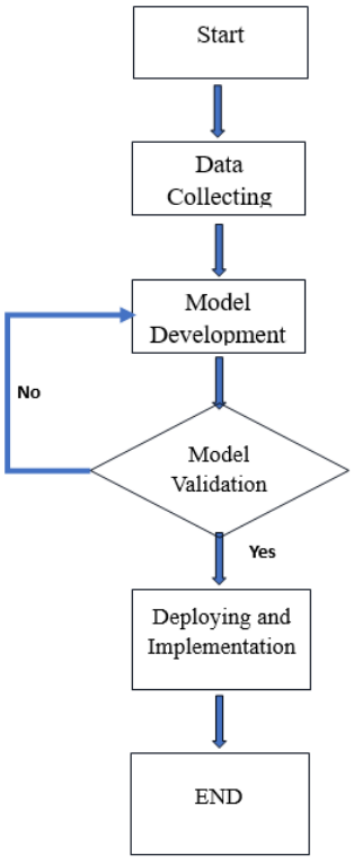

Figure 3: Process Flowchart.

2. METHODOLOGY

In this paper, we propose the development of an intelligent system for anomaly and fault detection in electric motors used in cooling towers. The flowchart outlining the development process is illustrated in Figure 3.

2.1 Data Collection and Processing

The data used in this paper's methodology for implementing artificial intelligence for fault detection comes from Baldor electric motors, which are manufactured with an RPM of 1485 and operate at a frequency of 50 Hz. This

data set comprises vibration data collected from 8 motors installed in a cooling tower. Each motor was carefully monitored to gather comprehensive vibration data, ensuring a diverse and representative sample of operational conditions. All data was obtained through manual measurements taken at various critical points on the drive end and non-drive end of each motor, covering horizontal, axial, and vertical axes. These measurements provide a multi-dimensional view of the motors' vibration characteristics, capturing any anomalies or deviations that may indicate potential faults. The detailed data collection points for each motor on all axes can be seen in Figure 4.

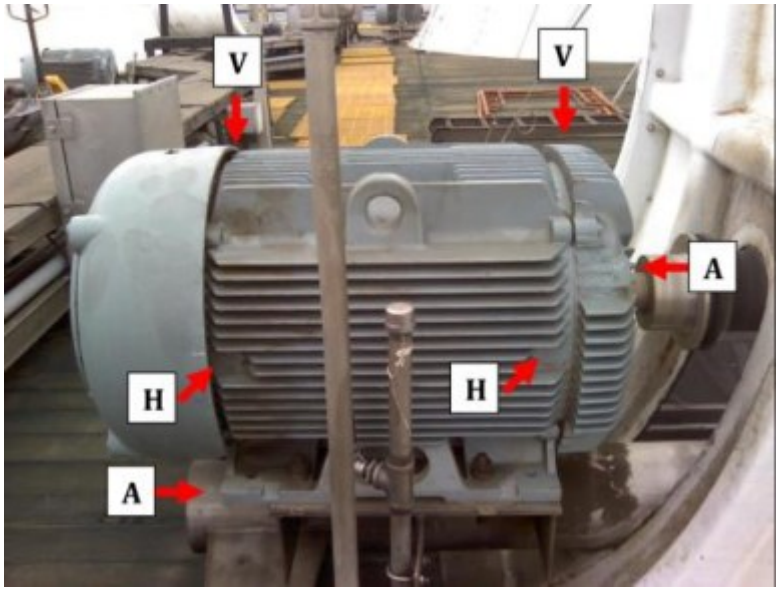

Figure 4: Data Collection Points for Electric Motor.

Each data sample has a duration of 500 ms, with measurements taken monthly over a span of 5 years from 2019 to 2024. The displacement data obtained is transformed into velocity and bearing envelope acceleration, which are then converted from time series to frequency series. Based on ISO 10816, the overall amplitude of the motor ranges from 0 to 5 Hz to 1000 Hz. In the Wayang Windu best practice, frequencies in the range of 0 to 1600 Hz will be used as input for the artificial intelligence model. Following data collection, the dataset was classified based on the motor's condition, with analysis reports conducted by the Condition based Maintenance (CbM) team Wayang Windu team serving as references for determining motor conditions. Classification and labeling were restricted to three categories: motors in normal condition, motors showing anomalies but still acceptable for operation, and motors exhibiting anomalies indicative of potential failure.

The selection of these three categories is based on the diverse possibilities of failure conditions, where each failure type does not have enough samples for artificial intelligence modeling. This presents potential for further development to classify each failure type individually, enabling identification of every possible failure. However, given the current data constraints, it will be necessary to augment the data for each failure type using various transformations. This will create variations from the original data and increase the amount of failure data for each type of failure which will be interesting for further development. Examples of input data for each label can be observed in figure 5 to Figure 10.

After classifying the vibration data into velocity and bearing envelope acceleration categories, a comprehensive dataset was compiled, consisting of 2,805 data points for velocity and 2,501 data points for bearing envelope acceleration. These data points were meticulously collected and analyzed to capture variations across different operational conditions of the motors. The specific breakdown of this dataset, including detailed statistics and distributions for both velocity and bearing envelope acceleration measurements, can be found in Table 1.

Table 1: Original Data Distribution for each label.

Label Category	Velocity	Bearing Envelope
Healthy	960	835
Acceptable	900	819
Potential Failure	945	847
Total	2.805	2.501

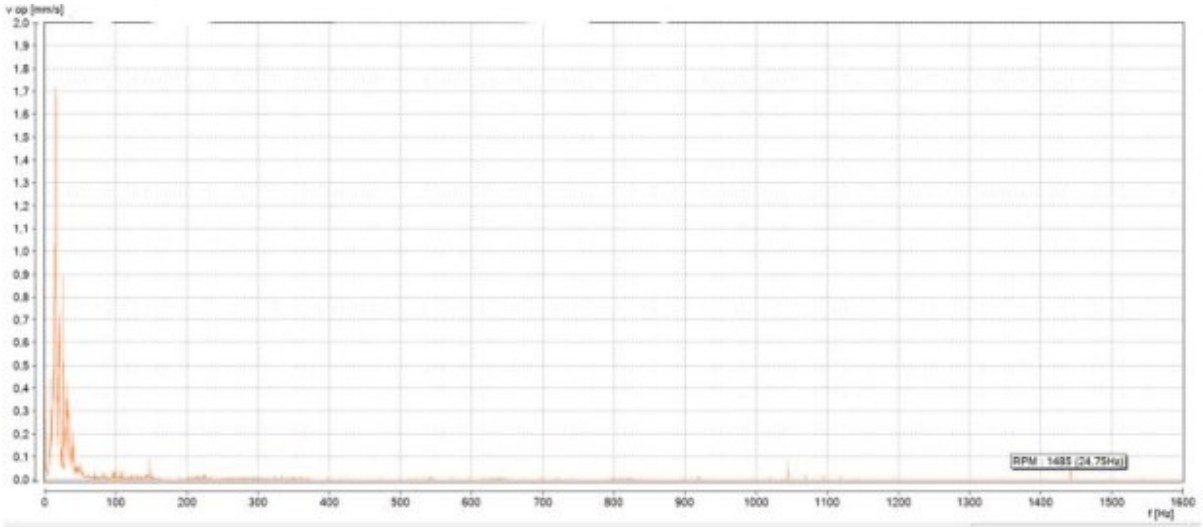

Figure 5: Velocity Domain Normal Condition.

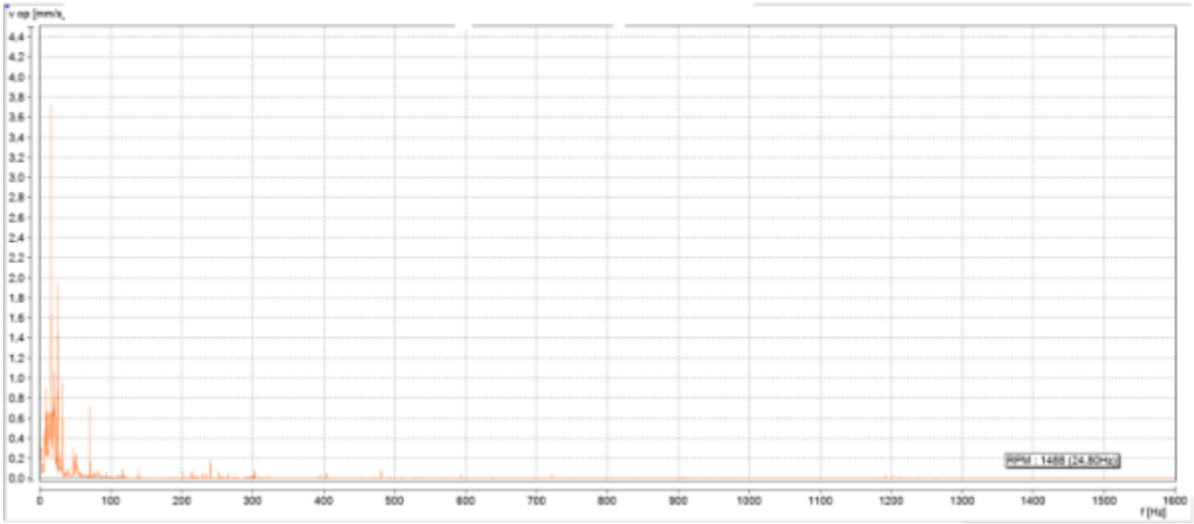

Figure 6: Velocity Domain Quite High in 1x Order but still Acceptable.

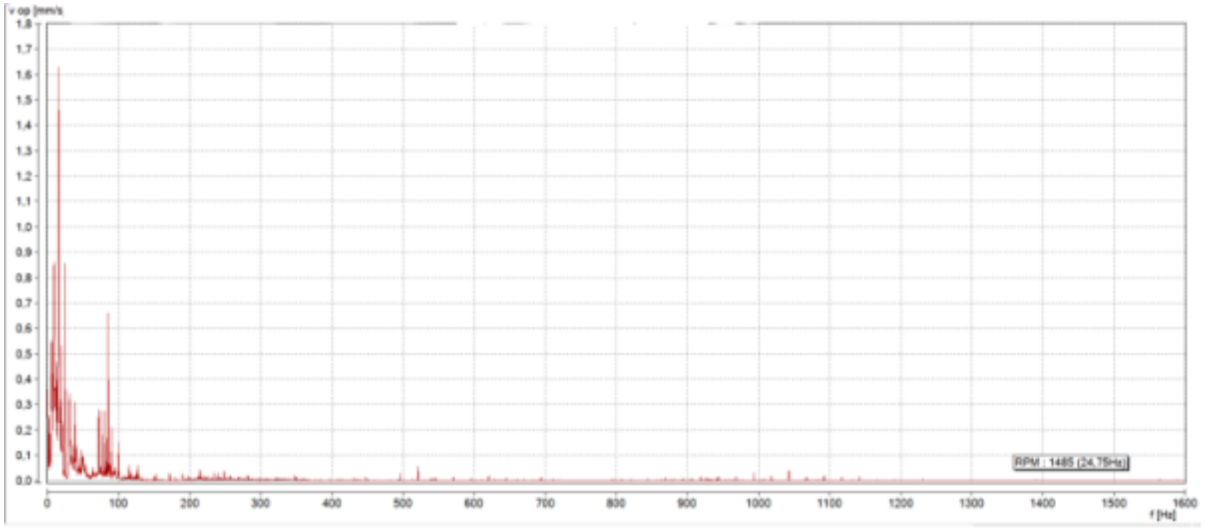

Figure 7: Velocity Domain Potential Failure indicates early defect on both bearings and mechanical looseness.

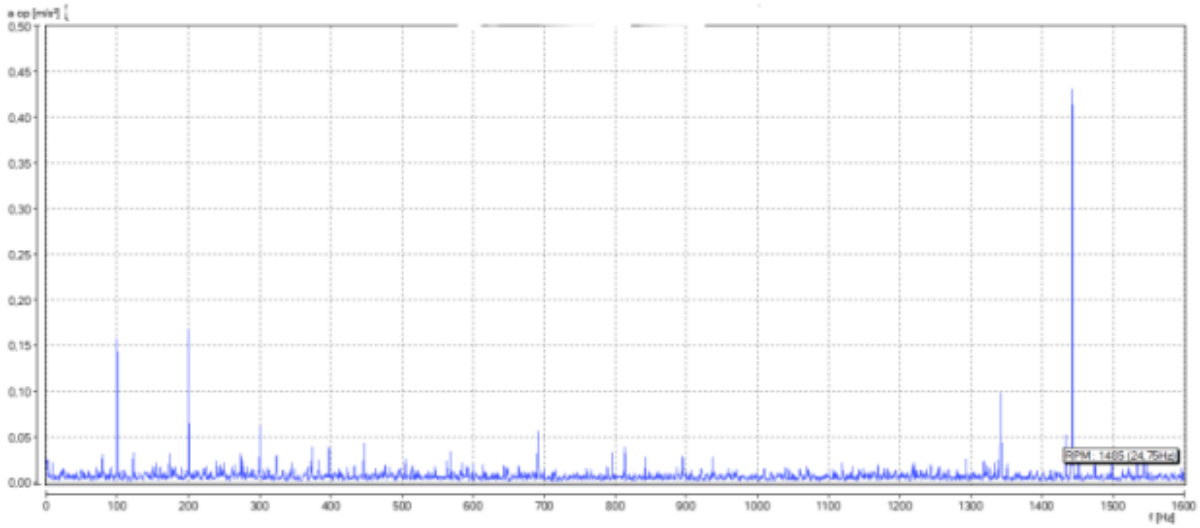

Figure 8: Bearing Envelope Acceleration Domain: Normal Condition.

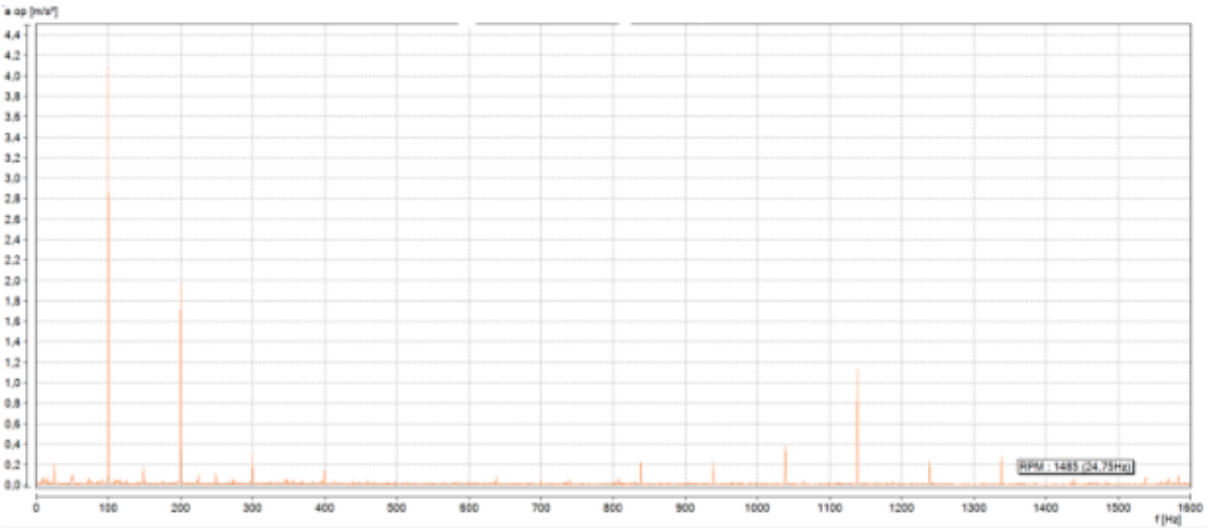

Figure 9: Bearing Envelope Acceleration Domain: Electrical Noise Symptom Detected in 100 Hz but Still Acceptable.

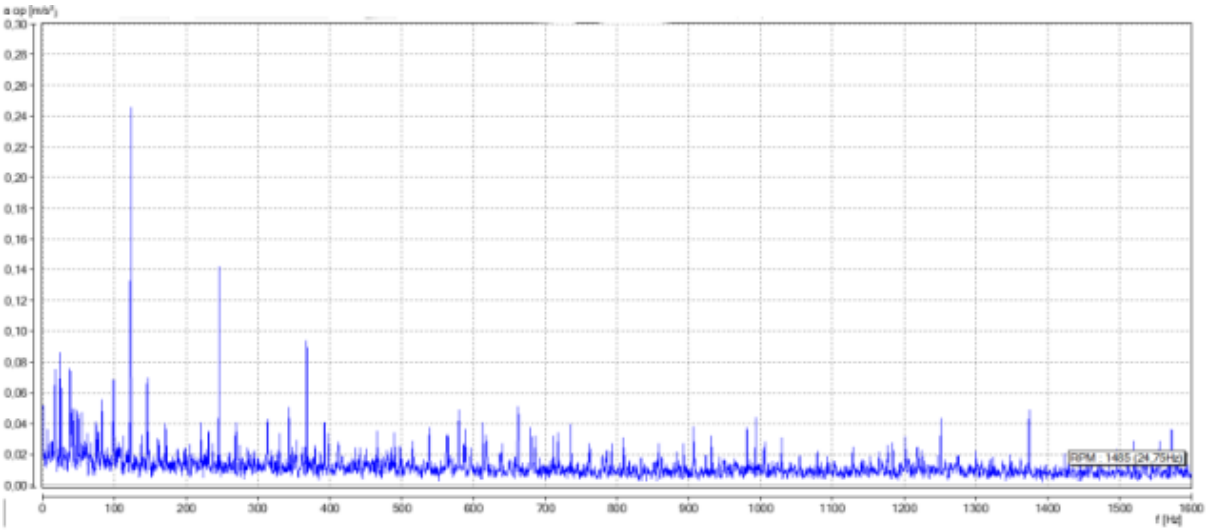

Figure 10: Bearing Envelope Acceleration Domain: Potential Failure Because Bearing Defect Frequency Detected.

The data categorized into three classes exhibit significant variation due to the diverse conditions grouped under each label. For instance, within the failure category, different failure modes such as misalignment and bearing defects each with distinct patterns are combined under a single label. This complexity also applies to the other labels. To address potential underfitting in the model for each label, it is crucial to increase the amount of data that shares similar variations and patterns. Following the data collection process, data augmentation is implemented to generate additional data with comparable variations. One approach widely adopted in existing research is the application of Gaussian noise and data scaling for augmentation. (Victor & Ali, 2024) Specifically, Gaussian noise with a standard deviation of 0.03 is introduced to add minor perturbations to the data, while scaling is performed within the range of -0.02 to 0.02. These methods help to create augmented data that retains the essential characteristics of the original data while introducing slight variations. An example of the augmented data compared to the original data is presented in Figure 11 and Figure 12.

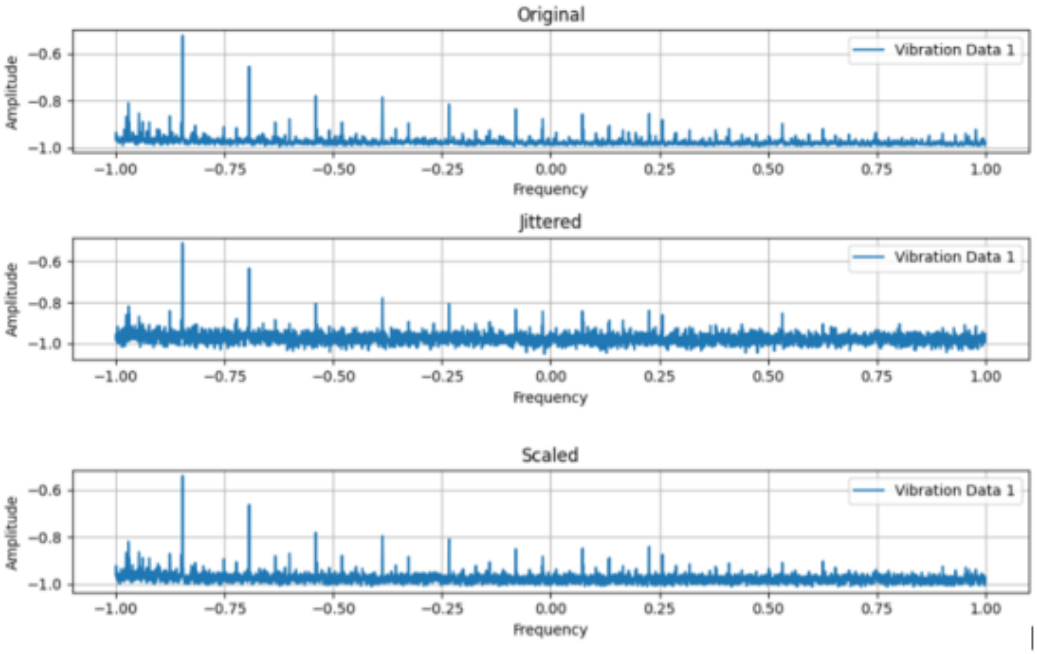

Figure 11: Example of Bearing Envelope Acceleration Original Data and its Augmentation version.

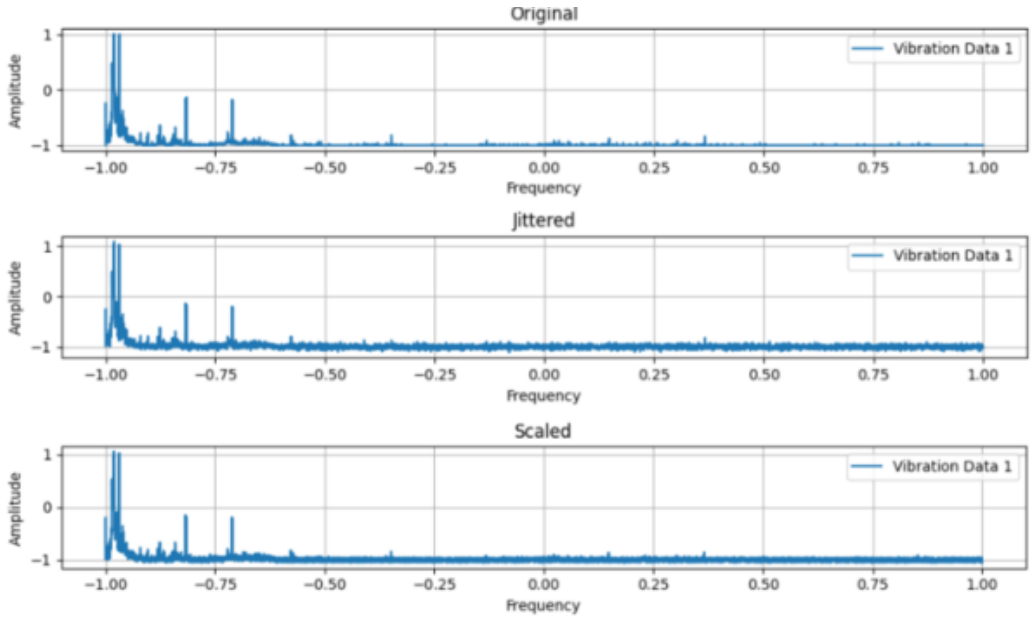

Figure 12: Example of Velocity Original Data and its Augmentation version.

Consequently, the total dataset used as input for the artificial intelligence model will be tripled compared to the original data, as shown in Table 2.

Table 2: Data Distribution for each label.

Label Category	Velocity	Bearing Envelope
Healthy	2880	2505
Acceptable	2700	2457
Potential Failure	2835	2541
Total	8415	7503

2.2 Model Development

This section details the methodology employed in the development of the artificial intelligence model. Initially, vibration data were collected and transformed into the velocity and bearing envelope acceleration domains. Subsequently, the data were converted from time series into the frequency domain to extract crucial parameters. Following these transformations, normalization was applied to standardize the frequency domain data within the range of -1 to 1, thereby enhancing model performance. The normalized vibration data were then structured into arrays consisting of frequency values and their corresponding measurements. This step is pivotal as it facilitates the capture of intricate patterns inherent in vibration signals. The dataset utilized for this process was derived from vibrations recorded across eight motors, serving as primary inputs for training the artificial intelligence model. Next, the dataset was partitioned into two subsets: training data and validation data. This segregation is imperative to mitigate overfitting, a phenomenon where the model performs excessively well on training data but fails to generalize to unseen data. Based on best practice data splitting for train and test an 80:20 split ratio was selected, allocating 80% of the dataset for training and reserving 20% for validation and testing purposes.

The model development was executed in a Python environment utilizing the PyTorch library, a robust framework for constructing artificial intelligence models. The development process encompassed several steps:

1. Selecting Appropriate Architectures: Identifying and choosing artificial intelligence architectures best suited for the classification task. In this research, two machine learning models and two deep learning models are selected. The two machine learning models used are Decision Tree and Random Forest, while the deep learning models chosen is Residual Network 1D. Separable CNN1D is selected for its faster training, lower memory requirements, and potentially superior performance in tasks like time series analysis by breaking down convolutions into efficient steps, making it suitable for intricate pattern recognition tasks (Pazos et al., 2024).
2. Tuning Training Parameters: Systematically adjusting hyperparameters such as learning rate, batch size, and the number of epochs is crucial to optimize the performance of the model. This process involves fine-tuning these parameters to find the optimal combination that maximizes the model's accuracy and efficiency in classifying vibration data.
3. Optimizing the Model: Implementing techniques such as regularization and dropout is essential to mitigate overfitting and improve the model's ability to generalize. Regularization techniques help in preventing the model from memorizing noise or irrelevant details in the training data, thereby enhancing its robustness when applied to new, unseen data. Dropout, on the other hand, aids in reducing interdependent learning among neurons during training, promoting better generalization and preventing the model from becoming too specialized to the training dataset.

2.3 Model Validation

Next, Deep learning model and machine learning model algorithms are developed to compare their performance in classifying vibration signals into three categories based on the available data. The analysis results from previous P2RM reports are used as a basis to validate the developed artificial intelligence models. This involves comparing metrics such as confusion matrix, accuracy, precision, recall, and F1 score of these models with the reported outcomes. By leveraging these documented results, a comparison is made to evaluate how well the models classify the conditions of motors in cooling towers based on vibration data (Lee et al., 2021). This approach ensures a comprehensive analysis and confirms the models' capability in effectively detecting anomalies and faults. One of the commonly used tools in predictive analysis is the confusion matrix, which evaluates the performance of classification-based models. It provides a summarized table of the number of correct and incorrect predictions made by the classifier. A confusion matrix is an N x N table used for assessing the performance of a classification model. By visualizing the confusion matrix, one can determine the model's accuracy by examining the diagonal values, which represent the number of correct classifications. Confusion matrix consists of TP (true positive), TN (true negative), FP (false positive), and FN (false negative) are terms used in the evaluation of the models. These terms help measure how accurately the models classify vibration data from cooling tower motors. TP represents cases where the model correctly identifies a condition as positive (correctly detects an issue), TN represents correctly identified non-issues, FP indicates cases where the model incorrectly flags a non-issue as an issue, and FN shows cases where an actual issue is missed by the model.

From the confusion matrix, we can calculate various performance metrics: Accuracy measures the proportion of correct predictions made by the model out of all predictions and is expressed as a percentage (%). It provides an overall indication of the model's performance by evaluating how often the model makes correct predictions across both positive and negative classes. The formula for calculating accuracy is given by Equation (1).

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

Precision computes and estimates the number of positive classes that are correctly identified as truly positive among all instances that were predicted as positive. The formula for calculating precision is given by Equation (2).

$$Precision = \frac{TP}{TP + FP} \tag{2}$$

Sensitivity, also known as recall, measures and predicts the number of positive classes in the dataset by determining the proportion of actual positive instances that are correctly identified by the model. The formula for calculating sensitivity is given by Equation (3).

$$Sensitivity = \frac{TP}{TP + FN} \tag{3}$$

The F1 score is the harmonic mean of precision and recall, providing a balanced measure that considers both the precision (the accuracy of positive predictions) and sensitivity (the ability to identify all positive instances). The F1 score is expressed mathematically as shown in Equation (4), where a higher F1 score indicates a better balance between precision and recall.

$$F1\ Score = \frac{2\ .Precision.Sensitivity}{Precision + Sensitivity} \tag{4}$$

An ROC curve (receiver operating characteristic curve) is a graph showing the performance of a classification model at all classification thresholds. This graph plots two parameters, the true positive rate (TPR) vs false positive rate (FPR) (Fawcett, 2006). The equation for true positive rate is same as sensitivity or equation (3) and the equation for the false positive rate is given by equation 5.

$$FPR = \frac{FP}{FP + TN} \tag{5}$$

ROC graphs are an excellent tool for visualizing and assessing classifiers. They offer a more comprehensive measure of classification performance compared to scalar metrics like accuracy, precision, sensitivity etc. This is because they separate classifier performance from class imbalance and errors (Fawcett, 2006).

This methodology ensures a thorough approach to analyzing and classifying vibration data, crucial for enhancing the detection of anomalies and faults in cooling tower motors. By achieving high scores in these metrics' accuracy, precision, recall, and F1 score the models demonstrate their reliability in effectively assessing the motors' conditions based on vibration data. This validation approach not only strengthens the analysis process but also builds upon insights gained from previous P2RM studies. It leverages prior knowledge to improve the models' capability to identify and predict potential issues.

2.4 Deploying and Implementation

After validating the model, the next step is to implement Artificial intelligence into the existing maintenance process. There are two methods available for implementing AI models into maintenance operations in the geothermal industry. The essence of these methods depends on the approach to vibration data acquisition. One method involves manual collection of data, which is then fed into an AI model for instant analysis. Alternatively, the AI model can be integrated with a continuous condition monitoring system. The first method is generally easier to implement but may be constrained by its reliance on time-based data collection systems. In contrast, the second method facilitates the establishment of a continuous condition-based maintenance system but requires modification of the existing monitoring system.

Deploying artificial intelligence model to existing condition monitoring system involves a structured series of steps to ensure it operates efficiently and effectively. Initially, data collection begins with sensors and monitoring devices attached to the equipment, capturing parameters like vibration that indicate its operational state. This data is then securely transmitted to a centralized storage system, typically cloud-based or a dedicated local database.

Next, the raw data undergoes preprocessing to eliminate noise, handle outliers, and standardize formats. This critical step enhances data quality and ensures consistency across datasets. Following preprocessing, feature extraction identifies significant patterns from the data, essential for the accuracy of the AI models. The trained AI model is then deployed to continuously analyze real-time data, detecting anomalies and predicting potential equipment failures. Results from the model are interpreted by the condition analysis module, which assesses the equipment's health status. An alert system promptly notifies maintenance personnel of detected anomalies or predicted failures, enabling timely intervention and minimizing unexpected downtimes.

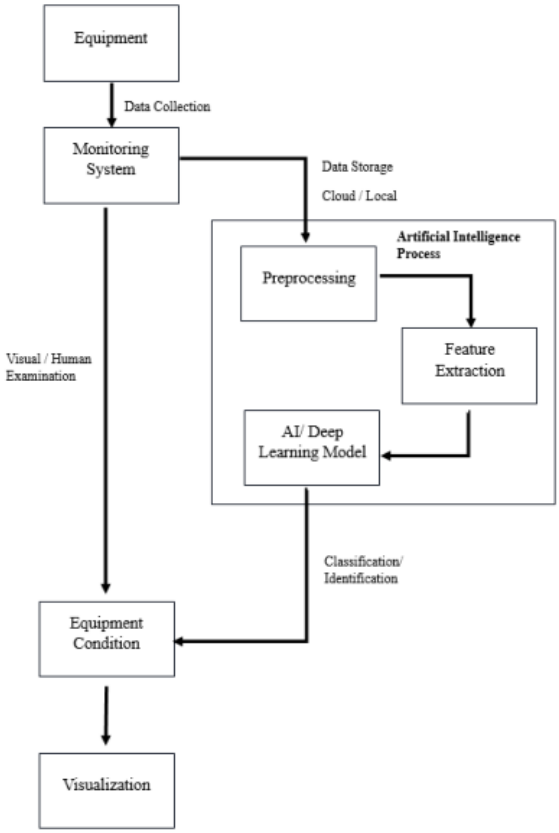

Figure 13: Implementation Scenario for Continuous Monitoring.

Visualization tools, such as dashboards and reports, are employed to provide users with real-time insights and historical data analysis. These tools simplify decision-making by presenting complex data in a user-friendly format. Additionally, a supervisory role ensures that decision-making processes are guided effectively, enabling the condition-based maintenance team to maximize system performance through continuous monitoring. In conclusion, deploying an AI -based condition monitoring system involves a holistic approach from initial data collection to continuous learning aimed at optimizing equipment performance. The diagram of the implementation process can be seen in Figure 13.

3. RESULT AND DISCUSSION

After completing model development and data preprocessing, the artificial intelligence model will undergo rigorous testing to accurately identify and classify motor conditions. This testing phase is crucial to assess how well the model performs in real-world scenarios. The analysis results will be validated using several key performance metrics, including a confusion matrix, accuracy, precision, recall, and F1 Score. These metrics provide a comprehensive evaluation of the model's ability to correctly classify different motor conditions.

It's important to note that the dataset used includes a wide range of possibilities for both failure conditions and acceptable operating conditions in the equipment. This variability in the data reflects diverse scenarios and conditions that motors may encounter in practical use. Such diversity can significantly impact the performance of the artificial intelligence model, influencing its ability to generalize across different types of anomalies and operational states. The performance results for each model and architecture, including these metrics, are summarized in table 3, providing a clear comparison of their effectiveness in fault detection and classification tasks.

Table 3:Artificial Intelligence Model performance comparation.

Model	Validation Accuracy	
	Velocity	Bearing Envelope Acceleration
Separable CNN1D	95.37%	91.59%
Random Forrest	84%	80 %
Decision Tree	79%	74 %

Based on the analysis presented in Table 2, the deep learning model demonstrates better accuracy than the machine learning model, highlighting its ability to learn the vibration patterns of the equipment. Among the deep learning models, the Separable CNN1D model stands out as the most accurate, effectively distinguishing between normal operating conditions, acceptable anomalies, and potential failure scenarios. Its robust performance in classifying these distinct motor conditions is particularly noteworthy, highlighting its capability to reliably identify subtle patterns and variations in vibration data indicative of different operational states.

The detailed performance metrics to this model can be found in Table 4 for velocity and Table 5 for bearing envelope acceleration domain. This selection is grounded in the Separable CNN1D model's exceptional performance metrics, which include high accuracy, precision, recall, and F1 Score.

Table 4: Separable CNN1D Velocity Frequency domain.

Label	Precision	Sensitivity	F1-Score
Healthy	0.9397	0.9449	0.9423
Acceptable	0.9428	0.9475	0.9451
Potential Failure	0.9762	0.9671	0.9716

Table 5: Separable CNN1D Bearing Envelope Acceleration Frequency Domain.

Label	Precision	Sensitivity	F1-Score
Healthy	0.9293	0.882	0.9050
Acceptable	0.9214	0.9395	0.9303
Potential Failure	0.8982	0.9212	0.9096

Furthermore, the performance of the model also visually uses confusion matrix and receiver operating characteristics parameter that shown in Figure 14 and Figure 15.

Where class 0 is equipment in normal condition, class 1 is equipment exhibiting acceptable condition, and class 2 is equipment exhibiting potential failure.

The experimental results demonstrate that the implemented deep learning approach effectively predicts the vibration conditions of cooling tower motors at geothermal power plants. Analysis of the training and validation loss graphs indicates that the model is not overfitting and performs well, achieving an accuracy exceeding 90% for two parameters. Currently, the model classifies motor equipment conditions into three categories: normal condition, acceptable, and potential failure condition.

For now, implementation still involves manually inputting vibration data into the deep learning model for classification. To facilitate this process, a simple graphical user interface (GUI) was created to ease data input. The user will input the data, which has already been gathered using a Handled vibration instrument. After that, the deep learning model will classify the condition of the equipment. Examples of the user interface and the output of the user interface of deep learning model are shown in Figure 16.

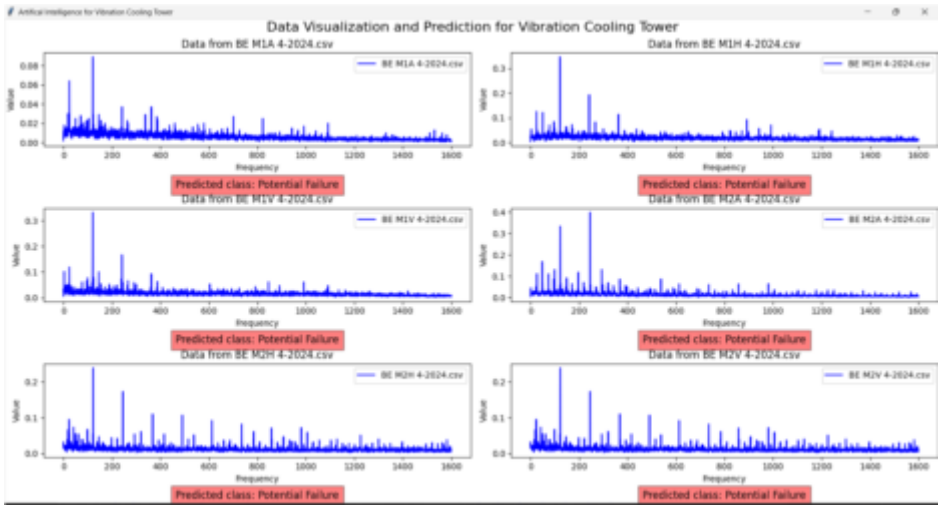

Figure 16: Example of user interface for Deep Learning Vibration Analysis.

Integrating deep learning to continuous monitoring of condition-based maintenance into the geothermal power plant's condition monitoring system remains challenging due to necessary modifications to the existing infrastructure. Nevertheless, this research offers valuable insights into applying deep learning for condition monitoring systems. These insights lay the groundwork for integrating artificial intelligence in the Wayang Windu geothermal power plant, enhancing productivity by automating time-consuming manual processes into instantaneous ones. This transformation reduces the manual workload on human resources, shifting their role from performing manual analyses to supervising decisions made by automated systems. Consequently, this approach minimizes the man-hours required for each condition-based maintenance cycle, optimizing the allocation of human resources.

4. CONCLUSION

The implementation of deep learning for diagnosing vibrations in cooling tower fan motors at the Geothermal Power Plant has shown promising results. The models achieved an accuracy of 95.37% for classifying vibration in the velocity frequency domain and 91.59% in the bearing envelope acceleration frequency domain. These findings demonstrate the effectiveness of deep learning in assessing the motor's condition based on historical data. Currently, the models can classify three conditions: normal operation, acceptable anomalies, and potential failures. The integration of artificial intelligence, specifically deep learning, into condition monitoring systems requires further exploration to ensure seamless and reliable implementation. This includes accurately diagnosing complex equipment failures and integrating with existing monitoring processes in the geothermal industry. Deep learning has proven effective in classifying motor conditions, paving the way for automated condition-based maintenance or intelligent condition-based maintenance. This automation improves productivity in data analysis, reducing downtime and enhancing overall cooling tower operational efficiency. As the dataset continues to grow and the models are refined further, we anticipate improvements in condition-based accuracy and diagnostic capabilities. This solidifies the role of deep learning as a powerful tool in industrial maintenance, especially geothermal, supporting continuous advancements in condition-based maintenance strategies.

5. FUTURE DEVELOPMENT

Deep learning holds significant promise for future development, provided we have sufficient data for training. As datasets for vibration analysis grow and diversify, it will become increasingly feasible to identify specific issues such as misalignment, bearing defects, and other types of failures. Moreover, leveraging current data trends, artificial intelligence can also estimate the remaining life of equipment until failure. This progress will greatly enhance the diagnostic capabilities of systems, leading to more precise maintenance recommendations that can be acted upon promptly. Additionally, techniques such as data augmentation can simulate failures without damaging equipment, enabling us to refine our failure categories beyond the current three to more detailed classifications.

Furthermore, with adequate data, artificial intelligence can be applied to other equipment and systems. The potential for artificial intelligence in geothermal power plants is particularly vast, with numerous possibilities yet to be explored. This research represents an initial step toward harnessing artificial intelligence to turn challenges into opportunities, ultimately achieving unprecedented levels of productivity.

Keywords: CSI Analyzer 2130, VibExpert, Vibration, Frequency, Spectrum, Waveform, Crack, Twist, Turbine Rotor, Segregate Unbalance, System-1, PI System

ABSTRACT

Most Vibration Analysts in the world agree that looseness is one of the five most common causes of breakdowns that result in excessive engine vibration, along with eccentricity, unbalance, and misalignment. The best solution to the looseness problem is to install the machine properly. But how if we found non-harmonic (independently) 5x or 6x or 7x or 8x, etc. on the old and/or refurbished turbine rotors a device designed to have the same reaction frequency as the dominant vibration direction of the structure itself that will counteract the initial motion? Vibrations from the machine will form a signal that can be detected by the CSI Analyzer 2130 tool to produce a vibration signal. The signal can be analyzed as damage to the machine from this vibration. As the damage done to the Turbine Rotors base frames. The study analyzed vibrational signals in damaged Base frames by monitoring the times of 50 Hz spectrum signals at 250 Hz to 400 Hz, the difference was seen in the shape of the spectral signal and vibrational waveform. In addition, the overall value also shows an increase in the Turbine Rotors Side. The overall value produced on the turbine casing can reach more than 15 mm/sec RMS on the turbine horizontal side. In contrast to the system under normal conditions with an overall value of 1.433 mm/sec RMS. The overall value of the damaged system has exceeded the vibration limit of 7.5 mm/sec RMS.

1. INTRODUCTION

The mechanical vibrations generated from the machine come from the internal high- speed rotating activity of the system itself, so the vibration symptom has a frequency that cannot be felt significantly by the human senses. One of the machines which a high-speed rotation with a stable vibration frequency is a Turbine Rotor. The Turbine The turbine rotor receives high-pressure steam or hot water from the geothermal reservoir. As this fluid passes through the turbine blades, it expands, and its pressure drops. This expansion causes the rotor to spin, converting the thermal energy of the fluid into rotational mechanical energy. And all the indications of a problem at the Turbine Rotor will determine from the fault frequency of vibration produced by the magnitude. The objective of this study is to get benefit by employing vibration signal analysis to anticipate and assess potential damage to the Turbine Rotor, thereby fostering proactive measures against unforeseen harm resulting from the 'Bhakti Twist Phenomenon'.

2. LITERATURE

Vibration analysis is one of the methodologies usually used in performing predictive techniques for Rotating Equipment (rotating machines). This technique utilizes the characteristics of the vibration generated by a rotating machine. Some of the defects that often appear on rotating machines are base-frames defects (resonance), unbalance, and misalignment. Each failure defects cases have its specific characteristics in the generated vibration signal pattern. There are three main parameters analysis should we concerned with vibration analysis performing, namely amplitude, frequency, and phase.

Amplitude is the size or magnitude of the vibration signal generated or identified as the magnitude of the generated force by the vibration. The higher the indicated amplitude, the greater the disturbance that occurs. The magnitude scale of the amplitude depends on the type of engine and its damage. The increase in amplitude at specific faults frequencies identifies the suspects of disturbances in the engine. By knowing the frequency when the machine vibrates, precision observation can determine the cause or source of the problem.

Measurement trending will send information about the increasing level of engine vibration. When the engine vibration level increases beyond the baseline signal, it is necessary to carry out special handling on the engine. Baseline data is a collection of data obtained through measurements when the machine is operating stably. The baseline data serves as a comparison of measurement data to determine the engine condition. Meanwhile, to classify the level of damage or severity of the large turbo machinery, several standards are used to evaluate damage, Vibration Standard:

Mechanical vibration — Evaluation of machine vibration by measurements on non-rotating parts, part 2 : Land-based steam turbines and generators in excess of 50 MW with normal operating speeds of 1500 r/min, 1800 r/min, 3000 r/min and 3600 r/min.

Zone boundary	Shaft rotational speed r/min			
	1 500	1 800	3 000	3 600
	Peak-to-peak relative displacement of shaft µm			
A/B	100	90	80	75
B/C	200	185	165	150
C/D	320	290	260	240

Figure 1: ISO 7919-2:2001.

Special-Purpose Steam Turbines for Petroleum, Chemical and Gas Industry Services:

2.8.5.5 During the shop test of the machine, assembled with the balanced rotor, operating at its maximum continuous speed or at any other speed within the specified operating speed range, the peak-to-peak amplitude of unfiltered vibration in any plane, measured on the shaft adjacent and relative to each radial bearing, shall not exceed the value calculated from Equation 6 or 25 micrometers (1.0 mil), whichever is less:

$$A = 25.4\sqrt{\frac{12,000}{N}} \qquad (6)$$

In U.S. Customary units,

$$A = \sqrt{\frac{12,000}{N}}$$

Where:

A = amplitude of unfiltered vibration, in micrometers (mils) peak to peak.
N = maximum continuous speed, in revolutions per minute.

At any speed greater than the maximum continuous speed, up to and including the trip speed of the driver, the vibration shall not exceed 150 percent of the maximum value recorded at the maximum continuous speed.

Figure 2: API STANDARD 612.

In this case:
N = 3000 RPM

$$A = 25.4 \times \sqrt{\frac{12000}{3000}} = 50.8 \mu m \text{ p-p}$$

Most Japan Manufacture Standard:
Warning Level : 125 microns
Fault Level : 250 microns

Mechanical vibration — Evaluation of machine vibration by measurements on non-rotating parts,

Part 2: Land-based steam turbines and generators more than 50 MW with normal operating speeds of 1500 r/min, 1800 r/min, 3000 r/min and 3600 r/min.

Zone boundary	Shaft rotational speed r/min	
	1 500 or 1 800	3 000 or 3 600
	R.m.s. vibration velocity mm/s	
A/B	2,8	3,8
B/C	5,3	7,5
C/D	8,5	11,8

NOTE 1 These values relate to steady-state operating conditions at rated speed for the recommended measurement locations (see Figure 1). They apply to radial vibration measurements on all bearings and to axial vibration measurements on thrust bearings.

NOTE 2 These values are valid for steam turbines and generators mounted on rigid and flexible foundations. However, in general, vibration magnitudes observed on machines on massive concrete foundations are lower than those for machines with more flexible foundations.

Figure 3: API ISO 10816-2.

3. METHODOLOGY

The method used in this research is to take vibration signals with the CSI Analyzer 2130 and System-1 on the vertical, horizontal, and axial Turbine Rotors. The procedure is as follows:

1. Turbine Rotor in operating condition with a rotating speed of 3000 RPM, measured using a CSI Analyzer 2130, VibeExpert, and Bently Nevada Module.
2. Measurement of vibration signals using this tool on the vertical, horizontal, and axial on each inboard side and also by using proximity probes.
3. After obtaining a vibration signal indicating damage to the inboard side, the data is entered into the AMS Suite software database: Machinery Health Manager, Omni trend and System-1.
4. The next measurement on the system uses a monitoring signal on the Normal Averaging amplitude value at maximum frequency = 1000 Hz.

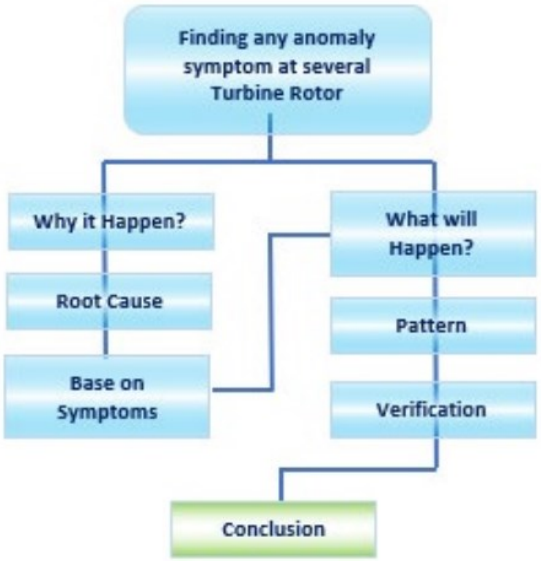

Figure 4: Workflow.

4. DATA ACQUISITION

Data Collecting -Correct and accurate data collection will be helpful in the process of analyzing research results. The data collection method also determines the quality of the data obtained. In this study, researchers took data directly by observing several data of trending, Orbits, waveform, and spectrum patterns of the damage on the system.

After more than 20 years of working with turbo machinery systems, I have discovered a trend indicating that older or improperly refurbished turbine rotors tend to exhibit symptoms akin to looseness. However, unlike typical looseness, these symptoms are synchronous but not harmonics.

Rotor Turbine Outboard Horizontal

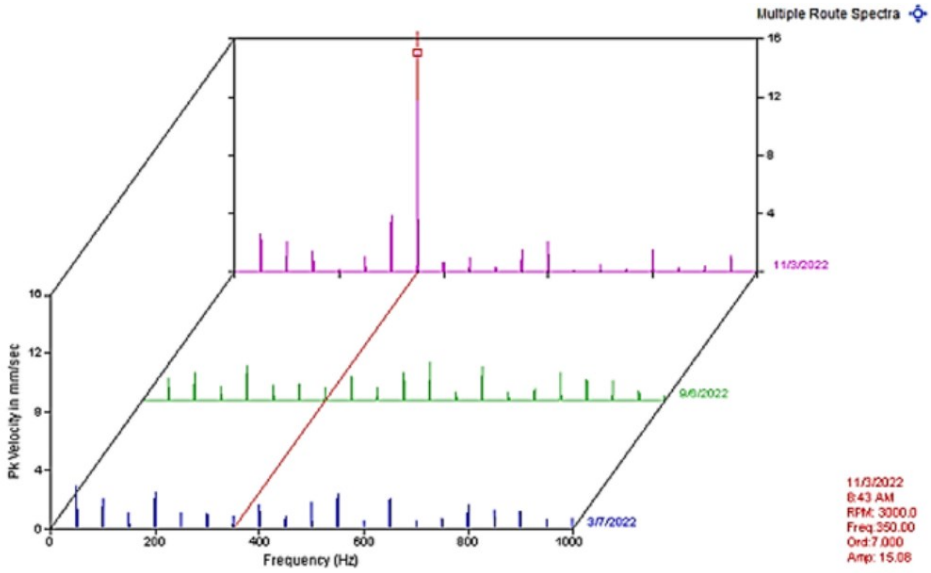

Figure 4: Spectrum shown 7X at Turbine Rotor.

Spectrum shown that 7X pattern at refurbished rotor turbine was occur, maybe it's acceptable for overall value but 15 mm/sec is too high for a single pattern. Vice versa to the previous, inboard side also shown that 7X pattern at refurbished rotor turbine was occur, maybe it's acceptable for overall value but 17 mm/sec is too high for a single pattern. On another Geothermal Plant and different manufacture, Rotor Spectrum after 8 years of operation shown increasing at 6X order.

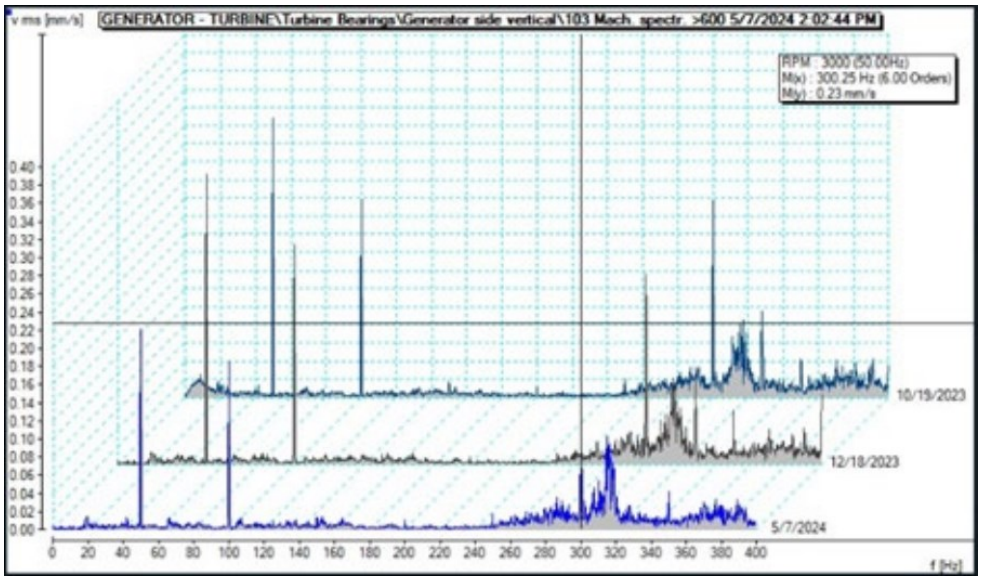

Figure 5: Spectrum shown 6X at Turbine Rotor after 8 years of operation.

And then the other Rotor Spectrum after 12 years of operation on another Geothermal Plant and different manufacture, also shown increasing at 6X order.

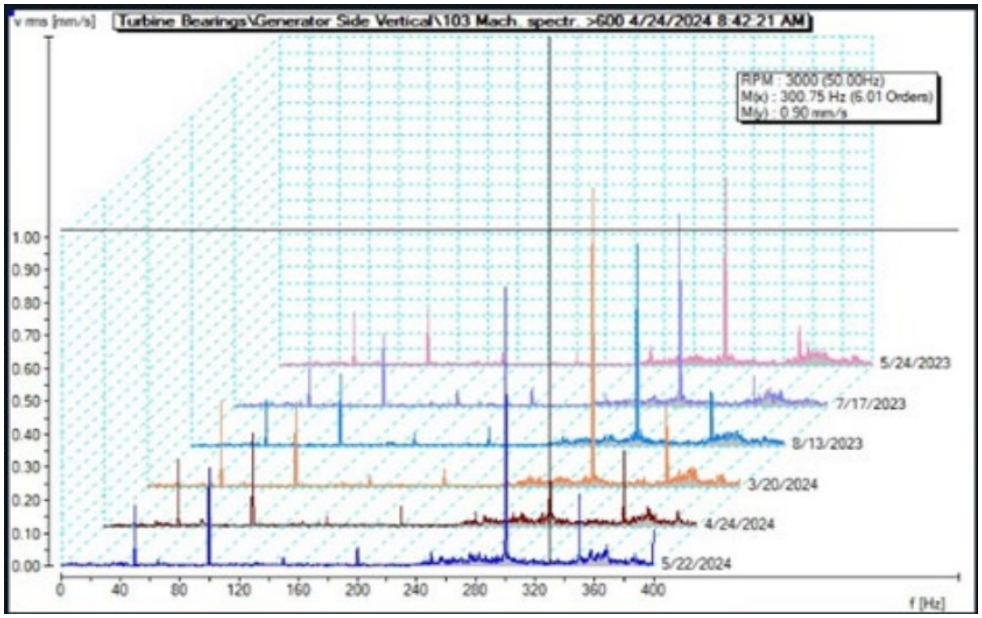

Figure 6: Spectrum shown 6X at Turbine Rotor after 12 years of operation.

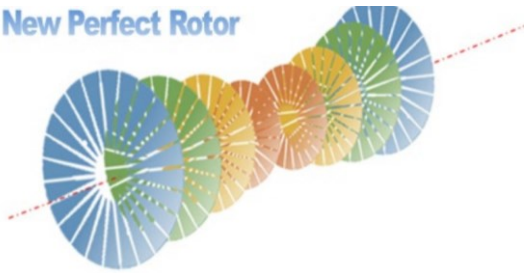

Figure 7: Illustration of the New Turbine Rotor.

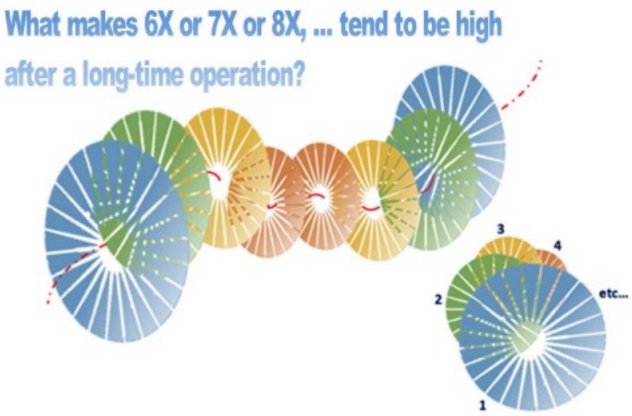

Figure 8: Illustration of the Turbine Rotor after a long-time operation.

5. DATA ANALYSIS

So, the question is, “What has happened to the mentioned rotors above?” The hypothesis regarding this phenomenon posits that it arises from the twist effect induced by 'segregated unbalance', which develops and accumulates over its operational lifespan.

Performing balancing operations may effectively reduce vibration amplitudes by compensating for overall vector forces. However, it cannot eliminate the phenomenon of 'segregated unbalance'. The next analysis is to determine, what will happen then or how harmful the twist phenomenon to the equipment? A cascade plot, in the context of vibration analysis, typically refers to a type of spectrogram or frequency-time plot. It displays how the spectral content of vibration signals changes over time or with varying operational conditions.

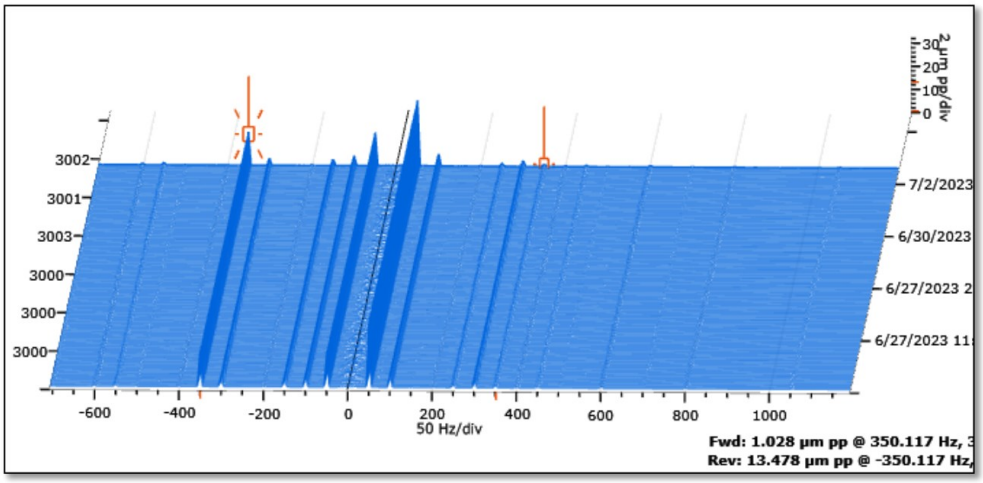

Figure 9: Cascade Plot of Full Spectrums.

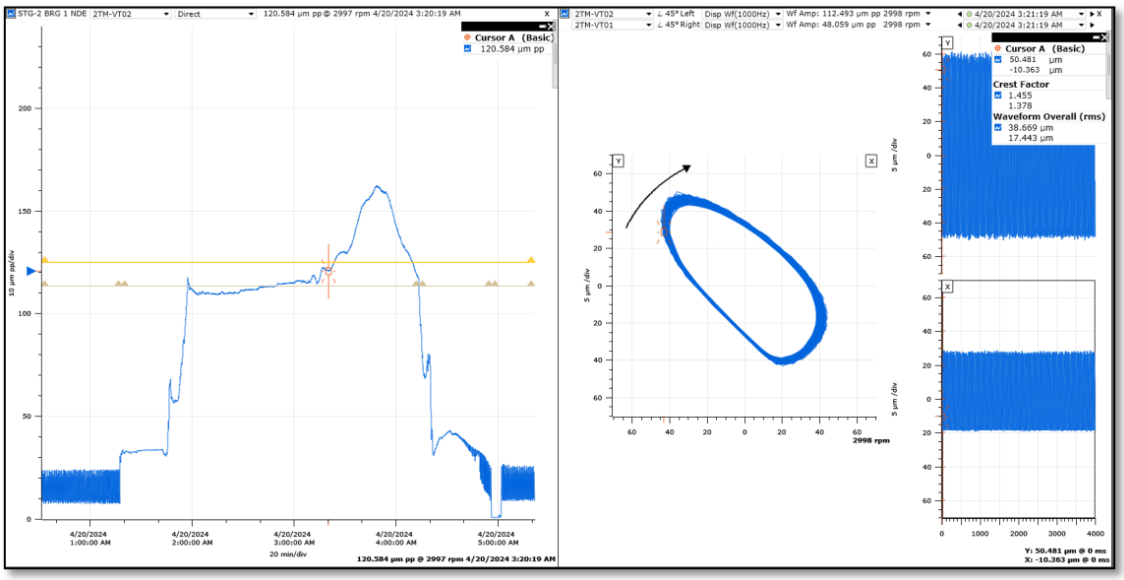

Figure 10: Trending and Orbit.

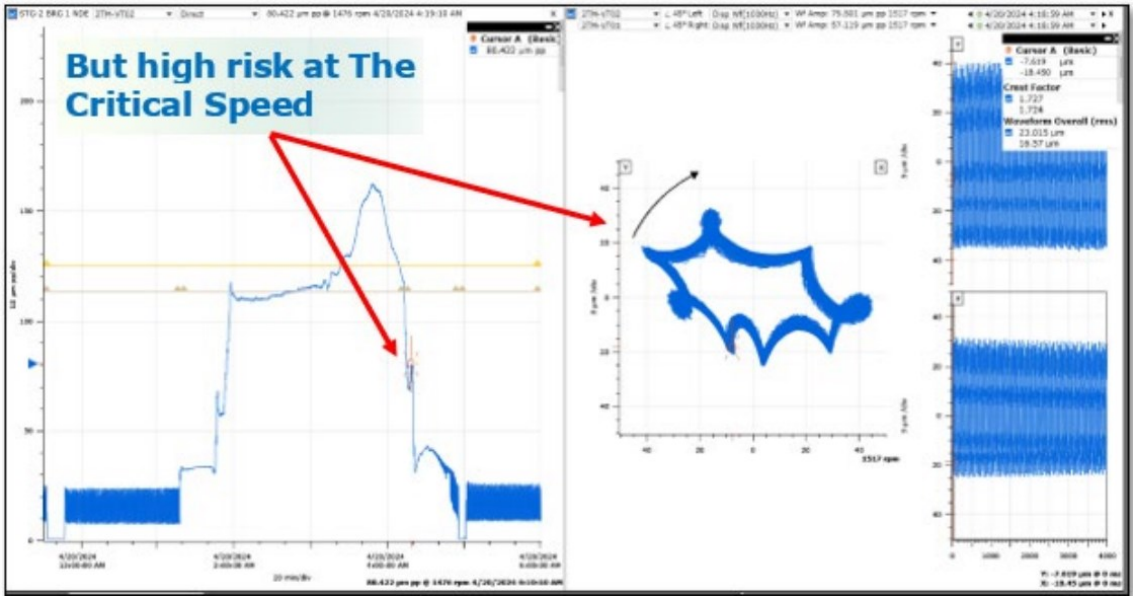

Figure 11: Trending and Orbit.

Cascade plot shows symptoms frequency on the horizontal axis and time on the vertical axis. The plot is formed by plotting successive spectra side by side, showing how frequency components evolve over time or with changes in operating conditions and it's shows that 7x were dominated in reverse spectrum area, which mean it can generate partial reverse orbits.

And as we all know that Increased reverse orbit correlates with heightened risk of turbine rotor rubbing occurrences and generate the Newkirk Effect. The new kirk effect occurs due to the high heat and mechanical pressure generated during rubbing due to high friction, which can cause atoms to migrate from the base metal to the regions subjected to high heat and pressure. This phenomenon can alter the chemical composition of the metal around the weld area, potentially affecting its mechanical properties and corrosion resistance.

The data shows that orbit seems good at normal operation by using Fmax 1000 Hz. Even though the amplitudes are too high but overall shape still look like a normal acceptable eclipse.

There is the potential for turbine rotors to experience operational challenges during start-up or shutdown periods. 'The Twist Phenomenon' can generate and amplify the overall vibration amplitude. In many cases, the rotor eccentricity increases significantly, and the rotor will bow more rapidly just before turbine failure occurs.

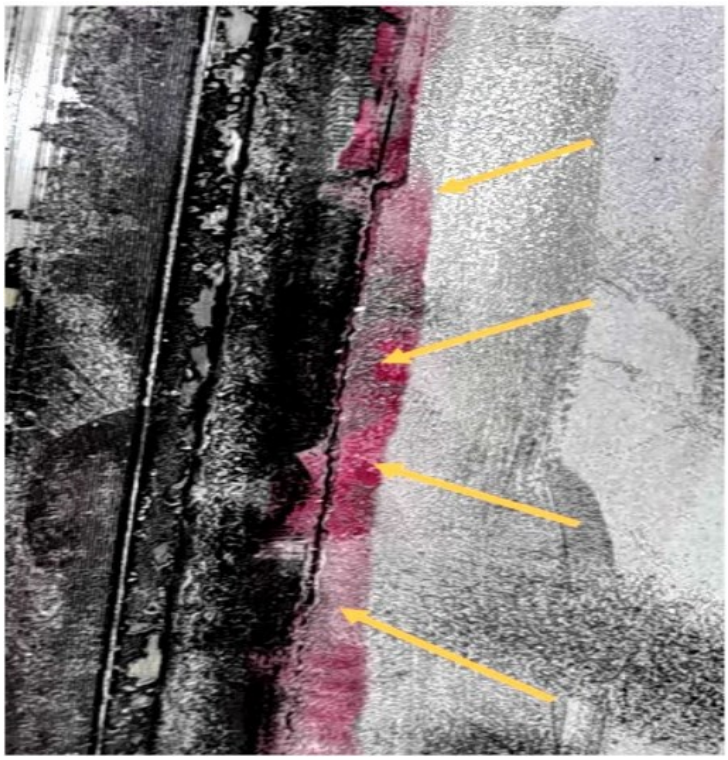

Figure 12: Rotor Crack.

Nearly two years after the detection of the Bhakti Twist Phenomenon at one of Indonesia's largest geothermal power plants, the turbine rotor has ultimately ceased to function.

6. CONCLUSION

If we found non-harmonic (independently) 5x or 6x or 7x or 8x, etc. on the old and/or refurbished turbine rotors a device designed to have the same reaction frequency as the dominant vibration direction of the structure itself that will counteract the initial motion. As the objective of this study is to employ vibration signal analysis to anticipate and assess potential damage to the Turbine Rotor, thereby fostering proactive measures against unforeseen harm resulting from the 'Bhakti Twist Phenomenon'. The results of the research on the Turbine Rotor symptom's, the following conclusions are drawn:

1. Cascade plot of full spectrum can reveal potential problem of Bhakti Twist Phenomenon.
2. Bhakti Twist Phenomenon can generate new kirk effect occurs due to the high heat and mechanical pressure generated during rubbing due to high friction, which can cause atoms to migrate from the base metal to the regions subjected to high heat and pressure.
3. Bhakti Twist Phenomenon increasing the potential for turbine rotors to experience operational challenges during start-up or shutdown periods.

4. Bhakti Twist Phenomenon' can generate and amplify the overall vibration amplitude. In many cases, the rotor eccentricity increases significantly, and the rotor will bow more rapidly just before turbine failure occurs.
5. Monitoring the Bhakti Twist Phenomenon provides benefits by allowing for the anticipation and assessment of potential damage to the turbine rotor, thereby enabling proactive actions to prevent unexpected damage.

ABSTRACT

Most Vibration Analysts in the world agree that resonance is one of the five most common causes of breakdowns that result in excessive engine vibration, along with eccentricity, unbalance, and misalignment. The best solution to solve the resonance problem is to install the machine properly. Another possible temporary solution to solve the resonance problem is to install a dynamic absorber, a device designed to have the same reaction frequency as the dominant vibration direction of the structure itself that will counteract the initial motion. Based on ISO 10816-1-1995 standard, the SEGD U2 Hot Well Pump operation severity level shall be less than 6.36 mm/sec-peak and must be shut down when it reaches 15.8 mm/sec-peak. Meanwhile, vibration amplitude rapidly increased and fluctuated at 13.6 mm/sec-peak and tended to be high which was caused by imbalance, Cavitation, and Resonance due to improper structure. Shutting down the Hot Well Pump will impact to de-rating of the power plant by up to 60% of power production or equals to US$ 178,700 per day. Installing Tune Mas Dynamic Absorber (TMDA) on SEGD U2 Hot Well Pump successfully reduced vibration significantly, avoided de-rating, and saved electrical power production for several months.

1. INTRODUCTION

The mechanical vibrations generated from the machine come from the internal high- speed rotating activity of the system itself, so the vibration symptom has a frequency that cannot be felt significantly by the human senses. One of the machines which a high-speed rotation with a stable vibration frequency is a Hot Well Pump. The Hot Well Pump aims to inject the volume of water to the system. The impeller element itself is generally placed in the pump which held by the stools to support the rotation force of the system. And all the indications of a problem at the Hot Well Pump will determine from the fault frequency of vibration produced by the magnitude.

The purpose of this paper is to determine the damage to the Hot Well Pump with vibration signal analysis and how to solve it according to the condition that surrounded by H2S enclosure and zero downtime issue, during Covid-19 pandemic period based on real experience.

2. LITERATURE

Vibration analysis is one of the methodologies usually used in performing predictive techniques for Rotating Equipment (rotating machines). This technique utilizes the characteristics of the vibration generated by a rotating machine. Some of the defects that often appear on rotating machines are base-frames defects (resonance), unbalance, and misalignment. Each failure defects cases has its specific characteristics in the generated vibration signal pattern. There are three main parameters analysis should we concerned with vibration analysis performing, namely amplitude, frequency, and phase.

Amplitude is the size or magnitude of the vibration signal generated or identified as the magnitude of the generated force by the vibration. The higher the indicated amplitude, the greater the disturbance that occurs. The magnitude scale of the amplitude depends on the type of engine and its damage. The increase in amplitude at specific faults frequencies identifies the suspects of disturbances in the engine. By knowing the frequency when the machine vibrates, precision observation can determine the cause or source of the problem.

Measurement trending will send information about the increasing level of engine vibration. When the engine vibration level increases beyond the baseline signal, it is necessary to carry out special handling on the engine. Baseline data is a collection of data obtained through measurements when the machine is operating stably. The baseline data serves as a comparison of measurement data to determine the engine condition.

Meanwhile, to classify the level of damage or severity of the rotating machine, one of the standards is used to evaluate damage based on the class and type is ISO- 10816.

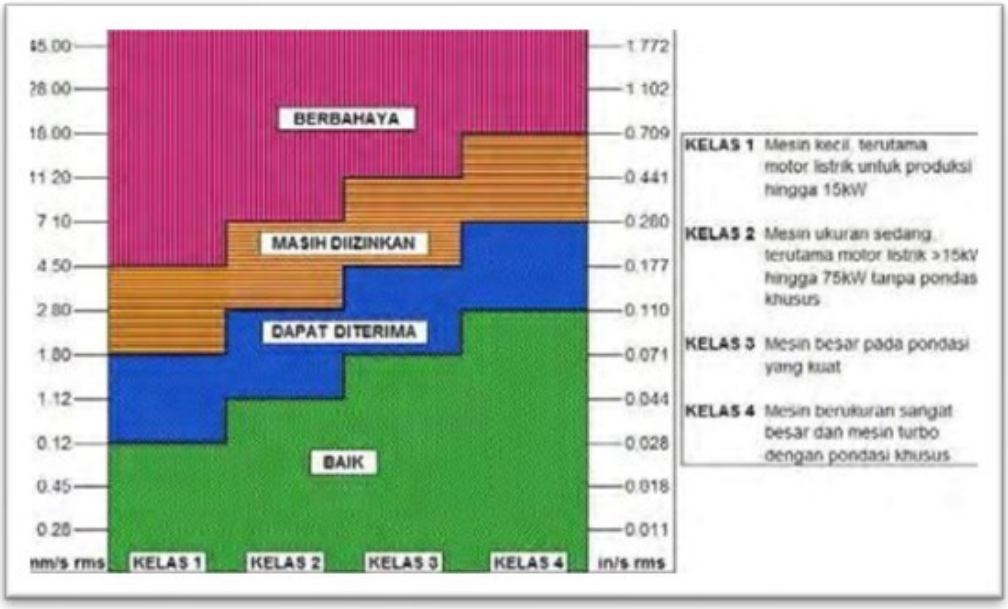

Figure 1: ISO 10816-1.

3. METHODOLOGY

The method used in this research is to take vibration signals with the CSI Analyzer 2130 and T-Wave on the vertical, horizontal, and axial Hot Well Pumps. The procedure is as follows:

1. Hot Well Pump in operating condition with a rotating speed of 750 RPM, measured using a CSI Analyzer 2130.
2. Measurement of vibration signals using this tool on the vertical, horizontal, axial, and peakvue on each inboard side.
3. After obtaining a vibration signal indicating damage to the inboard side, the data is entered into the AMS Suite software database: Machinery Health Manager.
4. The next measurement on the system uses a monitoring signal on the Normal Averaging amplitude value at maximum frequency = 1000 Hz.

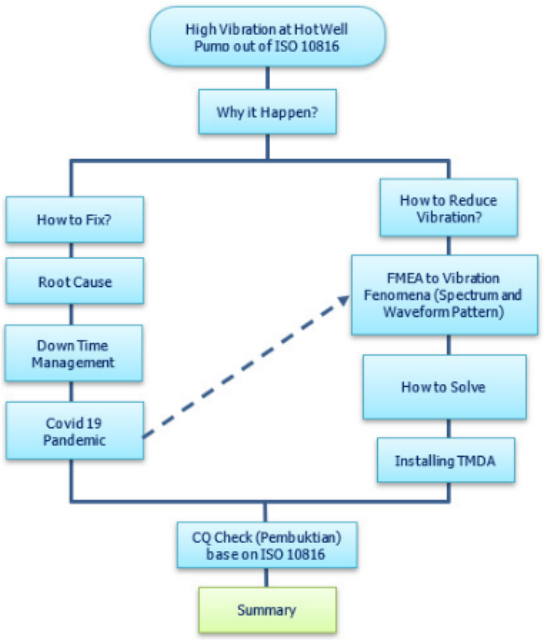

Figure 2: Workflow.

4. DATA ACQUISITION

Data Collecting -Correct and accurate data collection will be helpful in the process of analyzing research results. The data collection method also determines the quality of the data obtained. In this study, researchers took data directly by observing several data of trending, waveform, and spectrum patterns of the damage on the system.

Overall vibration amplitude data shown acceptable value except for Motor Outboard Y Axis, and it's looks so directional especially at Y direction.

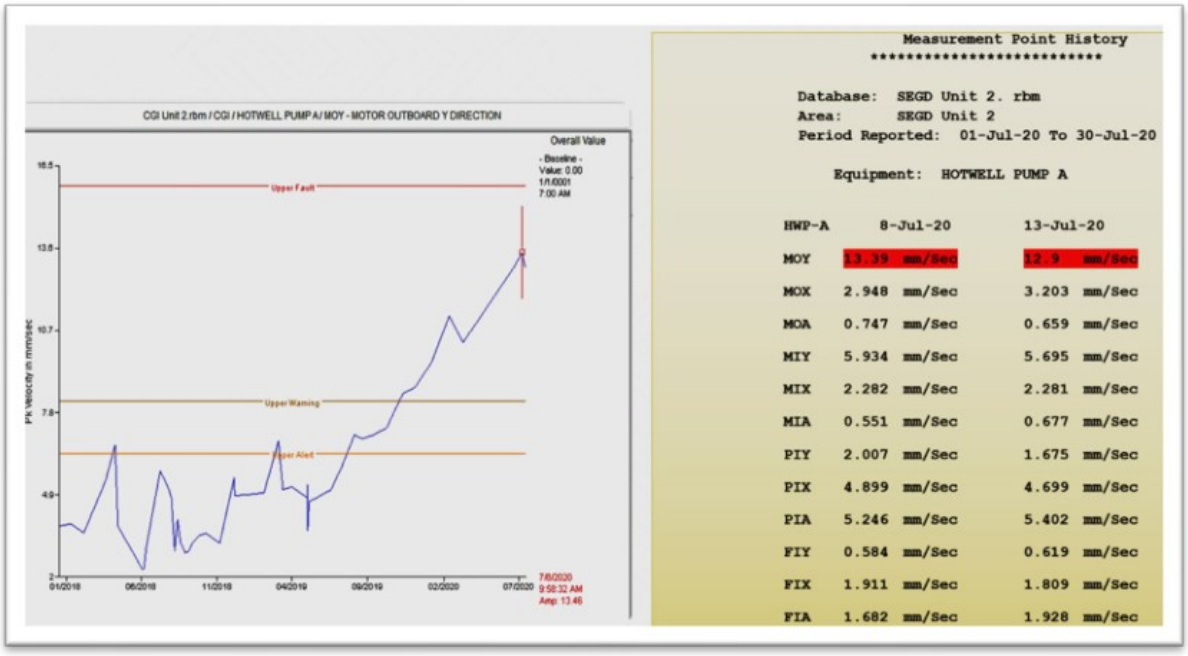

Figure 3: Overall data of HWP.

5. DATA ANALYSIS

The graph of the measurement results on the vertical direction of the outboard motor side, shown in the spectrum and waveform vibration signals. This spectrum and waveform signal indicates that the vertical outboard vibration signal is out of ISO-10816 severity. Coast down Analysis and Bump test are the way to confirm the phenomenon of resonance.

Both Coast down and bump test analysis shown that critical speed or natural frequencies approximately at 10Hz -12.5Hz, which mean it's too close to the operational rotating speed (750 RPM).

The SEGD U2 Hot Well Pump operation severity level shall be less than 6.36 mm/sec-peak and must be shut down when it reaches 15.8 mm/sec-peak. Meanwhile, vibration amplitude rapidly increased and fluctuated at 13.6 mm/sec-peak and tended to be high which was caused by imbalance, Cavitation, and Resonance due to improper structure. Shutting down the Hot Well Pump will impact to de-rating of the power plant by up to 60% of power production or equals to US$ 178,700 x 60% per day.

Since we found that vibration at Hot Well Pump was generated by 12.5 Hz and dominated by vertical axis or 'Y' direction, and it's confirmed as resonance effect, so we need to reduce the amplitude. Natural frequency is a root of Stiffness (k) divided by mass (M):

$$Nf = \sqrt{\frac{k}{M}}$$

Hence, we can change the stiffness of the HWP structure, or we can change the mass of the HWP structure, but there's another way to solve this problem by installing TMDA.

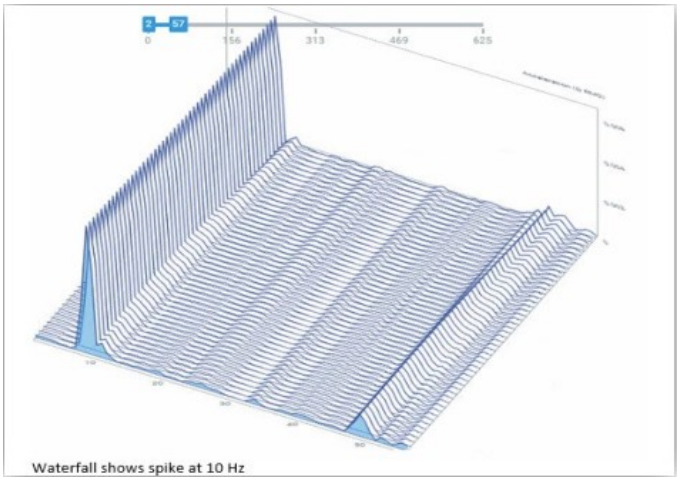

Figure 4: Coast down of HWP.

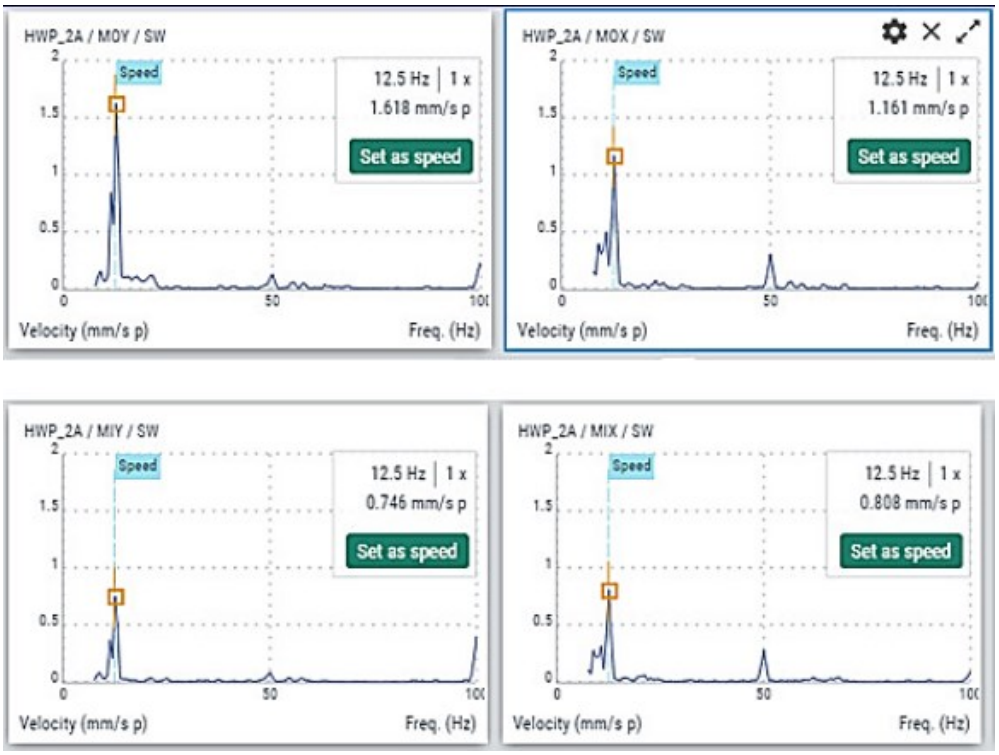

Figure 5: Bump Test Analysis.

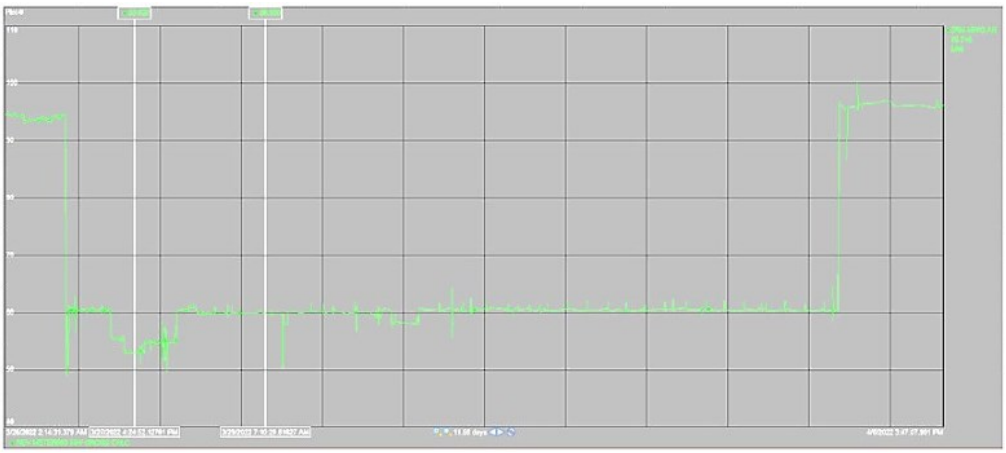

Figure 6: Generation by using single HWP Only.

6. VERIFICATION AND SOLUTION (CALCULATION METHODOLOGY)

By utilizing two degrees of freedom equation, then the next step is entering identify data into the calculation formula:

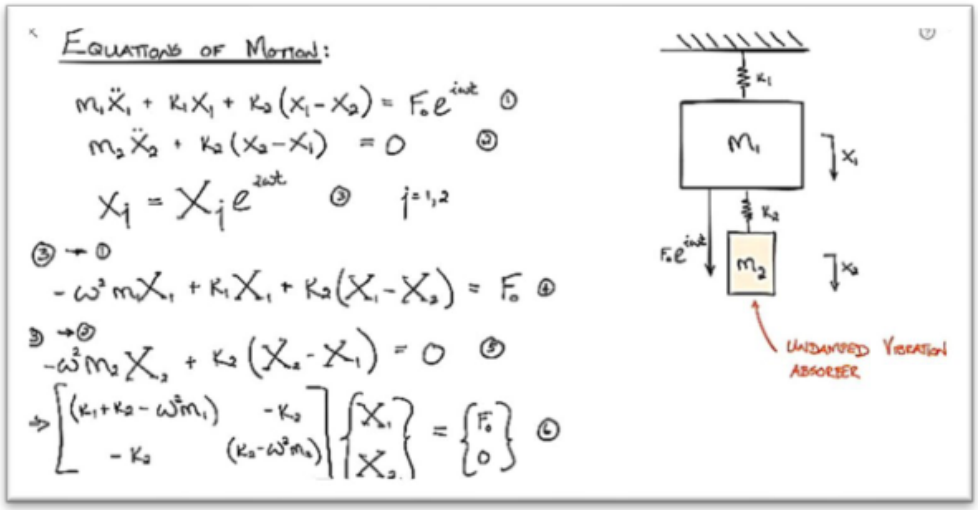

Figure 7: Two degree of freedom formula without damping.

$M\ddot{X}1 + k1X + k2\ (X2 - X1) - Fa \sin \omega t$ (1)

$m\ddot{X}2 + k2\ (X2 - X1) = 0$ (2)

Put X1 = Asin ωt and X = B2 sin ωt it's mean Ẍ1 = rees-ω² Asin ωt and Ẍ2 =-ω² B sin ωt Subtitute to equations (1) dan (2)

$k1 + k2 - M\omega^2)\ A - k2B = F$ (3)

$-k2A + (k2 - m\omega^2)\ B = 0$ (4)

Hence:

$$A = \frac{F_a\,(k_2 - m\omega 2)}{(k_1 + k_2 - M\omega 2)\,(k_2 - m\omega 2) - k_2 2}$$

So, to counter all resultant of force in Hot Well Pump with mass M, then the number of A needs to the limit of zero, A

□0, then k2 = mω² or ω² = k2/m = k1 /M.

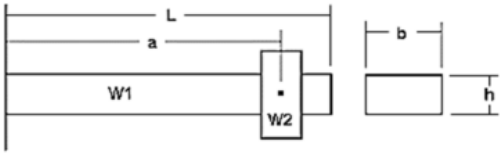
→ ***k1/M = k2/m or f1 = f2 ….*** (Seto. William W 1985)

It's hard for us to estimate the mass of the Hot Well Pump on the site, but there are two keys that we can use to solve the problem:

1. First, we got the magnitude.
2. Second, we have the number of frequencies (12.5 Hz)

Since f1 = f2, then what we've to do now is find the tunning to create a 12.5 Hz

Dynamic Absorber to counter the force with 12.5 Hz of frequency. Here we adopt the journal of Randy Fox in Entek IRD International Corp. Houston, TX to create a simple Dynamic Absorbers:



$$W2 = \frac{(2.114 \times 10^5)\ E\ I}{N_f^2\ (3a^2L - a^3)} - \frac{0.75\ w\ L}{3a^2L - a^3}$$

WHERE: N_f = DESIRED NATURAL FREQUENCY (CPM)

w = WEIGHT PER INCH OF SPRING (lbs) = b x h x d

E = MODULUS OF ELASTICITY

STEEL = 29,000,000 psi
ALUMINUM = 10,000,000 PSI
COPPER = 16,000,000 PSI
IRON = 18,000,000 PSI

$I = \frac{b\,(h^3)}{12}$ MOMENT OF INERTIA FOR RECTANGULAR CROSS SECTION "b" and "h" dimensions in inches

W2 = REQUIRED WEIGHT IN POUNDS (lbs)

DENSITIES (d): STEEL = 0.282 lbs/in^3

ALUMINUM = 0.099 lbs/in^3

COPPER = 0.321 lbs/in^3

IRON = 0.260 lbs/in^3

Figure 8: Simple Dynamic Absorbers.

Then the next step is simulating the formula above into the excel program to calculate the dimension of dynamic absorber that we need:

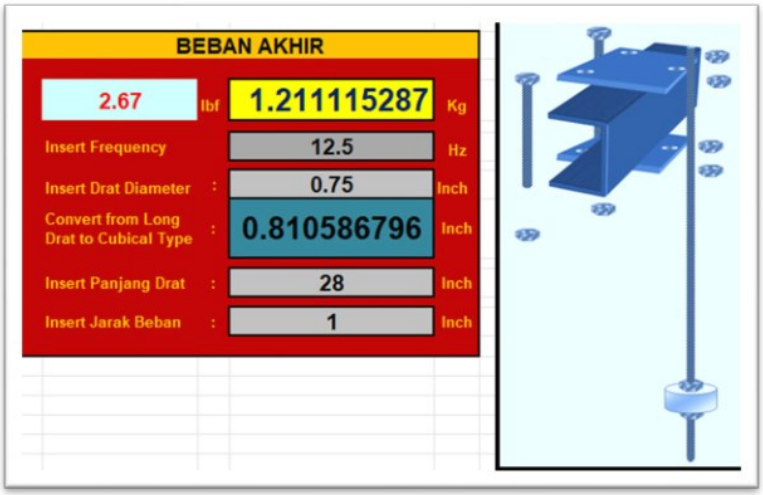


Figure 9: Simple dimension of TMDA.

Iron bar with a pendulum (weight) was chosen as the construction of the Dynamic Absorber as shown in the picture below, here in after the Dynamic Absorber Trial is named Dynamic Absorber Trial-1 (DAT-1).

Figure 10: Installed of TMDA Trial-1 (DAT-1).

As the result, all vibration value at Hot Well Pump tends to decrease after Dynamic Absorber Installation and this also confirms and proves the truth of the Failure Analysis first hypothesis regarding the cause of the alleged damage at Hot Well Pump.

Data -The presentation of research data is in the form of spectrum graphs and vibration signal waveforms from the research process on damaged Hot Well Pump Stuhl and after installed TMDA.

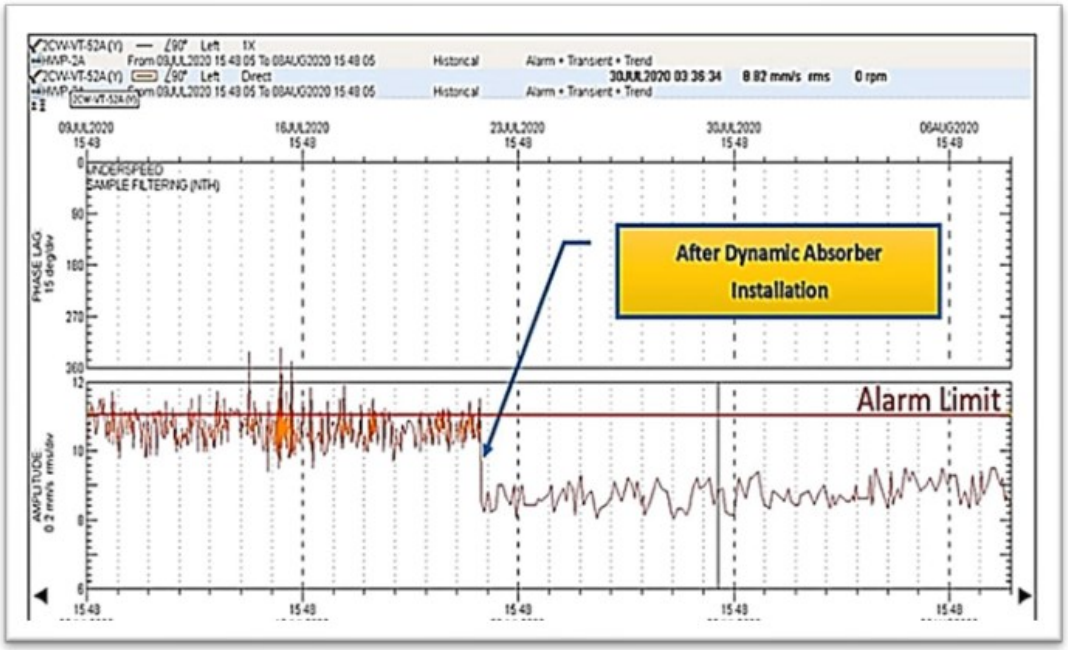

Figure 11: Vibration Amplitude After Installed TMDA.

Figure 12 confirming at the time of dynamic absorber installation according to the recommendations, that the overall vibration tends to decrease.

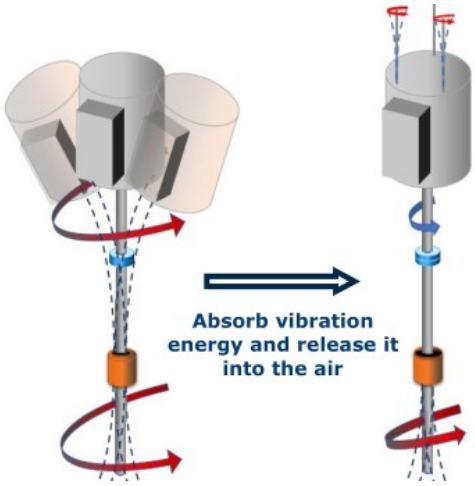

Figure 12: TMDA Absorb vibration energy and release it into the air.

7. CONCLUSION

The best solution to solve the resonance problem is to install the machine properly. Another possible temporary solution to solve the resonance problem is to install a dynamic absorber, a device designed to have the same reaction frequency as the dominant vibration direction of the structure itself that will counteract the initial motion.

As the purpose of this paper is to determine the damage to the Hot Well Pump with vibration signal analysis and how to solve it according to the condition that surrounded by H2S enclosure and zero downtime issue, during Covid-19 pandemic period. The results of the research on the Hot Well Pump symptom's, the following conclusions are drawn:

1. Vibration analysis can produce failure diagnosis stages in the machine that been occurred due to the interaction between vibration and improper quality of the structure.
2. The cause of the Hot Well Pump failure is due to initial deformation that caused by resonance, confirmed by Coast down analysis and Bump test result.
3. In the case of resonance, the accuracy of the absorber dynamic personal frequency value is the most influential factor in reducing the machine vibration amplitude value.
4. Installing the TMDA on the hot well pump has been shown to reduce the vibration amplitude by up to 30%, thereby avoiding a loss of more than USD 26 million per year during the COVID-19 pandemic.

Keywords: Drilling Performance, Drill Bits, Refurbished PDC Bits, Geothermal

ABSTRACT

The cost of drilling typically constitutes a significant portion of the total cost of a geothermal power project. On average, drilling costs can account for about 30% to 50% of the total cost. The percentage can vary depending on several factors, including the depth and complexity of the drilling, the geological conditions, the type of geothermal system being installed, and the location of the project.

Reducing drilling costs is critical to making geothermal projects more economically viable. Several strategies and technological advancements have been implemented to reduce the costs, including lowering drilling equipment costs. One visible way to reduce drilling equipment costs is through refurbishment.

Recent advancements in Polycrystalline Diamond Compact (PDC) drill bits have made them widely used in geothermal drilling applications due to their improved performance compared to Roller Cone (RC) bits. The PDC bit can also improve cost efficiency through repairability. However, how does the refurbished PDC bit perform in geothermal drilling? This paper provides a performance review of several refurbished bit runs in geothermal drilling in Sumatera, along with key lessons learned from the bit design that could contribute to optimal performance and cost-effectiveness.

1. INTRODUCTION

The cost of drilling wells represents a significant portion of the overall expenses in geothermal energy projects. One key area that contributes a significant amount to the production cost is the drilling process (Sugiura et al., 2021). And the drilling cost can account for up to 50% of the capital cost of developing a representative 50-megawatt (MW) geothermal plant (Tester et al., 2006). As the industry strives to make geothermal energy a more viable and competitive option, reducing these drilling costs has become a primary focus.

To address the high costs associated with drilling, several strategies have been proposed and implemented. These strategies range from optimizing drilling techniques to enhancing the performance and longevity of drilling equipment. Among these strategies, one particularly effective approach is the repair or refurbishment of polycrystalline diamond compact (PDC) drill bits.

Practically, the PDC bit is more feasible to repair as it was made from replaceable materials as long as the body itself was still in good condition with some criteria compared to Roller Cone (RC) bits or hybrid bits that combine PDC and Roller Cone (Aribowo et al., 2023).

Rather than incurring the substantial costs of purchasing new PDC drill bits, repairing and reconditioning used bits also offers a cost-effective alternative. This practice not only extends the service life of the drill bits but also significantly reduces the overall drilling expenditures. By focusing on the repair of PDC drill bits, geothermal projects can achieve substantial cost savings while maintaining operational efficiency and effectiveness.

The question now is how the refurbished PDC will perform in geothermal drilling. Will it be the same as the new bits in terms of achieving its targets? This paper evaluates several refurbished bit runs in geothermal drilling in Sumatera, along with key lessons learned from the bit design that could contribute to optimal performance and cost-effectiveness.

2. PDC REFURBISHED BIT

Refurbishing drill bits is often much cheaper than purchasing new ones. This can result in significant cost savings, especially in industries where drill bits are used extensively, especially in geothermal drilling.

The PDC refurbishment process is basically to restore the bit condition to its prime condition after the bit passes through several criteria, such as no severe erosion, excessive damage on the bit body or cutter pocket, and less than 2/16-in. undergauge (Aribowo et al., 2023). The bit is then going to the main process, as shown in Figure 1.

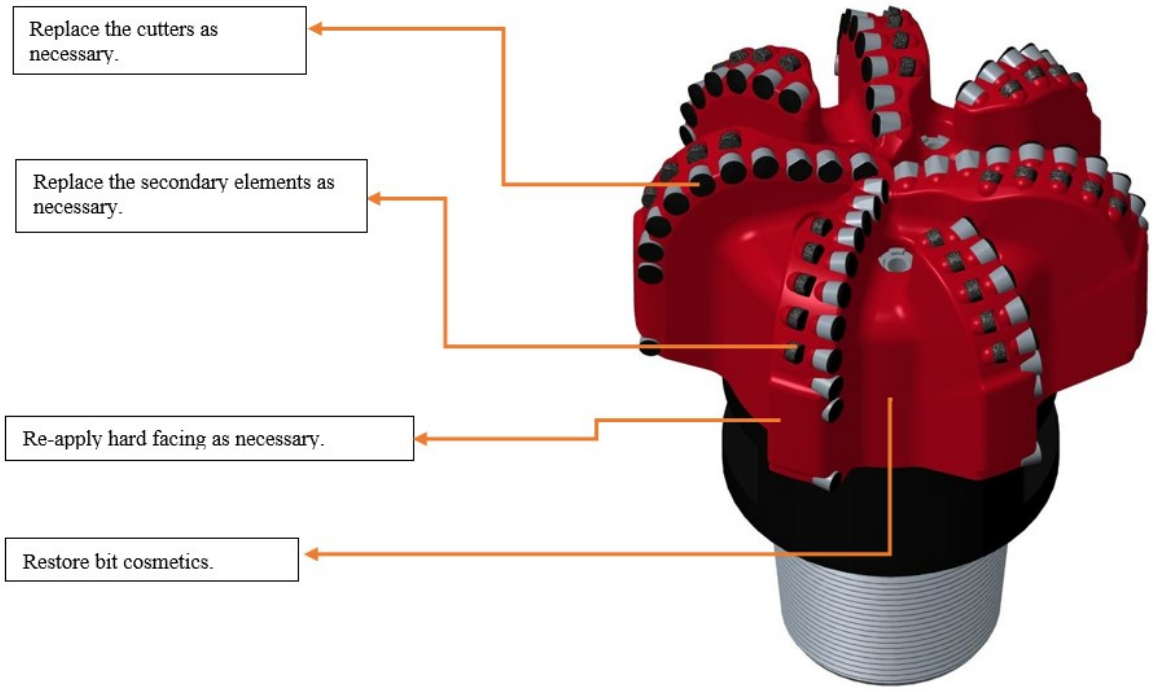

Figure 1: PDC bit refurbishment main process.

Proper refurbishment can significantly extend the life of a drill bit. By repairing worn and damaged PDC cutters, a refurbished bit can perform almost like new, thereby maximizing the return on the initial investment.

3. METHODS IN PERFORMANCE REVIEW OF REFURBISHED PDC BIT

As known, refurbished drill bits are less expensive than new ones. By ensuring that refurbished bits perform well, companies can reduce costs significantly without compromising on drilling efficiency. There are several methods and indicators for reviewing the performance of refurbished PDC bits:

1. **Bit Performance**: The assessment of refurbished bit performance can be seen from several runs and its parameters, including total interval drilled, rate of penetration (ROP), and reason pulled. A well-refurbished drill bit can maintain or even improve its performance. This ensures that the drilling process remains efficient and effective, reducing downtime and increasing productivity.
2. **Repair Quality**: One indication of an optimal repair process that adheres to high-quality standards is the absence of lost cutters. A lost cutter indicates a poor repair process, as the cutter is completely gone from the cutter pocket. This typically occurs when the braze bond fails to retain the carbide substrate. Figure 2 shows an example of a lost cutter on the PDC bit.

Figure 2: Example of a lost cutter on PDC bit.

In addition to the above indicators, evaluating the performance of refurbished bits introduces new design criteria, which will improve their repair capabilities and reliability for continued use.

4. RUN PERFORMANCE OF REFURBISHED PDC BITS

The performance review was taken from one of the major geothermal operators in Sumatera. Several refurbished PDC bits, consisting of 17.5-in., 12.25-in., and 9.875-in. sizes, were run. This data is intended to serve as reference material for the performance of refurbished bits, provide insights into whether poor bit performance is due to poor repair quality or not, and guide the optimization of bit design to ensure continued use.

4.1 The 17.5-in. PDC Refurbished Bits

One type of 17.5-in. FTKC76 bit has already been run in several geothermal wells in Sumatera. Based on the bit record, the 17.5-in. FTKC76 serial number A1 had been refurbished two times, and it was used to drill about 300- to almost 1,000-m intervals. The bit drilled a volcanic rock such as andesite lava, rhyolite, and tuff in directional wells with a mud motor assembly. In summary, the refurbished bit that ran in the XA-03 and XP-117 wells demonstrated a very good performance compared to the new ones. Although it was a refurbished bit, the final average ROP achieved was between 10 m/hr and 14.6 m/hr, or around 50% faster than the new one. In terms of bit performance, it can be concluded that a refurbished bit does not downgrade the performance; instead, it is similar or even improves the performance.

The second 17.5-in. FTKC76 serial number B1 was refurbished once and run in the XV-01 well. The bit was picked up to continue drilling the entire 17.5-in. interval after the previous bit was pulled out due to penetration rate and bit hours. However, it only drilled 195 m before experiencing a hole problem that led to pulling out of the hole. In terms of bit performance, the bit achieved an average ROP of 7.62 m/hr, which was considered moderate as the drilling was controlled due to a hole issue. Table 1 shows the whole run record for the 17.5-in. PDC716 refurbished bit, including serial numbers A1 and B1, along with new ones for comparison.

Table 1: Run performance results of the 17.5-in refurbished PDC bit.

Well	Size (in.)	Bit Type	SN / Status	Depth In (m)	Depth Out (m)	Interval (m)	ROP (m/hr)	Rig Dull Grading
XP-119	17.5	FTKC76	A1 / New Bit	400	1,215	815	9.31	0-1-WT-S-X-I-PN-PR
XA-03	17.5	FTKC76	A1 / Refurbished #1	405	775	370	14.62	0-1-WT-S-X-I-NO-TD
XP-117	17.5	FTKC76	A1 / Refurbished #2	400	1,350	950	10.0	1-4-BT-G-X-1-NO-TD
XP-118	17.5	FTKC76	B1 / New Bit	394	1,351	957	10.35	1-1-WT-A-X-I-BT-TD
XV-01	17.5	FTKC76	B1 / Refurbished #1	1,226	1,421	195	7.62	1-3-CT-S-X-3-BT/PN-HP

Figures 3 and 4 show the dull condition of the 17.5-in. FTKC76 serial number A1 for the second and third runs in refurbished condition.

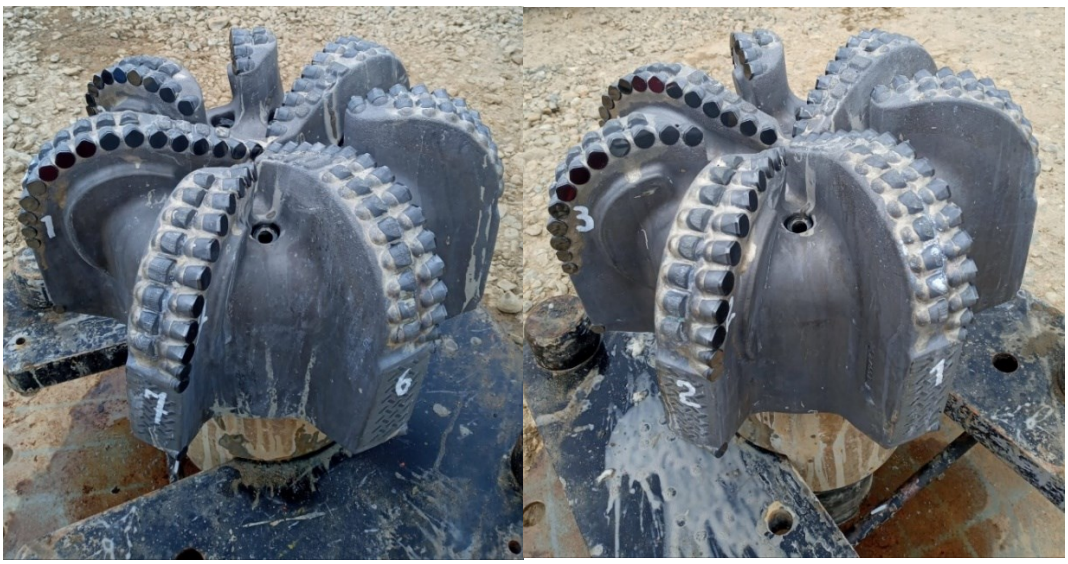

Figure 3: The dull condition of the 17.5-in. refurbished bit run in the XA-03 well.

Figure 4: The dull condition of the 17.5-in. refurbished bit run in the XP-117 well.

Figure 5: The dull condition of the 17.5-in. refurbished bit run in the XV-01 well.

Reviewing the dull condition of the 17.5-in. FTKC76-A1, none of them are indicating any lost cutter condition. The last run in SP-117 well shows that the major dull condition is mostly broken cutters (BT) and worn cutters (WT) on the secondary elements, which are not related to the poor repair quality. The broken cutters are most likely due to the high impact. In terms of gauge durability, the bit got wear and slightly chipped, resulting in an undergauge of 1/16 in. Based on the repair criteria, the bit should still be in repairable condition.

Figure 5 shows the dull condition of the 17.5-in. FTKC76 serial number B1 refurbished bit.

In terms of bit durability, the dull condition of the 17.5-in. FTKC76 serial number B1 run in the XV-01 well is still considered in acceptable condition. There are no indications of lost cutters, only broken cutters, indicating no major issues with the bit's repair quality. Looking at the dull grading measurement, it was reported that the bit got 3/16-in. undergauge. According to the acceptable refurbishment criteria, the repairable condition should not be more than 2/16-in. undergauge. Therefore, the 3/16-in. undergauge exceeds the acceptable limit for continued repairability.

4.2 The 12.25-in. PDC Refurbished Bits

Data records reveal that PDC bits have dominated several geothermal wells drilled in Sumatera. Based on the 12.25-in. bit record, seven refurbished bits were run, with one able to be rerun in a different well. Table 2 shows all 12.25-in. bit runs for refurbished bits, including the new ones, for comparison.

The refurbished bits tend to have shorter intervals, as most were picked up to continue after a previous run failed to finish the section. In terms of ROP, the bits were very competitive, ranging from 5 m/hr to 16 m/hr, indicating the varying challenges and characteristics of each well. However, most of the bits could finish the section to total depth (TD).

Table 2: Run performance results of the 12.25-in. refurbished PDC bit.

Well	Size (in.)	Bit Type	SN / Status	Depth In (m)	Depth Out (m)	Interval (m)	ROP (m/hr)	Bit wear
XT-09	12.25	FTKC76	A07 / New Bit	1,441	2,100	659	7.31	1-2-WT-S-X-I-NO-TD
XT-10	12.25	FTKC76	A07 / Refurbished	892	1,100	208	16.00	1-2-WT-A-X-2-BT-TD
XT-03L2	12.25	FTC76	A63 / New Bit	810	1,279	469	19.14	1-2-BT-G-X-I-NO-BHA
XT-03L3	12.25	FTC76	A63 / Rerun Bit	874	1,000	126	11.45	1-2-WT-G-X-I-BT-TD
XAAE-08	12.25	FTC76	A63 / Refurbished	2,000	2,157	157	13.66	1-3-BT-G/S-X-I-CT-TD
XP-119	12.25	FTKC76	A98 / New Bit	1,700	2,305	605	12.17	0-1-WT-S-X-I-NO-TD
XAAE-06	12.25	FTKC76	A98 / Refurbished	1,287	1,466	179	5.52	1-2-WT-S-X-1-CT-PR
XAAE-03	12.25	FTKC76	A27 / New Bit	1,501	2,200	699	11.15	1-2-WT-S/G-X-1-CT-TD
XAAE-06ST2	12.25	FTKC76	A27 / Refurbished	1,466	1,730	264	6.00	0-1-WT-S-X-I-BU-BHA
XAAE-06ST2	12.25	FTKC76	A27 / Refurbished Rerun	1,730	1,858	128	6.61	1-1-WT-A-X-I-NO-TD
XAA-01	12.25	FTKC76	A02 / New Bit	1,337	1,655	318	9.09	1-3-WT-S-X-1-BT-TQ
XP-117	12.25	FTKC76	A02 / Refurbished	1,650	1,749	99	5.13	2-3-BT-S-X-1-CT-PR
XP-118	12.25	FTC76	A37 / New Bit	1,739	2,577	838	9.96	1-2-WT-S-X-I-CT-TD
XV-03	12.25	FTC76	A37 / Refurbished	2,100	2,550	450	5.51	1-3-WT-S-X-2-BT-TD

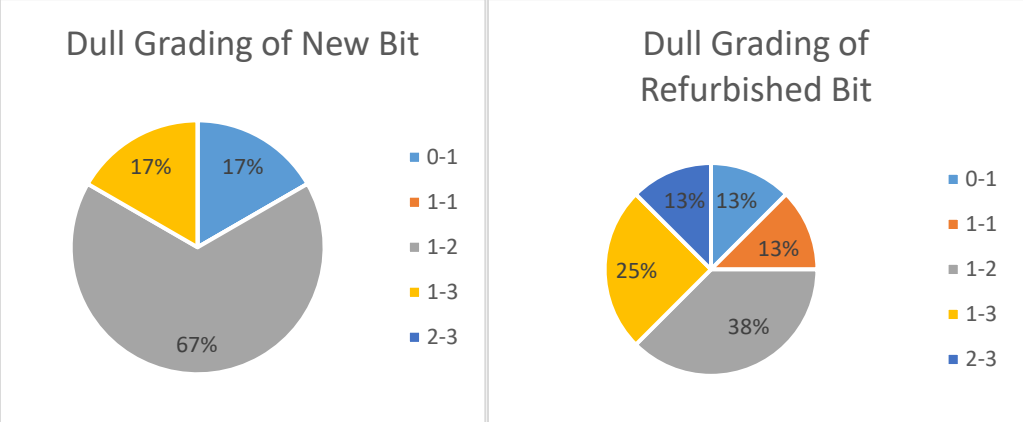

Figure 6: The dull grading percentage of the 12.25-in. new and refurbished conditions.

Figure 6 shows the major dull condition to represent the bit durability. The percentage of dull grading results showed similarity in the highest dull grading percentage with 1-2. Again, this data shows that refurbished bits can perform comparably to the new bits.

The dull pictures of the 12.25-in. FTKC76 refurbished bit run in the XT-10 well, as shown in Figure 7, show that the cutting structure has very minimal wear. However, based on the gauge measurement, the bit got 2/16-in. undergauge, with several broken cutters and wear on the gauge pads.

The12.25-in. FTC76 refurbished bit run in the XV-03 well had similar results. The bit was picked up to finish the section with a total interval of 450 m, as the previous bit could not complete the section due to penetration rate and bit hours. The bit got significant wear on the gauge and several broken cutters on the gauge area, leading to a 2/16-in. undergauge, as shown in Figure 8. This finding necessitates a step change in the bit's durability to

potentially enhance the bit in future designs, particularly in the gauge area. Improving gauge protection will lead to extending the life of a drill bit for continued use.

Figure 7: The dull pictures of the 12.25-in. FTKC76 refurbished bit run in the XT-10 well.

Figure 8: The dull pictures of the 12.25-in. FTC76 refurbished bit run in the XV-03 well.

Figure 9: The dull pictures of the 12.25-in. FTC76 refurbished bit run in the XV-03 well.

4.3 The 9.875-in. PDC Refurbished Bits

Based on the run record, only one 9.875-in. bit was used in geothermal drilling in Sumatera. Initially, the bit completed a 750-m interval to TD in the XAA-01 well. After this run, several worn cutters were observed in all areas. These worn cutters were subsequently replaced with new ones, and the refurbished bit was deployed to drill the entire 9.875-in. section in the XV-03 well. The results showed that the bit completed the section to TD with an average ROP of 6.12 m/hr. Performance-wise, the refurbished bit demonstrated strong capabilities by achieving TD in a single run. Although the ROP was slower than the new ones, this is suspected to be due to factors beyond the bit itself, as the dull was still rated at 1-1-WT. Figure 9 shows the dull pictures of the 9.875-in. FTKC76 refurbished bit after running in the XV-03 well.

Table 3: Run performance results of the 9.875-in. refurbished PDC bit.

Well	Size (in.)	Bit Type	SN / Status	Depth In (m)	Depth Out (m)	Interval (m)	ROP (m/hr)	Rig Dull Grading
XAA-01	9.875	FTKC76	A92 / New Bit	1,800	2,550	750	8.20	1-1-WT-A-X-I-CT-TD
XV-03	9.875	FTKC76	A92 / Refurbished	2,550	2,750	200	6.12	1-1-WT-A-X-I-CT-TD

5. NOTABLE PERFORMANCE, LESSONS LEARNED, AND FUTURE WORK

The following highlights the notable performances of the refurbished bits:

1. The 17.5-in. FTKC76 refurbished bit drilled a cumulative interval of 950 m and achieved a good ROP of 10 m/hr despite being in the second refurbished condition.
2. The 12.25-in. FTC76 refurbished bit drilled the longest interval, 450 m to TD, in the challenging XV-03 well.
3. The 9.875-in. FTKC76 refurbished bit drilled the entire section from shoe to shoe and still came out in excellent dull condition 1-1-WT.

The lessons learned from the above performance runs indicate that there are still bits with good cutting structures in the face but have undergauge. Undergauge is crucial as it is a part of the bit body. Once the bit got significant undergauge (more than 2/16 in.), it can no longer be repaired.

The standard gauge protection for the PDC bit uses *Thermally Stable Polycrystalline* (TSP) material on the gauge pads. Once the bit gets undergauge more than 2/16 in., its gauge durability may decrease as there is only a little to no TSP material remaining. In the repair process, installing TSP material can be complex and difficult, unlike just applying hard facing. As a result, modifications to the bit design, particularly on the gauge pads, may be necessary for the continued use of a refurbished bit.

Replacing TSP material with a PDC dome insert as gauge protection in future bit designs improves wear resistance. Furthermore, the PDC dome insert is a more changeable component in the repair process, increasing the likelihood of continuous bit refurbishment. **Figure 10** shows the new bit design featuring improved gauge protection with PDC dome inserts for future refurbishment.

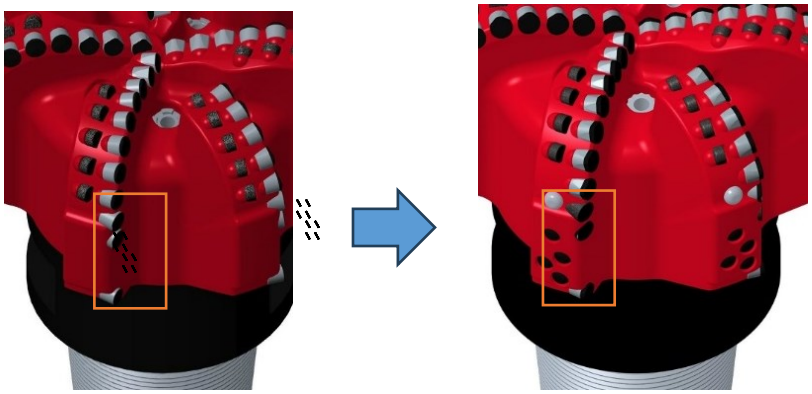

Figure 10. The new bit design for improved gauge durability and repair capabilities.

6. CONCLUSION

Following the performance review of all refurbished bits runs in geothermal Sumatera, it was concluded that the refurbished bits could maintain or even deliver better performance than the new ones. Most of the bits achieved the drilling targets without downgrading their performance, although some bits might come out with 1-3 or 2-3.

However, general observation found that the most refurbished bit was also able to complete the section to TD with good dull grading.

There are no findings to suggest that the refurbished bits suffered from poor repair quality, as indicated by the absence of major dull conditions or lost PDC cutters.

In future work, installing PDC dome inserts on the gauge pads is expected to reduce the undergauge issues. This modification will also improve repair capabilities, as these components are more changeable. Secondly, supporting software for the refurbishment process, where we store the dull data, is beneficially required. The data can be used to observe the dull trend and help in future design iterations.

In summary, implementing refurbished bits remains beneficial for ensuring an efficient and effective drilling process. Their good durability allowed the bits to be run multiple times, resulting in:

- Reduced drilling costs.
- Better inventory management.
- Lowered carbon emissions and collaborative efforts toward global decarbonization objectives.

Keywords: corrosion free, condensate pipeline, polyethylene, PE100

ABSTRACT

The Wayang Windu geothermal plant, which is owned and operated by Star Energy, was initially completed in 1999 and today generates up to 227MW of electricity using the natural hot fluids from a reservoir deep beneath. Steam which is used to generate the electricity using steam turbines, will be returned to the underground reservoir through pipelines and injection wells after it has cooled and condensed. Unfortunately, the condensate is very corrosive due to high levels of dissolved solids and the relatively high condensate temperatures, which typically reaches 50°C. In addition, the Wayang Windu pipelines are laid in a hilly region and flow under gravity, which makes them prone to erosion. Therefore, the corrosion and erosion of the steel pipelines carrying the condensate cannot be avoided and after some years in operation, regular repairs are necessary due to leakages. Eventually, the steel pipelines need to be replaced.

After nearly 15 years of operation, half the length of the condensate pipelines at Wayang Windu had been extensively repaired, and this section was due to be replaced. Instead of replacing it with another steel pipeline, Star Energy's engineering team decided to explore other pipeline materials that are less prone to corrosion. The availability of polyethylene (PE) pipe systems in Southeast Asia has greatly increased over the past two decades, giving engineers new options for consideration. Additionally, the region has gradually adopted the use of specifically engineered PE100 pipe grade materials that comply with the requirements of international standards. Having reviewed the options, the Star Energy team decided to install a single 400 mm OD SDR 11 PE100 above ground pipeline in order to evaluate the performance of this material in a new application, together with identifying the practical challenges in constructing such a pipeline.

This paper will describe the above in more detail, while explaining the design and installation process the Star Energy team, together with their contractors and suppliers, went through. It will also detail the lessons that they learnt while working on the project.

1. INTRODUCTION

The first Wayang Windu geothermal plant was built in 1999 by Star Energy 40 km south of Bandung, West Java, to generate 110 MW of electricity using the earth's natural high-temperature fluids, as shown in Figure 1. A second 117 MW unit was added in 2009 and the facility, shown in Figure 2, which now has a capacity of 227 MW. It is operated under a joint operating agreement between Star Energy and Indonesia's state-owned oil and gas company PERTAMINA. This gives Star Energy the right to generate up to 400 MW of electricity on an area of 12,960 hectares for a period of 42 years. The sale of generated electricity to state-owned electricity company PLN and its delivery into the West Java grid is governed by an Energy Sales Agreement.

Thermal energy from the earth is extracted in the form of geothermal fluids from deep underground reservoirs through multiple production wells. This steam and brine mixture is sent to a cyclone separator where it is separated, and the steam is sent to the power plant. The brine is returned to the reservoir through a backsplash well to maintain pressure and extend the reservoir's life. The steam is passed through a turbine to generate electricity, condensed and sent to a cooling tower. The hot condensate is cooled in the cooling tower and some of the cooled water is returned to the condenser to condense the steam. Excess condensate is returned to the reservoir through a condensate injection well.

Similar to other geothermal plants, Wayang Windu has kilometers of pipeline that transport condensate – essentially brine that corrodes steel pipes. The focus of this technical article is on the replacement of some steel condensate injection pipelines with PE pipes.

2. PROJECT BACKGROUND

The original 16-inch steel condensate injection pipeline runs from the power plant interface to the injection wellpads WWF and WWP, shown in Figure 1 and in more detail in Figure 3. The figure also shows part of the route of the injection pipeline, which is approximately 7,750 m long.

Figure 1: Map showing the location and layout of the Wayang Windu Geothermal Power Plant.

Figure 2: View of the Wayang Windu Geothermal Power Plant showing the generating house and cooling towers.

Originally, carbon steel was used for the pipelines because of a lack of alternative materials and the expectation that corrosion would not be a major problem since the condensate had most of its oxygen removed by the power plant's condensers before entering the pipeline. The pipelines were designed as pressure pipelines with a maximum flow rate of 177 kg/s (just under 175 l/s) at a velocity of 1.5 m/s, but much of the pipeline operates in open channel flow conditions at much higher velocities and minimum pressures. The reason is that the gradient from the power plant to the injection well is steep. A portion of this is shown in Figure 4.

After commissioning in 1999, the pipeline was inspected periodically. In 2010, it was discovered that the pipe walls had thinned significantly and were leaking, especially in the first uphill half of the pipeline, where open

channel flow conditions prevailed. Although to a lesser extent, corrosion also occurred in the pressurised rear portion of the pipeline.

Since 2011, the Star Energy team initiated a series of temporary measures to address the leak. This includes spot repairing leaks, replacing badly corroded pipe spools, limiting low rates and rotating pipes where practical. This final step was done to move the thin walled, more corroded sections from the bottom of the pipe to the top. From this final mitigation, it is clear that the level of corrosion, resulting wall thinning and leakage along the base of the pipeline are significantly more severe, at least along the sections where open channel flow conditions were prevalent.

A failure analysis of a 4 km mountain section of the pipeline revealed that the pipeline was subjected to a combination of corrosion and erosion. Visual inspection of the defective pipe spool revealed directional metal loss with significant wall thinning along the base of the pipeline. Figure 5 shows a typical defective pipe and Figure 6 shows how the corrosion products have been eroded from the pipe invert. Erosion occurred when steep open channel flow conditions existed along the section of the pipeline, resulting in very high flow velocities. These sometimes exceeded the erosion limit, releasing corrosion products that were providing some protection to the underlying steel.

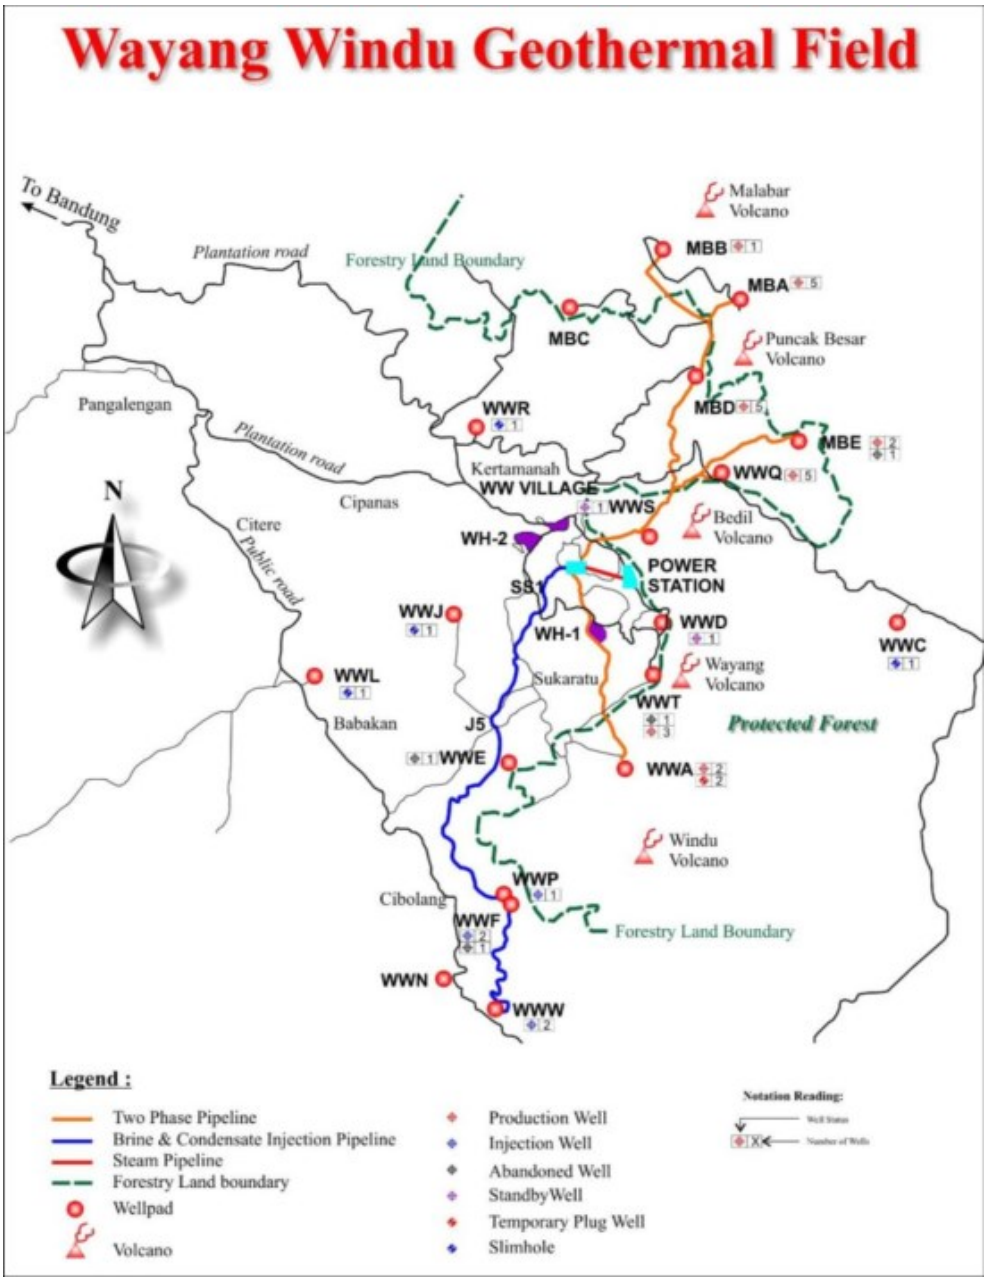

Figure 3: Plan of the Wayang Windu Geothermal Field showing the blue condensate injection pipeline, the first half of which was replaced under the project.

Figure 4: View of the Geothermal Power Plan showing the condensate pipeline replaced under the project.

Figure 5: View of a badly corroded steel pipe taken from the section replaced under the project.

Figure 6: Internal view showing where corrosion products have been scoured by erosion.

Despite mitigation measures implemented on site, the condition of the condensate pipeline continues to deteriorate, with 5 to 8 significant leaks per year. Hence, in 2012, Star Energy decided to replace the first 4 km of the condensate pipeline and commissioned an engineering firm to conduct a feasibility study.

3. FEASIBILITY STUDY

The feasibility study was undertaken by PT Gago Engineering, a Bandung based engineering consultancy specialising in the energy sector.

The feasibility study was titled "Condensate Pipe Replacement Using Non-Steel Base Material". It comprised three key sections, namely non-metallic pipe material selection, process design and piping design.

As the title suggests, Star Energy had already decided to explore the use of non-metallic pipe materials to avoid the well-known corrosion problem. The material selection process looked at the use of the following materials:

- High Density Polyethylene (HDPE)
- Polyvinylidene Fluoride (PVDF)
- Polypropylene (PP)
- Chlorinated Polyvinyl Chloride (CPVC)

To get a subjective look at each material, their relative performance against each of the following parameters was assessed:

- Mechanical strength
- Water and chemical resistance
- Erosion resistance
- UV degradation
- Ease and effectiveness of jointing systems
- Maintainability
- Total installed cost

When selecting the material, it was determined that each of the four polymer pipe materials was more or less suitable for the intended application at an operating temperature of 50°C and pressure of up to 12 bar and that none of them would suffer from corrosion.

It was found that locally available PP is not suitable for above-ground installation as it is exposed to sunlight and degraded by ultraviolet (UV) radiation. This effect can be slowed by adding UV stabilisers, but the only long term-term solution is to permanently coat the pipeline, which is not practical.

The same is true for CPVC, with the added complication that CPVC has very poor resistance to ammonia and limited resistance to most amines, even at ambient temperature. This is due to the high reactivity of amines with chlorine, which strips the chlorine from the CPVC, which weakens the material and leads to failure.

PVDF is an excellent all-purpose pipe material that can be used in temperatures up to 140°C and has excellent UV resistance. This material is typically used for demanding applications in the chemical industry, but it is only available in sizes up to 225 mm OD (Outer Diameter) because it is at least five times more expensive than HDPE.

In the manufacture of HDPE pressure pipe systems, ISO (International Organization for Standardization) and European standards only allow the use of pre-compounded PE80 and PE100 materials. Such materials can be fully protected from UV degradation by the dispersion of carbon black (2-2.5% by mass) throughout the resin and can be used at operating temperatures of up to 60°C. As shown in Figure 7, they also have very good abrasion resistance, an important property considering the erosion of existing steel pipelines due to high flow velocities.

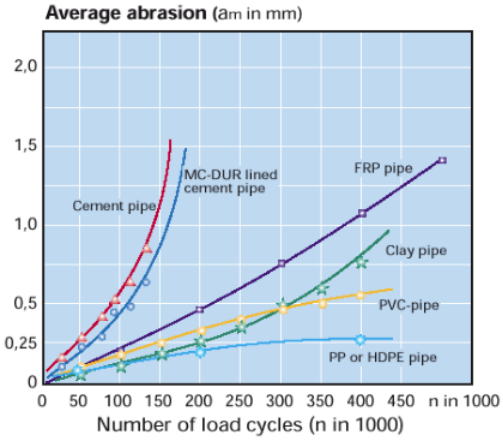

Figure 7: Chart showing abrasion (erosion) rates measured using Darmstadt Test.

With regards to jointing, CPVC pipes are jointed either with rubber rings or cemented joints. Whilst PP pipes can be jointed using butt fusion welding, but at that point of time only pipes with spigot and socket rubber ring joint are available in Indonesia. Both PVDF and HDPE can be jointed by butt fusion welding, effectively creating a continuous pipe with no seams.

The feasibility study concluded that while PVDF was the material of choice, PE100 (HDPE) offered the best cost-performance balance for this application and was adopted for the pipeline replacement project. The study also compared the estimated replacement costs of the PE100 pipeline with that of carbon steel pipeline. Despite PE100 having a lower cost per unit weight, the difference between the two materials was found to be relatively small, especially at lower operating temperatures, when considering the higher density and hoop stress capacity of carbon steel. The most significant difference was for the installation cost, with PE100 averaging about 60% lower than that of carbon steel.

3.1 Detailed design

Detailed planning was also undertaken by PT Dago Engineering and essentially involved designing an above ground PE100 pipeline mounted on prefabricated concrete supports running alongside the existing carbon steel pipeline.

The consultancy was apparently unaware of the ISO 15494 standard, which covers the design of plastic piping systems for industrial applications and therefore the design was developed using a combination of ASME B31.3, the code for process piping, along with information taken from several sources concerning the design of PE100 pipe systems.

The pipeline itself comprised a PE100 pipe with 400 mm OD SDR 11 (Standard Dimension Ratio, is the ratio of the pipe outside diameter divided by its minimum wall thickness and determines the pipe pressure rating) with a minimum wall thickness of 36.3 mm. At a temperature of 20°C, such a pipeline would have a design pressure of 16 bar (232 psi) but at a temperature of 50°C this should be reduced to 9.8 bar using the temperature derating factor given in ISO 4427 Part 1. This was considered more than sufficient considering this section of pipeline being replaced was operating under free-flowing conditions and at minimal pressure.

The design also called for the PE100 pipes and fittings to be butt fusion welded together whenever possible to effectively create a continuous pipeline with no seams. It should be noted that PE100 has a thermal coefficient of expansion of 0.18 mm/m/°C, more than 15 times that of carbon steel, this continuity required the provision of expansion loops at regular intervals.

3.2 Construction and commissioning

Following the completion of the detailed design and after going through a tendering process, the contract to supply and install the new PE100 pipeline was awarded to PT Wirana Jayatama Abadi, a Jakarta-based general contractor that principally works in the energy sector.

The manufacture and supply of the PE100 pipes and fittings was sub-contracted to PT Indopipe (now owned by PT Wahana Duta Jaya Rucika), a company based in Surabaya with over 10 years' experience and can produce pipes up to 1000 mm OD. All pipes and fittings were produced using the BorSafeTM HE3490-LS and BorSafeTM HE3490-LS-H PE100 pipe grades manufactured in the United Arab Emirates by Borouge. Both materials have long track records of being used for industrial pipeline applications and have been used to produce pipes and fittings of up to 2000 mm OD.

Following the contract award in August 2013, construction work started in November. As the new pipeline was to be laid alongside the existing one, as shown in Figure 8 and 10, the route was straightforward with a repetitive construction process comprising the following steps:

- Supply of materials to site
- Production of the precast concrete pipe supports
- Laying out of pipes and fittings along the pipeline route
- Installation of the pipe supports
- Jointing and installation of the pipes and fittings

Delivery and installation of the new 3,750 m pipeline was completed within 8 months and proven to be a significantly easier exercise than installing a new steel pipeline, partly because the PE pipeline had no lining or coating system that need to be completed after butt fusion welding.

Figure 8: The new PE100 condensate pipeline as it passes through the tea plantation.

Figure 9: A butt fusion joint on the condensate pipeline showing the QA system markings.

The Star Energy team implemented a simple quality control system for managing the jointing of the pipe sections to form the pipeline. Figure 9 shows an example of the quality control table that was marked on the pipe beside each butt fusion joint. The date indicates when the joint was made, while JN gives the joint number for record purposes on the project welding map. VC indicates that the joint has passed a visual check of parameters such as the pipe ends being square, cleanliness during butt fusion and the weld bead width being within tolerance. BFP on the fourth row stands for Butt Fusion Parameters and shows parameters such as the fusion pressure, temperature and heating time were within the required tolerances. Following pressure tests, the new pipeline was commissioned on 16 July 2014 and to date has been operational for over a decade without incident.

Figure 10: A view along the completed pipeline showing the precast concrete saddles.

4. LESSONS LEARNT

The following is a brief summary of the observations and lessons learnt by the project team during the design, construction and subsequent operation of the new PE100 pipeline.

4.1 Pipeline design

- Designers should be familiar with the pipe material properties, particularly the relationship between operating temperatures, hoop stresses and service life. If necessary, technical support should be sought from the PE100 resin manufacturer for technical assistance.
- The PE pipe grades supplied throughout Asia follow the ISO rather the ASTM (American Society for Testing and Materials) International. Therefore, designers should use ISO standards such as ISO 4427 and ISO 15494 whenever practical, and make sure there are no contradictions where reference is made to both ISO and ASTM.
- As the pipeline was laid through tea plantations, the Star Energy team was concerned with accidental damage due to agricultural activities. Where external surface damage of pipeline is a concern, either during installation or operation, Borouge recommends that designers specify the use of a High Stress Crack Resistant (HSCR) PE100 grade, such as BorSafeTM HE3490-LS-H. These materials have a very high resistant to the formation crack, initiated from external damages, and growth of cracks through the pipe wall.
- With regards to tapping and connections, designers need to be aware of the differences between how these are achieved on steel and PE pipelines and should not overlook the use of electrofusion (EF) tees and tapping saddles.

4.2 Jointing and installation

- The contractor and supervising engineering must implement a comprehensive quality assurance programme to ensure that jointing is undertaken in accordance with the ISO standards. It is recommended that all butt fusion and EF jointing machines have a data storage and export function to allow all the welding parameters to be reviewed by both the contractor and supervising engineer.
- As with the welding of steel pipelines, the fusion jointing of PE100 pipelines should be performed by properly trained and certified personnel. Only a few locally trained personnel with extensive experience in butt fusion jointing were available to work on the project and this limited the effectiveness of the quality assurance programme.
- Borouge recommends, as a minimum, the person managing the contractor's site jointing team and one member of the site supervision team to be trained, examined and certified in accordance with an internationally recognised PE pipe jointing qualification such as the German GW330.
- Once the logistics are properly arranged, the delivery, jointing and installation of PE pipes is a relatively fast process, as there is no requirement to complete the coating or lining of the pipeline after jointing.
- As mentioned earlier, there are a wide range of fittings that are available for PE pipelines and contractors need to be familiar with their availability and correct installation. Many of these fittings are produced using injection molding process and need to be imported from overseas.

4.3 Operation, maintenance and monitoring

- The use of PE100 for the condensate pipeline has removed the risk of corrosion, together with the associated costly, time consuming and disruptive monitoring and repair activities.
- Whilst the Star Energy team were very familiar with operating steel pipe systems, they had no experience in using PE pipe systems and therefore encountered some difficulty in developing an inspection, monitoring and preventive maintenance programmes. Pipe producers and the PE100 resin manufacturer should be able to provide information on failure mechanisms and give their recommendations on inspection and maintenance programmes etc.
- Small diameter tapping for instrumentation, off-takes and sampling can be installed using EF tapping saddles. These are fusion welded to the exterior surface of the pipeline whilst it is in operation and contain a cutting head, allowing a 'hot-tapping' to be undertaken, thereby minimising operational disruption.

5. CONCLUSION

To the best knowledge of the authors, the Wayang Windu project is the first project where PE100 pipeline has been installed to serve as a condensate return pipeline at a geothermal power plant.

This was surprising, likely because many engineers believed that PE100 is not suitable for use at high temperatures and pressures. They are unaware of example that such pipe systems have been used for over 15 years in the Sultanate of Oman to carry out very aggressive water and crude oil mixtures that have a constant temperature of

50°C. Such systems operate at pressures of up to 10 bar and in an environment where exposed pipe surface temperatures can reach 80°C.

In this paper, the authors have shown how a PE100 pipe system can be used for geothermal pipe applications at temperatures of up to 50°C. The authors also tried to provide some useful technical advice on the design and implementation of such projects, particularly when it comes to the lessons learnt during the process. The documentation of this project has been done to encourage other geothermal power plant owners, operators and designers to consider the use of PE100 pipe systems for lower temperature applications, such as condensate pipelines.

Keywords: Cooling Tower, Performance, Condenser Pressure, Power Generation

ABSTRACT

As heat transfer equipment the performance of cooling towers is mainly affected by the effective heat transfer area which may deteriorate due to fouling. The effect of decreased performance in Cooling tower also comes into effect in the condenser that leads to reduction in power generation. This paper will discuss the evaluation performance method using in house calculation of condenser modeling and Cooling Tower performance evaluation using four-point Tchebycheff method. Common remedial actions applied are cooling tower fill-pack replacement and condenser nozzle cleaning. Means that the remedial action based on condenser performance evaluation that continues with calculation of impacted power generation will drive the economic benefit resulting from the remedial action. Following the techno economic analysis it was found that the benefit from restoring power generation capacity could have positive gain in terms of financial benefit.

1. INTRODUCTION

In order to maintain performance of a single flash geothermal power plant it is crucial to keep the cooling water system in its best performance. Cooling water systems provide condensation process of exhaust steam turbine in subcooled condition to be fully condensed thus providing maximum vacuum condition leading to maximum power generation by creating as much as delta pressure of inlet and outlet of the turbine. Common problem in aging cooling tower is fouling on heat transfer surface media that reduces its effectiveness and the problem could be delivered to condenser and this condition lead to reduction of maximum capacity of single flash geothermal power plants such in Wayang Windu.

2. SINGLE FLASH GEOTHERMAL PLANT COOLING SYSTEM PERFORMANCE

There are three major components in a single flash geothermal power plant cooling water system which is condenser, cooling water circulation transfer pump (hot well pump) and cooling tower. This paper mainly focuses on performance of cooling tower and condenser that play a key role in power generation. Meanwhile Hotwell pump deteriorating performance could be straightforwardly identified by comparing its current performance against original performance and/or performance curve.

2.1 Cooling Tower Performance

Wayang Windu geothermal power plant uses the countercurrent type of cooling tower as the following schematic (Figure 1).

The predominant factor to maintain cooling tower performance is the available surface area. Wayang Windu uses a countercurrent cooling tower where the main medium for heat transfer is cooling tower fill-pack. Because of impurities in cooling water that mainly consist of silica, sulfur, calcite or other minerals it may form scaling and reduce effective heat transfer area for cooling process. If scaling happened then water spray from nozzle will make a phenomena like water fall where ideally the water falling down shall be distributed evenly. Overall heat transfer process as function of effective surface area for heat transfer process as the following:

$$Q = K * S * (hw-ha) \quad (1)$$

- Q = total heat transfer Btu/h
- K = Overall enthalpy transfer coefficient lb/hr.ft^2
- S = Heat Transfer surface area ft^2 where S equal to a x V
  - a → area of transfer surface per unit of tower volume (ft^2/ft^3)
  - V → effective tower volume ft^3
- hw = enthalpy of air-water vapor mixture at the bulk water temperature, Btu/lb dry air
- ha = enthalpy of air-water vapor mixture at the wet bulb temperature, Btu/lb dry air

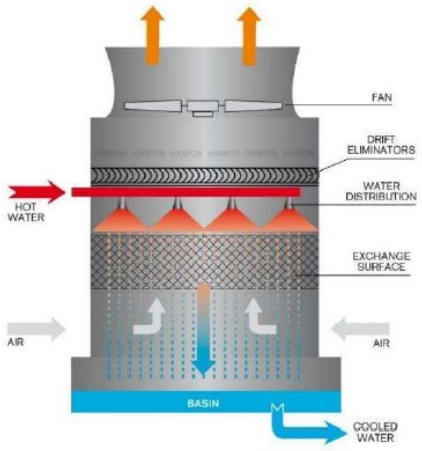

Figure 1: Schematic of Counter Current Flow Cooling Tower as Used in Wayang Windu Geothermal Plant.

Application to small element of heat transfer surface area ds then giving :

$dQ = d[K*S*(hw-ha)] = K*(hw-ha)*dS$ (2)

Water side	Air side
Q = Cw * L * Cooling Range dQ = d[Cw*L*(tw2-tw1) dQ = Cw * L * d (tw) …(3)	Q = G * (ha2 – ha1) dQ = d[G * (ha2 – ha1)] dQ = G d(ha) …(4)
K*(hw-ha)*dS = Cw * L * d (tw) $dS = \frac{\frac{L}{K}\frac{Cw}{(hw-ha)}}{} dtw$ $S = \frac{L}{K}\frac{cw}{(hw-ha)}\int_{tw1}^{tw2} tw$ $\frac{KS}{L} = \frac{KaV}{L} = \frac{Cw}{hw-ha}\int_{tw1}^{tw2} tw$	K*(hw-ha)*dS = G d(ha) $dS = \frac{G}{K}\frac{d(ha)}{(hw-ha)}$ $S = \frac{G}{K}\int_{ha1}^{ha2}\frac{d(ha)}{(hw-ha)}$ $\frac{KS}{L} = \frac{KaV}{L} = \frac{G}{L}\int_{ha1}^{ha2}\frac{d(ha)}{(hw-ha)}$

Where

Cw = specific heat of water (BTU/lb)
L = water mass flow rate (lb/hr)
G = Air mass flow rate (lb/hr)

Meanwhile the KaV/L is known as “Merkel Number” or NTU. Where NTU is “Number of Transfer Unit” independent factor from the tower size and fill configuration. From the above equation, plotting NTU vs L/G gives what is known as “demand curve”. NTU also showing “tower demand curve”.

$$NTU = \frac{KS}{L} = \frac{KaV}{L} = \frac{G}{L}\int_{ha1}^{ha2}\frac{d(ha)}{(hw-ha)}$$

The KaV/L value can be obtained from the Cooling Tower datasheet provided by the manufacturer. Subsequently, if the Merkle Number or KaV/L from actual data falls below the original values, a comparison can be made to determine the extent of the cooling tower's performance deterioration. Using the latest Merkle number values, the estimated cooling water temperature flowing to the condenser can then be calculated.

A decreasing trend in NTU values indicates a decline in cooling tower performance, signaling the potential need for corrective measures like replacing the fill-pack. However, since temperature variations can affect NTU, it's essential to collect and average data over time. This averaged data can then be used for an economic analysis to determine if fill-pack replacement is justified. Alternatively, referring to historical data on cooling water temperature improvements after previous fill-pack replacements may also help in decision-making.

Table 1: Current WW U-2 Merkle Number by Original Design.

Parameter	Value	Unit		Parameter	Value	Unit
Dry bulb Temp	73.4	F		Hot Water Temp	44.20	^{0}C
Dry bulb Temp	23	^{0}C		Hot Water Temp	111.56	F

tw_1 + 0.9 x Range	57.65	241.27	103.73	ha_1 + 0.9 x L/G x Range	70.25	33.48	0.03
						Sum of 1/(hw-ha)	0.25
				NTU = Sum of 1/(hw-ha)/4* Range= **K AV/L**			**2.42**

From the calculation model using four point Tchebycheff method as described in Table 1, we can calculate current NTU and compare it with design. Furthermore we might also estimate cooling water outlet temperature using NTU value that we had already found by using iteration process. The estimated cooling water temperature could then be used for condenser calculation as describe in the next part of this paper.

The four-point Tchebycheff method, illustrated in Table 1, allows for the calculation of current NTU. This calculated value can then be compared to the design NTU to assess performance. Additionally, an iterative process using the obtained NTU value enables the estimation of the cooling water outlet temperature. This estimated temperature will subsequently be used for condenser calculations, as detailed in the following section of this paper.

2.2 Condenser Performance

All the steam exhaust from the turbine in Wayang Windu power plant where it has direct condenser type for the main condenser exhaust steam from turbine contacted directly with cooling water from cooling tower basin using spray nozzles. However as seen in figure 2, the main condenser also use to collect and cooled down hot fluid that comes from utilities such as Liquid ring vacuum pump, auxiliary cooling water pump or other equipment a part of balance of plant such as steam ejector. Motive steam used in downcomer of steam ejector were collected in bottom flow of inter and after condenser then they flows directly to bottom part of condenser and take part in achieving equilibrium state of condenser.

In the Wayang Windu power plant, utilizing a direct condenser configuration, all turbine exhaust steam directly contacts cooling water from the cooling tower basin via spray nozzles within the main condenser. Additionally, as depicted in Figure 2, the main condenser serves to cool down hot fluid discharges from utilities (e.g., liquid ring vacuum pumps, auxiliary cooling water pumps) and balance of plant equipment (e.g., steam ejectors). Motive steam from the steam ejector downcomer is collected in the inter-condenser bottom flow, subsequently entering the main condenser's bottom section, contributing to the overall condenser equilibrium.

A common challenge in the geothermal industry is the lack of access to detailed condenser equilibrium calculations, which are often proprietary information held by manufacturers. This necessitates the development of in-house calculation methods to accurately estimate condenser equilibrium and, subsequently, condenser pressure. A viable approach involves utilizing heat transfer principles, where the cooling fluid (cooling water from the cooling tower) experiences an increase in enthalpy and temperature, while the cooled fluid transfers its heat, resulting in a decrease in both enthalpy and temperature, as illustrated in Table 1.

Input data used for calculation merely the turbine exhaust temperature, cooling water temperature and flow into condenser which is also cooling water from utilities as part of balance of plant as stated in figure 2. Main cooling water from cooling tower basin as major flow contributor. Meanwhile additional flow to main condenser from balance of plant are coming from ACWP (Auxiliary Cooling Water Pump), LRVP (Liquid Ring Vacuum Pump), Inter and after condenser drain in GRS (Gas Removal System). The spreadsheet developed for calculation then use to iterate equilibrium of temperature value where the convergence result showing zero sum of enthalpy which correspondent to condenser pressure in equilibrium that take into effect to power generation output from turbine.

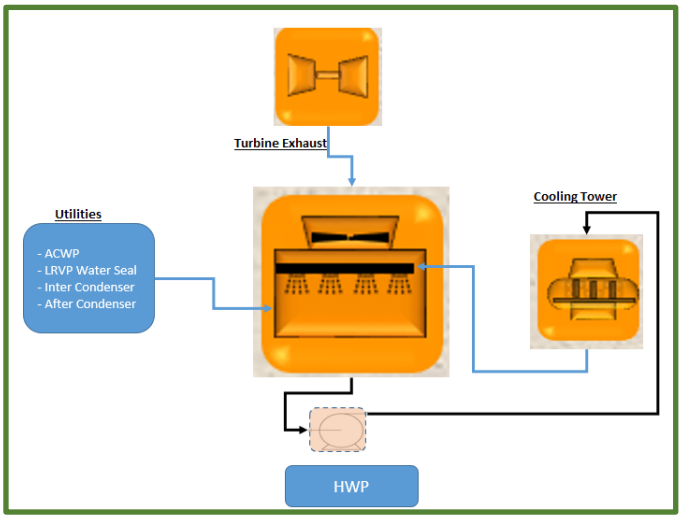

Figure 2: Direct Contact Mass Balance in Wayang Windu Geothermal Plant.

Figure 3: Megawatt Benefit of Cooling Tower Fillpack Replacement and Condenser Nozzle Cleaning.

3. PERFORMANCE EVALUATION RESULT AND TECHNO ECONOMIC IMPACT

Following the replacement of all eight cooling tower (CT) cells, the cooling water outlet temperature was analyzed using data collected over four years. The original design specified a CT outlet temperature of 22°C. However, with the new cells and a wet bulb temperature of 17°C (same as design), the final outlet temperature is around 24.5°C.

To assess if this lower temperature is sufficient to achieve the original design condenser pressure of 0.1 bara, a condenser performance evaluation was conducted. Further analysis, utilizing material and heat balance calculations, indicates that due to excess condenser capacity, the desired 0.1 bara pressure is achievable even with the increased cooling water temperature compare to original design.

It was found that merely from calculation and collected data that a decrease of 1^0C in cooling water outlet of cooling tower will shift the equilibrium in condenser that lead to increase of power generation around 1.2 MW that could be represented from figure 3 by comparing purple wedges (power generation increase) and green

wedges of the curve (CT outlet temperature decrease) along with completion of all 8 cells of CT fillpack. Meanwhile red wedges in the curve of figure 3 showing do nothing possible case in effect to the power generation (in MW). However the red wedge seem linear in the early phase due to power demand actual from buyer that is not maximum that lead to reduce in actual power generation did not take into significant effect as remaining capacity of cooling otwer still able to handle the required demand by user (PLN) which not reach maximum load due to decrease of power demand in Jawa Bali areas at that time.

Table 2: In House Calculation for Equilibrium in Condenser.

Total Enthalpi	KJ/H	2.19E+08	2.18E+08	**-7.06E+05**					

4. CONCLUSION

The evaluation of cooling tower performance and condenser, followed by remedial actions such as cooling tower fill-pack replacement and condenser nozzle cleaning, along with techno-economic analysis, leads to several conclusions:

1. Every 1°C increase in cooling water temperature results in an approximate 0.008 bara increase in condenser pressure, causing a power generation impairment of about 1.2 MW at the Wayang Windu U-2 geothermal power plant.
2. The in-house calculation approach provides acceptable results for actual condenser pressure, with a variation of 5%. This method proves valuable for predicting power generation and evaluating economic benefits.

From Lab to Field: A Review of The Scaling Phenomenon in Geothermal

Hande Sile, Duygu Disci, Argyro Spinthaki, and Ugur Kaymakci

Kurita Europe GmbH, Mannheim, Germany

Keywords: Geothermal, scaling, downhole scaling, water treatment, anti-scalant, inhibitor

ABSTRACT

Geothermal energy is a renewable and clean source of power that can provide electricity and heat for various industries as a key transition to achieving net zero emission targets. However, geothermal utilization faces a major challenge: scaling. Scaling is the formation and accumulation of mineral deposits which reduces the efficiency and sustainability of the geothermal system leads to an increase in operational and maintenance cost.

The scaling phenomenon is related to the reservoir characteristics and the harsh conditions of the process designed to extract more energy from the geothermal source. The geothermal fluid contains dissolved minerals that are in chemical equilibrium at the reservoir depth with corresponding pressure and temperature. When the fluid moves to the surface from bottomhole through the wellbore, the thermodynamic conditions change, and some minerals become supersaturated and tend to precipitate and deposit on the walls of the production wells. The most common scaling minerals are carbonates seen in the downhole.

Scaling can have detrimental impacts on the production wells, such as reducing the well diameter and the flow rate, triggering the corrosion and erosion on the casings and wellhead assembly, causing additional cost for well stimulation and workover operations.

Scaling solutions dedicated to geothermal technology start from the production well and are distinctively constituted regarding the surface conditions until the re-injection well. This study highlights global cases showing the benefits of effective water treatment in preventing scaling in geothermal systems. The demonstrations will include lab studies and following field applications.

1. INTRODUCTION

Geothermal energy is a solid candidate to make green energy transitions all around the world. It is renewable but not free of challenges. The natural problems that majorly appear in both explorational and operational periods can be listed as organic and inorganic precipitation (scaling), corrosion, and erosion. All these natural challenges are required to be treated due to their potential damage to almost all the parts of the process.

Geothermal systems can be classified according to distinct aspects such as reservoir thermodynamics, geological setting, utilization characteristics, and process type, etc. Based on the reservoir temperature, they are classified as low, medium, and high temperature geothermal systems.

Liquid-dominated and vapor-dominated geothermal systems refer to the physical state of geothermal flow in the reservoir (Bodvarsson, 1964; Axelsson and Gunnlaugsson, 2000). Utilization of this hot media at surface can be grouped into two parts as direct use and power generation. The type of heat extraction process is determined by the source capacity.

All types of geothermal fluids tend to create significant problems related with their specific chemistry. Depending on this specific chemistry, scaling, corrosion and even both can be faced at the same time. The variations in temperature, pH, non-condensable gas (NCG) content, permeability, rock types of the formation and hydrothermal activities change the composition of water which ends up with high degree of diversity in mineralization (Jamero and Zarrouk, 2016). It goes forward with co-precipitation turning into the most challenging mechanism for scale forming along the industrial processes.

Scaling forms at various locations within the process under different physical and chemical conditions:

- Downhole scaling in the well: due to the sudden pH change around boiling/flashing depth with changing in temperature (T) and pressure (P)
- Scaling at surface facilities: due to the sudden P changes regarding the mechanical design and flow regime
- Scaling in plant area: due to the cool-down of geothermal brine during the heat transfer in heat exchangers
- Scaling in re-injection process: due to the low process temperature

The prevalent deposit types encountered in geothermal are carbonates, silica and silicates, sulfides, and sulphates. Carbonates are majorly calcite and dolomite and minorly aragonite since fractured marble is widely distributed on subsurface as a rock formation for low-to-medium enthalpy geothermal reservoirs. Carbonate and silica mineralization also influenced by magnesium level in the system. Silica tends to form as amorphous silica (SiO_2) which may also co-precipitate with metal-silicates like Mg, K, Al-silicates. Sulphates precipitate as Ca-sulphate and Ba-sulphate in barite form. Sulfides occur in the form of many phases, and are usually in well-crystallized form (Corsi, 1986). Pb, Zn, Fe, Cu, As dominate the frequently observed deposits of sulfides while antimony-sulfide can be distinguished as the most specific scale type in geothermal deposition in stibnite mineral. All these scaling formations may cause considerable damage which lead to decrease in efficiency and total energy output, increase in downtime and maintenance, resulting in loss of energy and high operational costs.

There are different methodologies to control scale forming and protect geothermal facilities. The efficiency of each method is related to the process conditions, scaling mechanism, fluid content and project feasibility. This paper aims to indicate successful achievements in the field applications of inhibition and dispersion method against common scale ranges. Composed treatment programs which are applied to different process designs are supported by initial laboratory studies to ensure material compatibility, thermal stability, and desired performance rate for significant problems of the related geothermal fields.

2. METHODS

Geothermal is a unique process with harsh physical and chemical dynamics that create challenges to mimic in the lab conditions: elevated temperature, high pressure, high salinity, high amount of NCG, etc. Therefore, all the lab test results would require confirmation with industrial applications in the field. Kurita's technical team demonstrated standardized lab test concepts to get an initial approach of the viable solutions to be confirmed with the field trials.

Two comparative approaches are presented to reveal scaling cases in geothermal: laboratory tests and field applications.

2.1 Lab-scale tests

Several experimental methods are conducted to validate stability and performance of geothermal inhibitors in lab-scale.

2.1.1 Differential Scale Loop (DSL)

The Differential Scale Loop (DSL) is an automated versatile device to examine the precipitation and deposition tendency of scale (especially $CaCO_3$) under elevated temperature and pressure, e.g., simulated geothermal conditions. The apparatus includes a capillary tubing loop, oven equipped with the loop, pump and brine control unit for dosing, and PC control (Figure 1).

Pumping of the geothermal brine to scale loop as blank and/or treated with anti-scalant at different concentrations indicates a trend of differential pressure within the capillary loop. The evaluation of ΔP versus time corresponds with anti-scaling performance of related inhibitor at simulated elevated temperatures.

Figure 1: Showing the equipment setting of DSL in operation. From right to left oven equipped with scale loop, dosing unit and computer.

2.1.2 Beaker Tests for Antimony-Sulfide Dispersion

Principle: Tests are conducted in a brine of defined quality by in-situ precipitation of antimony sulfide and particle growth observation in presence and absence of chemical additives. Antimony sulfide formation and precipitation is highly pH-dependent, thus careful pH control is rendered crucial.

Trial brine composition: Test water is made by dissolving stock solutions into DI-water (Figure 2).

Ions	mg/L	mol/m³
Ca^{2+}	91.97	2.29
Mg^{2+}	12.1	0.50
Na^{+}	85.1	3.70
Cl^{-}	162.5	4.58
SO_4^{2-}	47.9	0.50
HCO^{3-}	225.9	3.70

Figure 2: The content of artificial brine simulated like geothermal conditions.

Dispersant stock solutions are prepared as 1000 ppm as actives, pH is adjusted to 6.3 and dosed in each trial. Common test dispersant concentrations are: 1, 1.86, 3, 7.75 and 15 ppm as actives.

Procedure: Tests are done with an antimony sulfide concentration of 20 ppm. 2L test water are prepared. After stirring 5.74 mL of Antimony (III) chloride – solution is added, and pH is adjusted to 6.3 (+/- 0.1) with sodium hydroxide and/or hydrochloric acid. In seven beakers, the calculated amount of dispersant is added. The 8th beaker is the control experiment (absence of dispersant). In each beaker 250 mL of test water are added the solutions are stirred at 300 rpm. 68.8 µL sodium sulfide solution 5% are added in each test beaker. This is the initiating moment of the experiment. After 15 min the beakers are removed from the stirring plate and placed in a row with a white background. A photo of all beakers is captured immediately after 22 hours.

2.2 Field Trials

By using the promising results from laboratory experiments, several field trials distributed around various geographies are conducted to confirm the performance of products at in-situ conditions. Kuritherm™ product range is dedicated to geothermal applications to avoid several types of inorganic and organic precipitation in the system.

2.2.1 Downhole Treatment

Background: A binary cycle geothermal power plant (GPP) suffered from carbonate and silica scaling in production wells and metal-silicate deposits in separation station at the surface. System data analyzed and the mechanism of scaling form examined.

Process conditions: Product is dosed to the 170 tph total mass flow rate of two-phase flow from the well. The capillary tubing is set around 2000 m depth for chemical injection.

Actions: Samples are collected from the outlet of accumulation tank located upstream of brine transfer pump through a condenser. Coupon monitoring ports are located at the production line near wellhead (two-phase flow) and downstream of separation (single-phase flow). Dosage optimization trial is performed for 1 week duration starting with the high dosage rate of 8 ppm.

2.2.2 Dispersion of Stibnite in ORC (Organic Rankine Cycle) Unit

Background: A binary GPP suffered from antimony-sulfide deposition as stibnite form in the heat exchangers of ORC unit. Especially in preheaters where the highest ΔT occurs to maintain desired heat capacity; the heavy scaling causes dramatic increase of ΔP in the heat exchangers. Scaling proceeds in re-injection lines and brine injection pump units (BIP) additionally. Not only the frequent maintenance periods but also less power generation result in higher operational costs for the plant.

Process conditions: The trial of new antimony-sulfide stabilizer is dosed at the upstream of ORC unit (inlet of the vaporizer) to protect the heat exchangers and re-injection facilities. The total flow rate of brine is approximately 800 tph and the outlet temperature of plant area is around 70 ^{o}C which is considered as re-injection temperature.

Actions: An exclusive Kuritherm™ product that contains organic polymers effective on sulfide stabilization and dispersion is tested for stibnite inhibition for more than 8 months at several dosage rates. Optimization studies completed and stabile treatment program is set for plant area. The sampling ports are at the inlet of ORC unit and outlet of Preheater under trial. ΔP is monitored to evaluate performance parallel to regular coupon controls.

3. RESULTS AND DISCUSSION

3.1 Stibnite Dispersion Lab Test Results

One of the Kuritherm™ state-of-the-art solutions can act as an effective dispersant of Antimony (III) sulfide scaling. Despite the widely conducted research on carbonate and silicate scaling, studies concerning the mitigation strategies towards antimony sulfide are limited. Presented indicate the effect of a new polymeric anti-scalant as a successful antimony sulfide stabilizer, Additional to the laboratory results, the superior efficiency of this product will be demonstrated with physical parameters observed during plant application. Demonstration to a test series with the best of candidates are shown below (Figure 3).

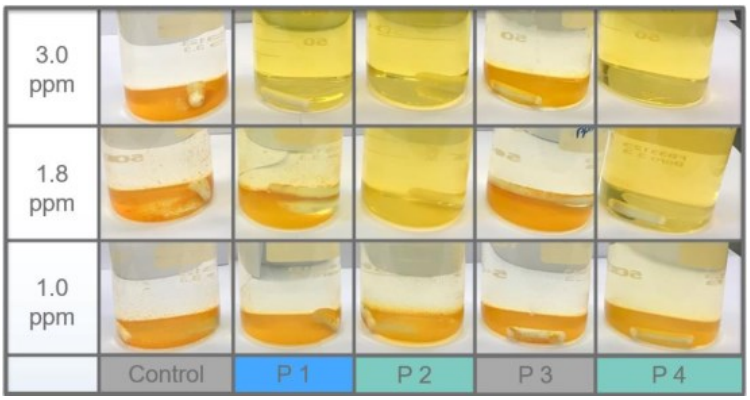

Figure 3: Showing the results of beaker test for antimony sulfide dispersion. P4 ≥ P2 > P1 ≥ P3 ≥ Control.

The evolution of precipitation in a variety of polymer concentrations in real-time pictures against the Control are presented. Upon experiment initiation, there are not any differences between the Control and the dispersant-containing solutions visually. The system is monitored for up to the first 22 hours after initiation of trial and the results shown in Figure 5 are evaluated. While conventional inhibition methods are rendered challenges of such insoluble scales, dispersion can be a very efficient alternative approach e.g., P4 and P2 (Figure 3).

3.2 Downhole Treatment Results

The trial is completed in 1 week including the steps of dosage optimization, sampling, and monitoring of product performance at related locations in the process. The coupons were checked physically every day and re-assembled to the pipelines without any cleaning. No scaling is observed on the wellhead coupon belonging to two-phase flow area (Figure 4). Some Mg-silicate traces are observed on the separation station coupon belong to the single-phase flow (Figure 5) which might be seen because of cleaning effect in the separation station.

Figure 4: The initial status of the coupons at the first day of trial with scale. Coupon on the left is at wellhead, the right at the outlet of accumulation tank.

Figure 5: The clean coupons from the last day of the trial. Coupon on the left is at wellhead, the right at the outlet of accumulation tank.

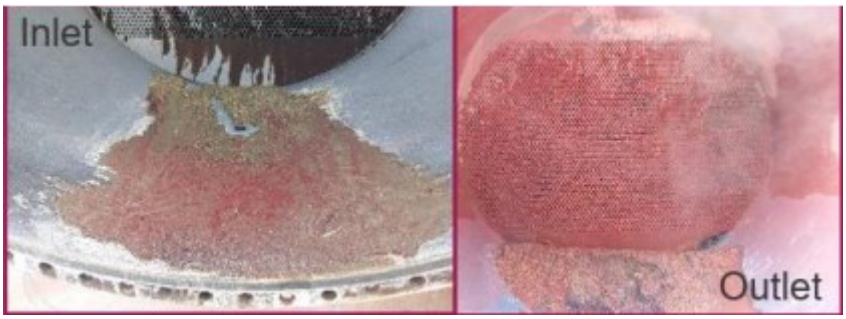

Figure 6: The cross-section view of a shell-and-tube heat exchanger (preheater) before the application of Kuritherm™ treatment program. The inlet on the left and outlet on the right show antimony-sulfide precipitation within the tubes.

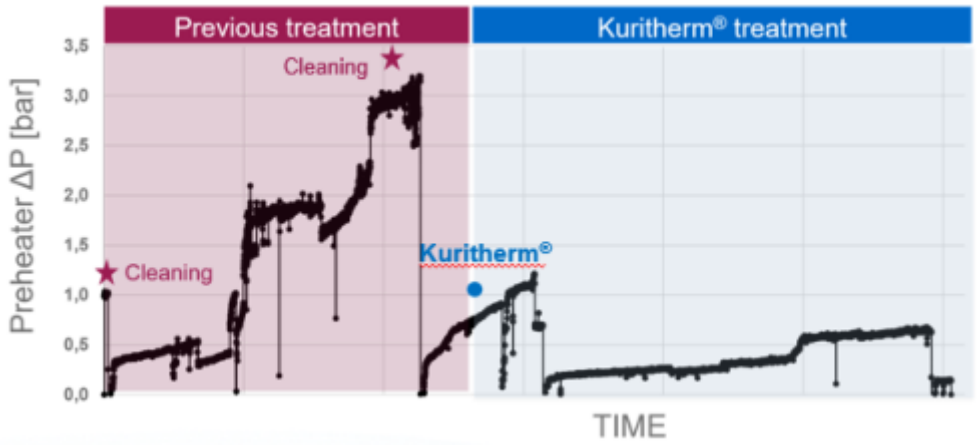

Figure 7: The trend of ΔP of the heat exchanger in ORC unit versus time. After a strong cleaning operation ΔP increases in a noticeably abbreviated time due to the fast scaling shown at the left side of the graph. Once the second cleaning operation is performed, Kuritherm™ treatment started and ΔP gets stabile even for a longer term shown at the right side of the graph.

The in-situ XRF analysis of deposits by using hand-held size mobile device at site show the distribution of inorganic components of scale in ratio. Dominant content of the deposit at wellhead coupons are determined as carbonate and silica scaling while metal-silicates are determined on the surface coupon.

The trends of results from regular chemical analysis are evaluated during the trial. Total Hardness (ppm $CaCO_3$) and Silica (SiO_2) values tend to increase at the initial phase of trial and become stabile by time until the last day.

3.3 Stibnite Dispersion Field Results

An effective stabilizer with particular dispersion effect is developed to inhibit antimony-sulfide precipitation in geothermal surface systems. The initial observations from the inside of heat exchanger reveal the critical status of equipment before treatment. The metal surface of heat exchangers where the heat transfer should occur, totally covered by reddish-blackish stibnite deposits. (Figure 6).

The stibnite scaling is hard to remove by any chemical or mechanical cleaning operation due to the common co-precipitation of silica and silicate minerals. Even at these challenging conditions, the new development of stibnite inhibitor presented promising results in the field trial which confirmed by the plant data monitoring and regular analysis (Figure 7).

Kuritherm™ stabilization and dispersion effect against stibnite and co-precipitated minerals such as metal-silicates verified by the long-term low ΔP values in the preheater. Less maintenance periods and more heat transfer bring saving in energy and cost.

4. SUMMARY AND CONCLUSION

Scaling is observed as a natural challenge in geothermal utilizations. What makes geothermal approach essential is considering it that starts in the production site and ends in the re-injection. The presented laboratory studies and field results subject to support controlling of major scaling issues faced in various regions under the operation of different geothermal technologies.

Two case studies were presented to compare successful lab test methods with their corresponding field applications. Carbonate precipatation is one of the common scaling problems in downhole conditions. That is why DSL equipment is used to simulate these conditions and check the scaling tendency. The field results which are monitored by well-determined KPI's confirmed the DSL results by achieving similar successful results of Kuritherm™ product. Additionally, a full study of product development for stibnite scaling control is examined starting from the research phase in lab. Initial field application results show that the product significantly increased the production efficiency in the plant by avoiding decrease in the heat transfer of preheaters.

The featured outcomes are listed below:

- The downhole scaling inhibition is monitored by wellhead coupon control as a visual observation together with periodic chemical analysis of hardness to keep track of precipitated levels in the well if any exist. A proper downhole treatment is able to control not only the scaling on the walls of the wellbore components but also the equipment at surface under two-phase flow conditions.
- The combination of inhibition and dispersion effect provides continuous protection of geothermal systems from variety of mineralization that occurs due to the co-precipitation mechanism.
- Antimony sulfide as a significant scaling type for geothermal is hard to inhibit and remove from the process. The stability and performance of a new development for stibnite stabilization is confirmed by the field results which show a parallel behavior observed during the laboratory tests.

Current Practices to Manage Silica-based Scaling in Geothermal Operations

Duygu Disci, Argyro Spinthaki, Ugur Kaymakci, and Hande Sile

Kurita Europe GmbH, Mannheim, Germany

Keywords: Silica, metal silicate, geothermal, scale prevention, inhibitors, solubility

ABSTRACT

Biofouling, scale precipitation, and corrosion can jeopardize the integrity of water treatment facilities and the efficiency of the plant, with scale and corrosion particularly posing significant challenges to geothermal systems. Downhole applications are severely affected due to brine characteristics, high ionic concentrations, high temperatures and the common presence of dissolved gases. While both problems can occur separately, they can also be commonly identified together (under deposit corrosion/pitting). Common scale types in geothermal systems are mainly carbonates, sulphides, and silica and silicates. Silica and metal silicate precipitation is especially in geographies like Turkey, New Zealand, and Indonesia cause severe problems and must be tackled with state-of-the-art mitigation strategies.

For improved plant efficiency and to avoid fatal material failures in any part of the massive installations, finding the proper treatment program has a vital role. While traditional approaches, such as acidic treatment and caustic applications are used, the safety risks can be significant and strict measures should be followed to avoid equipment damage in case e.g. proper dosing is not applied. Therefore, the focus and efforts of the scientific community over the past decades have been devoted to the utilization of different chemical additives such as polyacrylate based polymers and phosphonates for the mitigation of such issues. In this paper Kurita's approach will be presented to solve issues of scaling especially towards silicates commonly seen in geothermal plants.

1. INTRODUCTION

Silica is one most of the most widely encountered compounds in geosphere where the nature takes its source to generate heat and power through geothermal brine. While this compound has a vital role in several industrial and biological applications, the reason why it is widely mentioned in geothermal applications are due to its ability and affinity to form chemical bonds at various physical conditions such within a geothermal plant. These so-called deposits are formed due to the polycondensation of silicate particles to form amorphous silica and/or as metal silicate when different metal ions are involved in the brine, such as magnesium, aluminium, manganese, calcium, and iron.

Metal silicates bear some structural similarities to silica (such as the SiO4 tetrahedra) but present a vast number of differences in their composition, structural chemistry, and formation processes. It is worth mentioning that the composition of the nine rock-forming minerals reveals that they all belong to the silicate group of minerals, whose basic building block is the SiO4 tetrahedron. Metal silicates form in waters with high silica and low salinity contents in the presence of certain metal ions. Iron and magnesium silicates exhibit low solubilities in low enthalpy brines, while aluminium silicate usually precipitates in fluids of higher temperatures.

There are several kinds of such additives, named scale inhibitors, depending on the nature of the scale to be inhibited. Such scale inhibitors are usually either polymeric in nature, or smaller molecules, such as phosphonates. Scale inhibitors are widely applied in water governed systems in order to reduce system cleanings, shut - downs and to prevent system malfunctions. The quest for the ideal scale/deposition inhibitor is still on-going and unfortunately, a "universal" scale inhibitor is not available yet, due to each scale having its own idiosyncrasies and thus requiring special treatment. Several system variables must be considered in the process to ensure the proper selection of the scale inhibitor. These include system pH, supersaturation, presence (or absence) of oxidizing biocides, inhibitor tolerance to hardness, temperature, and potential of composite scale formation. In our studies in order to find the proper mitigation technique, a proper lab method for each scale has been investigated. From our extensive studies we can summarize the conditions of precipitation for widely encountered metal silicates (Table 1).

Among those detailed studies, this paper is focused on experimental and field results regarding Aluminium silicate based scales.

Table 1: Solubility Characteristics of the commonly encountered metal silicates.

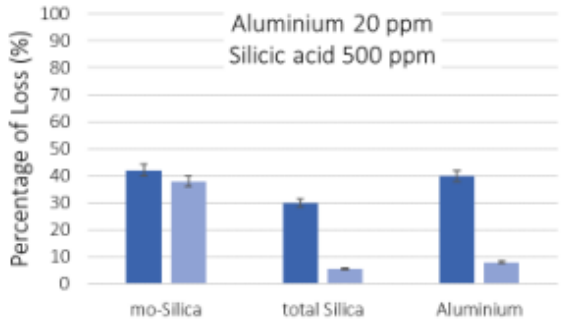
Scale Type	pH range of induced precipitation	Temperature Characteristics
Amorphous Silica	5 - 9	Normal Solubility
Magnesium Silicate	> 8.5	Inverse Solubility
Aluminium Silicate	5.5 - 8.5	Normal Solubility
Iron Silicate	5 - 9	Inverse Solubility
Manganese silicate	Under Study	Inverse Solubility

2. AL-SILICATE INHIBITION EXPERIMENTAL METHODS

Principle: This experimental protocol concerns inhibitor evaluation against aluminium-silicate scaling. It focuses on trial conditions that are commonly encountered in water treatment fields worldwide. The purpose is to identify chemical additives that will prevent the scale precipitation through threshold inhibition mechanisms.

Stock Solutions: The sodium silicate solution (solution A) used in all experiments containing 1000 ppm silicate, expressed as ppm SiO_2, is prepared by dissolving 4.08 g of $Na_2SiO_3 \cdot 5H_2O$ in 1 L of deionized water. A 10.000 ppm Al^{3+} solution (solution B) is prepared by dissolving 8.948 g of aluminum chloride in 100 mL of DI water.

Procedure: 50 or 80 mL of solution A (for a final concentration of 500 or 800 ppm silicic acid) and 49 or 19 mL respectively of DI water are placed in each flask, stirring is initiated at 250 rpm and the solutions are heated up to 70°C with well-sealed caps. When the desired temperature is reached, the calculated amount of inhibitors are added. One beaker serves as the control experiment (absence of inhibitor). Additionally, 0.125 or 0.2 mL of solution B are added to all beakers (for final aluminum concentrations 12.5 or 20 ppm respectively), the pH is adjusted to 7 (±0.08), caps are sealed, stirring speed is lowered to 150 rpm and this is the initiating moment of the experiment. After 3 and 24 hours, the following measurements took place: molybdate – reactive silica, total silica, soluble aluminum, and turbidity.



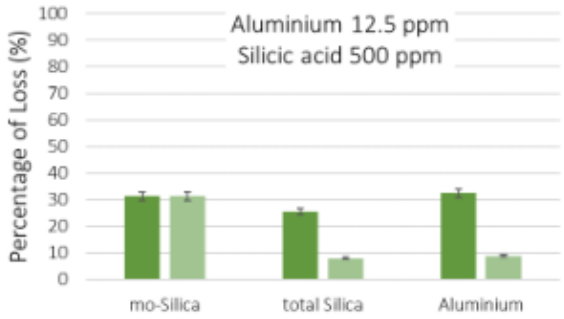


Figure 1: (left) and Figure 2 (right): Stabilization of silica and aluminum species leading to decrease in aluminum silicate scale precipitation (increasing Al3+).

3. FIELD TRIALS, SILICA AND SILICATE INHIBITION AT SURFACE

Background: A triple-flash GPP suffered from heavy amorphous silica and different types of metal-silicate precipitation at critical parts of the plant. The heavy scales decrease the power output and cause additional downtime. A possible number of deposits was calculated and estimated as 470 kg/h at 2000 tph mass flow rate in the process.

Process conditions: The physical parameters of High-Pressure (HP), Intermediate-Pressure (IP) and Low-Pressure (LP) flashing stations are examined in terms of P, T, and flow rate conditions. Products are dosed on averagely 2000 tph brine flow rate. The re-injection temperature is below 120 oC which makes the geothermal brine super-saturated with the silica content above 500 ppm in the system.

Actions: Different silica and silicate inhibitors which are customized as a functional product line, Kuritherm™, dosed at several injection points. The treatment program is composed to existing data and scaling simulations. During the field trial, chemical analysis, scaling coupon check, in-situ XRF analysis, online scaling sensors and physical observations are considered as performance monitoring tools. The existing data set of 1 year monitoring is reviewed to make a proper technical evaluation.

The interesting observation from these trials was the negligible difference in the soluble silica results with or without product, a clear stabilization effect in total silica and soluble aluminium is marked. These are promising results considering that aluminum can act as the catalyst of this reaction (Figure 1 and Figure 2).

4. AL-SILICATE INHIBITION EXPERIMENTAL RESULTS AND DISCUSSION

This work starts with revealing the true nature of the so-called “aluminium silicate”, through a series of bench-top synthesis experiments under various conditions and complete physicochemical characterization. The research proceeds with developing the control strategies to be implemented for its mitigation starting from beaker tests and working the way up all the way to pilot plant and field trial tests. Selected results of additives present potential as stabilizing agents, by complexing the aluminum species, and preventing “aluminium silicate” scale formation.

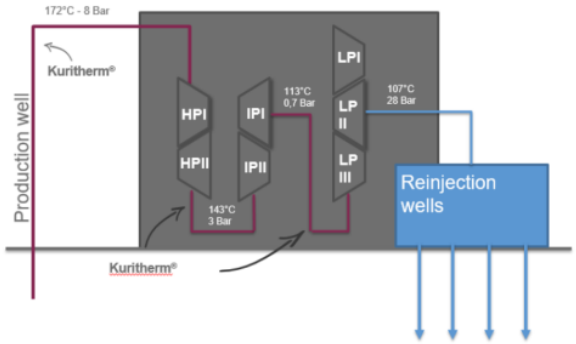

Figure 3: The general overview of process flow scheme of the triple-flash GPP with applied treatment program.

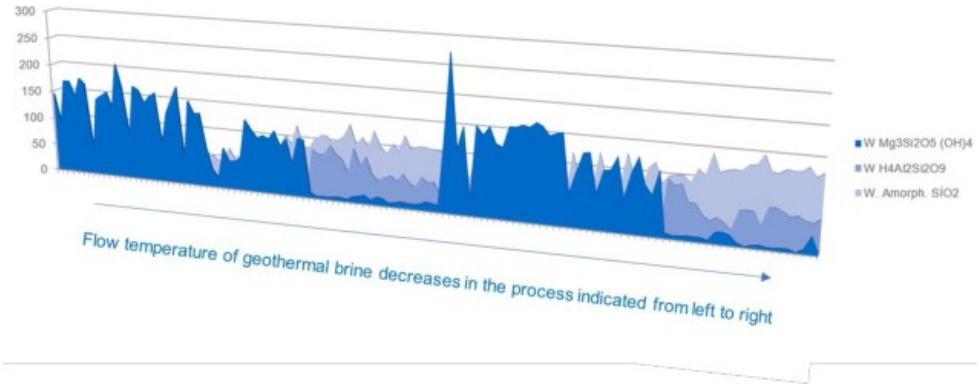

Figure 4: The XRF analysis of silica and silicate deposits from various parts of the process in GPP. From left to right the flow T decreases and the form of the deposit changes accordingly. Magnesium silicate tends to precipitate at high T while at lower T metal silicates such as Al, and K-silicate co-precipitate. Around the re-injection area where the lowest T is observed, the mechanism of scaling turns into creating amorphous silica.

Figure 5: The progress of improvement in product performance over time: the coupon above has traces of metal-silicates and silica deposits and the coupon below indicates the results of a more efficient treatment.

5. FIELD RESULTS

Steam-flash geothermal systems are exposed to dramatic P-T changes in the process. The chemical equilibria of two-phase flow coming from production well including NCG (Non-Condensable Gases) and high amount of dissolved minerals disturbed at the HP, IP, and LP levels of separation and requires individual treatment concept (Figure 3).

The kinetics of silica polymerization are overly sensitive to the temperature and pH variations in the system. Therefore, the form of the scale changes immediately on a dynamic T profile. From high T to low T environment which is recorded from HP to LP flashing vessels, the mineral composition of silica and silicate deposits starts to be evolved as it is verified with the XRF analysis of related scale layers (Figure 4).

Several products from Kuritherm™ solution portfolio are tried to retard silica polymerization process and to induce dispersion within the geothermal flow. The improvement of treatment programs over time can be seen on periodic coupon monitoring at different ports (Figure 5).

The observations of coupon monitoring are correlated with online scaling sensors which provide instant non-stop data within the pipeline. Inhibition of metal-silicates successfully verified and amorphous silica is dispersed by the effect of strong treatment program.

6. SUMMARY AND CONCLUSIONS

Scale and deposit mitigation has been at the epicentre of research for an extended period of time and research on this subject holds enormous potential. There is plenty of room for further growth, from different additives that can be evaluated against unwanted precipitation to altering and improving the evaluation methods.

A proper treatment is a key to keep the geothermal plants sustainable by protecting the equipment, lowering the production loses and increasing the heat transfer efficiency by lowering the scaling tendency. As seen in this paper a proper chemistry is necessary to obtain these conditions in the plant. The quest for the ideal scale/deposition inhibitor is still on-going and unfortunately, a “universal” scale inhibitor is not available yet, due to each scale having its own idiosyncrasies and thus requiring special treatment.

Silica and silicate precipitation is a complex genesis and needed to be treated regarding the individual characteristics of process and fluid chemistry. Long term monitoring applications verify the performance of executed treatment program.

Brine Management & Reinjection System for Dieng Two-Phase Fluid Geothermal Field

Akbar Putra, Hendra Ardi Kurniawan, Bhaskara Aji Pawitra,
Sarbeni Rangkuti, and Herdian Ardi Febrianto

PT Geo Dipa Energi (PERSERO), Aldevco Octagon Building, Indonesia

akbar.putra@geodipa.co.id

Keywords: Manual Cleaning, Scaling, Brine, Two-Phase Geothermal Field, Dieng

ABSTRACT

PT. Geo Dipa Energi (PERSERO) operates Dieng geothermal field with two-phase production fluid type. The production fluid characteristics are; 30% dryness level, up to 183 degrees Celsius temperature, 11 bar pressure, and contains dissolved Silica up to 1070-ppm concentration. The decrease in temperature and pressure on the surface facilities causes the initially dissolved Silica substance to condense into a solid and stick to the medium it passes through, this is usually known as “Scaling” phenomenon. To maintain asset operations, environment and subsurface water balance, a brine management system is needed at the Dieng geothermal field.

This case study was carried out by the Maintenance Department, PT. Geo Dipa Energi (Unit Dieng) in 2024. The output of this study is a best practice for brine management system from the surface to the subsurface in the Dieng geothermal field facility that is economical, environmentally friendly and can be applied on a scheduled basis to support company power generation business process.

This study method was carried out by collecting production fluid data for all wellpads in Dieng geothermal field, existing piping system & maintenance schedule, and costs incurred by different cleaning methods. The data is then subjected to comparative analysis both in safety, technical and financing terms to produce optimal and economical practices according to current conditions.

The results of study and field practice shows that the use of manual cleaning techniques in brine management & reinjection system is the most optimal and economical for Dieng geothermal field existing facility. This method is recommended for application in current two-phase Dieng geothermal field facility and other geothermal fields with similar conditions.

1. INTRODUCTION

1.1 Dieng Geothermal Field

The Dieng Steam Field is one of many geothermal fields to generate electricity, which is currently operated by PT Geo Dipa Energi (PERSERO). The Dieng Geothermal Steam Field is located 98 km from the west of Semarang city center.

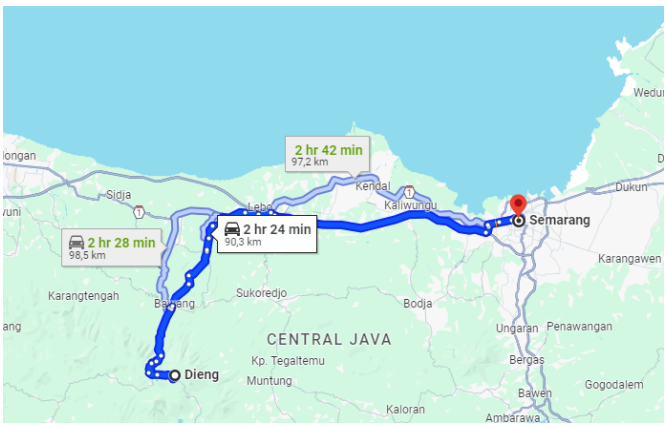

Figure 1: Dieng Geothermal Field is located in Central Java (Google.com/maps).

The first drilling well DNG-1 in the Dieng geothermal field was carried out in 1977 under the management of PT Pertamina and completed at 1978. In early 1990s, Dieng field development right was granted to HCE (Himpurna California Energy Ltd.). In 2002, the development right of the Dieng Field was granted to PT Geo Dipa Energi (PERSERO) and on September 2002 Dieng Unit 1 started to operate commercially (Sirait, et al., 2015). Currently Dieng Unit 1 and the small scale power plant produce around 52 MW.

1.2 Dieng Geothermal Field Production Fluid

The Dieng geothermal field operates with 7 online production wells, 5 injection wells. In June 2024. The production fluid is a 2-phase type with 70% brine and 30% steam. Field data shows a brine production rate of 438 TPH (Tons per hour) or 1,916 GPM (Gallons per Minute).

Table 1: Dieng Geothermal Field Brine Production 30th June 2024.

	Brine Production Rate	
Production Well	Ton / Hour	Gallon / Minutes
HCE-7B	20	87,5
HCE-7C	60	262,5
HCE-29	18	78,75
HCE-28A	13	56,875
HCE-28B	24	105
HCE-31	5	21,875
HCE-30	208	910
Condensate Power Plant	90	393,75
Total	438	1916,25

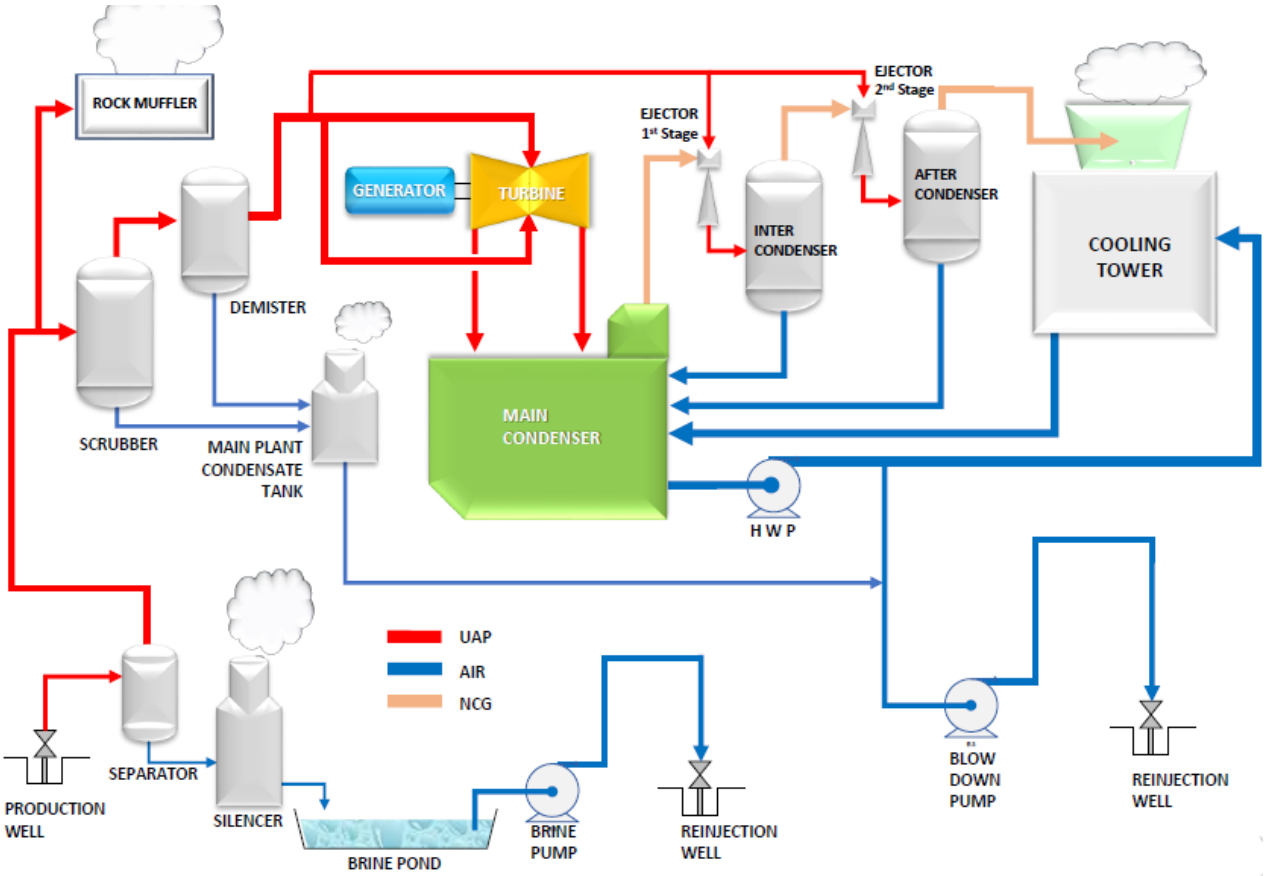

Figure 2: Dieng Geothermal Production System.

Production fluid from the Dieng field geothermal well is channeled to a separator system to separate the two types of production fluid phases. The steam phase resulting from the separation will flow to the generating turbine to rotate the generator turbine which produces electricity. The brine will flow into the flashing system AFT (Atmoshperic Flash Tank) or Silencer, open canal and pond to reduce pressure, temperature and noise. The brine then flowed with the help of a mechanical pump to re-enter the piping system which continue to reinjection wells. 5 reinjection wells were used to inject a total of 2,110 GPM. Brine produced from the Dieng geothermal field is classified as having high silica content. In the 2-phase pipe from the well head, the brine composition was found as in Table 3 (Juhri et. al., 2001).

Table 2: Dieng Geothermal Field Brine Injection 30th June 2024.

Injection Well	Brine Injection Rate (GPM)	Note
SLR-G-29B	710	
HCE-29A	750	Northern Injection
DNG-14	250	
DNG-15	200	
HCE-5A	200	Southern Injection
Total	2110	

Table 3: Sample from HCE-30 at Two Phase Line showing Dieng Geothermal Water characteristic. (Juhri et. Al., 2001).

Chemical Composition	Concentration (ppm)
Cl	21.200,0
SiO4	74,4
HCO3	25,0
Na	10.249,0
K	2.817,0
Ca	708,8
Mg	0,5
SiO2	1.064,5
Al	0,0
Fe	1,4

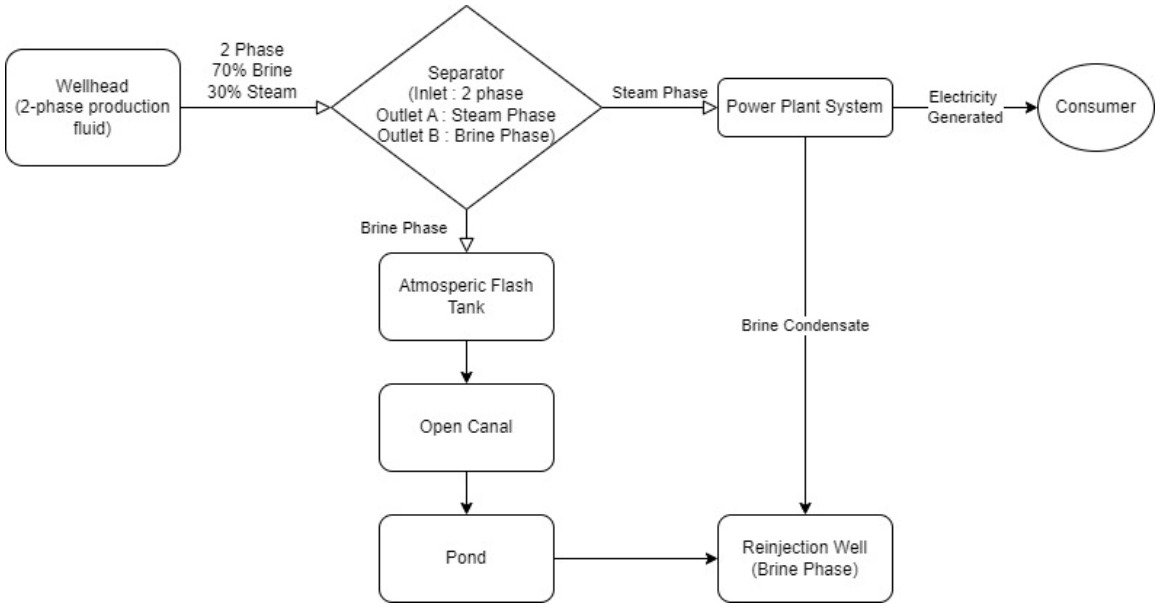

Figure 3: Dieng Geothermal Field Brine System.

The production fluid from the geothermal wellhead has a pressure of 11 bar and a temperature of 183 degrees Celsius. The brine that flows through the system at Wellpad Dieng experiences a significant drop in temperature until at the open pond the brine temperature is only 90 degrees Celsius.

1.3 Dieng Geothermal Field Piping Facilities

Piping facilities in the Dieng geothermal field are used as a fluid transportation medium. The fluids transported include 2-phase fluids (brine & steam), steam, brine and condensate. Piping facilities use 2 types of pipes, welded pipes and flange to flange pipes.

At wellpads, flange-to-flange type piping facilities are used to transport 2-phase fluid from the wellhead to the separator, then from the separator to the Atmosperic Flash Tank and to SAGS (Steam Above Ground System). At brine lines system that connect between Wellpads, the use of 8", 12", and 16" welded pipes are common practice with some use of 8" flange to flange type pipes. The specification of the pipe are Carbon Steel material with 40 schedule.

Figure 4: Dieng Geothermal Pond & Open canal system.

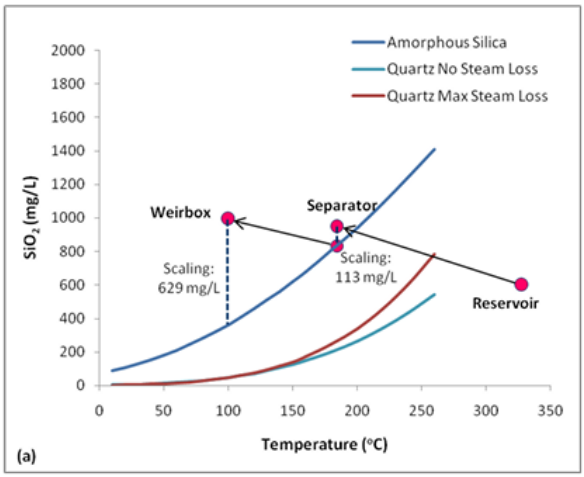

Figure 5: a) Amorphous Silica Saturation Curve of Dieng Geothermal Well. (Utami et. al., 2014). b) Silica Deposition on pipeline.

Table 4: Dieng Geothermal Brine Line Piping Facilities.

No	Type of Pipe	Material	Size (inch)	Total Count (lines)	Total Length (meters)	Sub total Length by type	Proportion
1	Flange to Flange	Carbon Steel Schedule 40	8"	11	12.072	12.072	24%
2	Welded	Carbon Steel Schedule 40	8"	23	29.826	37.560	76%
3	Welded	Carbon Steel Schedule 40	12"	2	2.358		
4	Welded	Carbon Steel Schedule 40	16"	5	5.376		

1.4 Maintenance schedule.

Company's Maintenance Division carries out routine maintenance on Dieng geothermal field assets, including the piping system used for brine management & reinjection. The difference in pressure between points on the pipeline indicates a disturbance causing the pipe did not function properly. The pressure drop will become greater as time goes by, the inspection and maintenance need to be carried out to return the pipe to its original condition. Maintenance aims to ensure that piping facilities remain reliable to support maximum and environmentally safe geothermal electricity generation operations.

2. LITERATURE REVIEW

2.1 Deposition of Silica

One of the chemical components that can be found in brine is dissolved silica. The silica solubility as presented by Amorphous Silica Saturation Curve are scaled with increase of Temperature and pH. The decrease of temperature will decrease the silica solubility forcing the excess dissolved silica to be deposited at the piping medium until it reaches the saturation limit.

At the beginning, the silica solubility is relatively high on reservoir until the wellhead (183 degree celcius). As the brine moves to lower temperature at the weirbox (98 degree celcius), the dissolved silica concentration is

higher than the solubility of amorphous silica. Thus, would potentially form the solid silica deposition (Utami et. al., 2014).

Silica Saturation Index (SSI) is Dissolved Silica Concentration divided by Solubility of Amorphous Silica, by first taking a brine sample to determine the silica content in the brine and determine the operating temperature (F. Dwiputra et al., 2022).

The SSI value is determined by the following equation :

$$SSI = \frac{Dissolved\ Silica\ Concentration}{Solubility\ of\ Amorphous\ Silica}$$

The occurrence of silica scaling can be predicted by the SSI value provided that SSI > 1 means silica scaling is possible, SSI < 1 then silica scaling is not possible. The Dissolved Silica Concentration was determined by laboratory tests using the Direct Nitrous Oxide-Acetylene Flame Method. The Solubility of Amorphous Silica is determined by the following equation :

$$Log\ C = -\frac{731}{T} + 4{,}52$$

Where,

C =Solubility of Amorphous Silica (mg/kg)

T = Absolute temperature (K)

Below are the calculation result and simulation from brine chemistry for Silica Saturation Index in Dieng Geothermal Well.

Table 5: Silica Concentration & Silica Saturation Index (SSI) for Dieng Geothermal Well sample (F. Dwiputra et. al., 2022).

Parameter	*Flashing*	*Line 2 Single Flash*			
	Separator 1	*Inlet Holdup vessel* 2	*Holdup vessel* 2-A	*Holdup vessel* 2-B	*Holdup vessel* 2-C
Temperature °C)	215,6	210,6	206,8	202,4	200,2
Temperature (K)	488,75	483,75	479,95	475,55	473,35
Silica Total (mg/kg)	1116	1126	1108	1116	1110
Silica Amorf (mg/kg)	1057,66	1020,68	992,94	961,24	945,56
SSI	1,055	1,103	1,116	1,161	1,174
Titik Sampel	S01	S21	S22	S23	S24

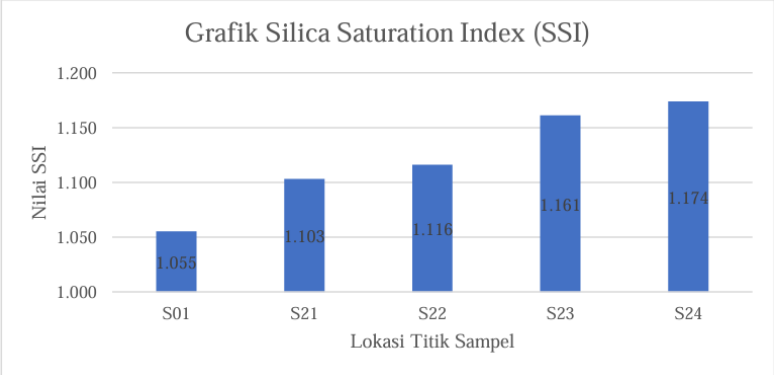

Figure 6: SSI Graphic for Dieng Geothermal Well sample (F. Dwiputra et. al., 2022).

Silica deposition can take the form of a solid material that sticks to the piping media it passes through. Over time, the buildup of silica causes the internal diameter of the pipe to narrower.

2.2 Welding Pipe Connection

One of the most common practices used to connect pipes is using welding method. The welding process is where the two ends of the pipe are connected using a heating application. This type of connection is permanent and

requires cutting to separate the pipe later on. The welding connection method is applied without using connection fittings or bolting.

There are several types of welding methods for pipe connections, including: 1) Butt Weld, which is a welding method by bringing the two ends of the pipe together without touching each other and making a connection. This welding method is the simplest and easiest to apply in various situations. 2) Lap Weld, is a welding method by bringing two pipes together with one of them squeezing the other and then welding. 3) Plug Weld, is a welding method by inserting one pipe into another.

Figure 7: Butt Weld application on pipe.

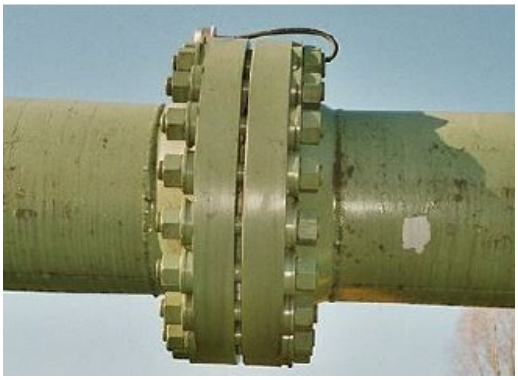

Figure 8: Flange to Flange connection on pipe.

Connection using the welding method has several advantages including; 1) There are rarely or no leaks at all. 2) cheaper costs when compared to flange to flange connections. 3) Easy to apply insulation material and requires less material. 4) More resistant to vibration. 5) easier to repair without risk of losing fittings.

Connection using the welding method also has several disadvantages including; 1) Requires Welding personnel expertise. 2) The use of heat in welding has the potential to affect the characteristics of the pipe material. 3) Does not provide room for expansion. 4) Requires longer time for the Inspection process. 4) Require penetrant test for leakage.

2.3 Flange to Flange Pipe Connection

Apart from connecting pipes using the welding method, the flange to flange method can also be applied to piping systems. Connection using this method requires 3 main components, including; Bolts, Gaskets and Pipe Flange. This type of connection is a temporary / non-permanent connection.

A flange is a connection between pipes that functions as a base for using bolts in the connection. Flange is needed in a pair so that it can be connected from each end of the pipe. Bolts are components used to provide compressive pressure on the flange to flange connection system. There are several types of bolts that are commonly used, including Stud Bolts and Machine Bolts. Gaskets are components that provide a sealing function to pipe connections. The gasket will be pressed from both sides and is usually a type of silicon and stainless steel material. Gaskets should only be used once and not for reuse to avoid leaks at the Flange to Flange connection.

The advantages of the Flange to flange connection method include: 1) The connection is much faster than the welded type. 2) Suitable for use when the pipe will be paired with other equipment. 3) Easier for the dismantle and assembly for maintenance purposes.

The disadvantages of the Flange to flange method include; 1) A leak test needs to be carried out to ensure that there are no leaks at the flange to flange connection. 2) Requires more expensive costs compared to the welding

type because of the flange and gasket material. 3) Less resistant to vibration systems. 4) Use of damaged gaskets may result in leaks. 5) requires tension to produce effective sealing.

Table 6: Comparison of Welded Connection & Flange to Flange connection on pipe.

No.	Parameter	Pipe Connection	
		Welded	Flange to Flange
1	Cost required	Low	High
2	Duration required for Connecting & Dismantling	High	Low
3	Resistance to Vibration	High	Low
4	Require specific skilled personnel	Yes	No
5	Potential heating damage to material	Yes	No
6	Potential tension damage on material	No	Yes

Figure 9: Temporary Office.

Figure 12: NDT Penetrant test after Manual Cleaning process on Dieng Brine line.

2.4 Manual Cleaning for Silica Deposition

Manual Cleaning Method is the simplest and the earliest method that has been used. This method only uses simple mechanical equipment such as hammers, rod, and spades. Manual cleaning of silica can be done according to the welded type of pipe and flange to flange type of pipe connection.

Preparation for manual cleaning method includes; Permit to work approval, material dan tools mobilization, schedule acceptance and initial field survey. A temporary office is required for temporary placement of material, tools, and documentation. The temporary office should be placed in such way that allow ease access from any cleaning points.

Preparation for manual cleaning method includes; Permit to work approval, material dan tools mobilization, schedule acceptance and initial field survey. A temporary office is required for temporary placement of material, tools, and documentation. The temporary office should be placed in such way that allow ease access from any cleaning points.

Personnel required in manual cleaning method are consisted of Site Coordinator, Safety Man, Welder, Pipe Fitter, and helper. Aside from the specific personnel required for welding and fitting pipe, the personnel specifically for manual cleaning is mainly unskilled and helper.

The main step of Manual cleaning method is consisted of 3 substep such as; Dismantling pipe, Manual Cleaning, Reassembly and testing connection pipe. Dismantling pipe for welded connection type will cut the pipe for each 6 meters, while for flanged pipe only by removing studbolts. If cutting or dismantling flange pipe is not accessible due to field condition, Lap Patch can be secondary alternative. The lap patch will partly trim the body of pipe, allowing manual cleaning without dismantling pipe connection.

Manual Cleaning for brine line can be done after making sure the dismantling or partial trimming process completed. After making sure the thickness of silica deposition then the cleaning process can be begin with.

Manual Cleaning starts with hammering process using 5 kgs hammer toward the body of pipe which will result the detachment of solid silica deposition from the internal pipe wall. The solid silica will be taken out using spades or rods. This process can be done repetitively until the internal pipe completely clean from silica solid. After that, the silica solid will be transported using bags and vehicle to designated place for further process / utilization.

After making sure the cleaning process done, all left to do is reassembling of the pipe body. For welding type connection, the welding procedure specification (WPS) should follow API 1104 and ASME Sec IX standard alongside with approved Procedure Qualification Record (PQR). For Flange to flange type connection, reassembling should follow bolting and using new gaskets. During connection of each end, the other end should be plugged using temporary plug to avoid any external solid to accidentally enter the clean pipe.

The manual cleaning process will ends with leakage testing using NDT Penetrant test for welding type or leakage test for flange to flange connection.

The manual cleaning process has several advantages such as; 1) Low cost as it only requires unskilled personnel and simple mechanical tools. 2) This method can be used effectively for small footprints during application. 3) This method allow the silica cleaning process to be manageable and avoid scattering to surrounding. 4) The use of simple task and equipment also making this process classified as low risk task avoiding pressure and temperature risk.

The main disadvantage of manual cleaning technique is its requires long duration as the process is mainly manual and labour works. Other disadvantage is potential physical damage or material deformation to pipe body due to hammering in long time. This can be resulted in thinning of pipe wall thickness and lower its strength. The use of routine wall thickness inspection is needed for extra precaution other than replacing with the new pipe all along.

2.5 Waterjetting Cleaning for Silica Deposition

The waterjetting method of silica cleaning uses water pressure to remove precipitated silica and considered a more advanced method for cleaning. Water is jetted using up to 20.000 psi pressure through equipment nozzle of the waterjetting equipment to be directed to the scaling pipe. The steps for waterjetting silica cleaning work are essentially same as manual cleaning except for the execution part where manual method hammering and using spades is replaced by jetting of pressurized water.

Waterjetting technique requires additional special jetting equipment and competent jetter and operator personnel. The use of water as jetting media also requires the sufficient water source to be easily accessible and connected to jetting equipment. Waterjetting technique also required temporary water containment equipped with filtration method to separate the water and the silica. The water can be used afterward.

Figure 13: Waterjetting for silica deposition line Dieng Geothermal field.

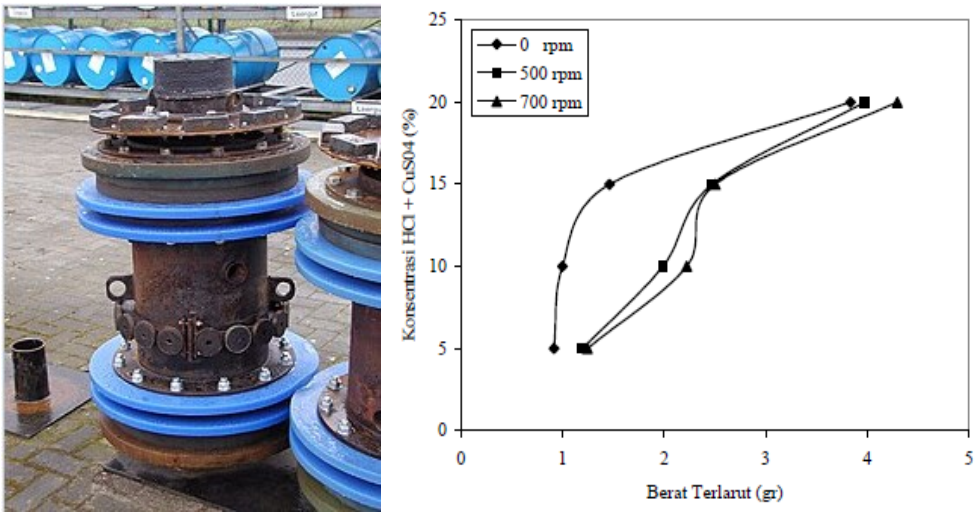

Figure 14: a) Pigging devices. b) HCL & CuSO4 concentration influence to dissolved scale (Syahri et. al., 2008) .

Waterjetting technique has the main advantage of completing the task much faster than using manual cleaning process. While the disadvantage of this technique are; 1) Higher cost as it requires additional equipment & skilled personnel. 2) require wide area to accommodate placement of waterjetting equipment. 3) require water supply. 4) potential environmental damage as the jetting result of high pressure water and silica scattering around. 4) higher risk as it consist of pressurized water work.

The Waterjetting techniques is suitable for advanced facilities such as the use of flange to flange connection pipe due to its short duration required for connection and dismantling, the use of dedicated cleaning yard for safer and allow cleaning of many pipe in very short time, also any means of transporting pipe from its location to the cleaning yard. The use of waterjetting technique on welded pipe connection is limited by the time requires for cutting and welding the pipe, this can result in longer equipment rent thus further increase the maintenance total cost.

2.6 Other cleaning methods: Pigging & Chemical Addition

Pigging requires "pigs" to be inserted into pipelines to perform cleaning activities. The pig was placed in one end of pipeline and pushed through the line by the product flow. It scrapes the insides of pipe as it travels, removing dirt and debris as it goes. This method is done without stopping the flow of product in the pipeline.

The use of chemicals to mitigate scaling can be used by injecting scale inhibitor chemicals. The use of chemicals includes HCl, CuSO4 and a mixture of HCL & CuSO4. The working principle of scale inhibitors is by forming complex compounds between scale inhibitors and scale-forming elements. The complex compound formed will dissolve in water, thereby blocking the growth of large crystals. Besides that, it can be used to prevent scale crystals from sticking to the pipe walls (Syahri et. al., 2008).

3. METHODOLOGY

The method used in this research is comparative analysis of multiple alternatives to determine the most suitable solution for the problem. This include stating the scope of the discussed problem, gathering required case data, determining the root of the problem and objective, researching potential alternatives, determining important parameters, testing alternatives resulting on quantitative and qualitative parameters, comparing tested alternatives data parameter, scoring, determining most suitable method based on scoring, completing with what-if situation and summarize the whole process to produce recommendation.

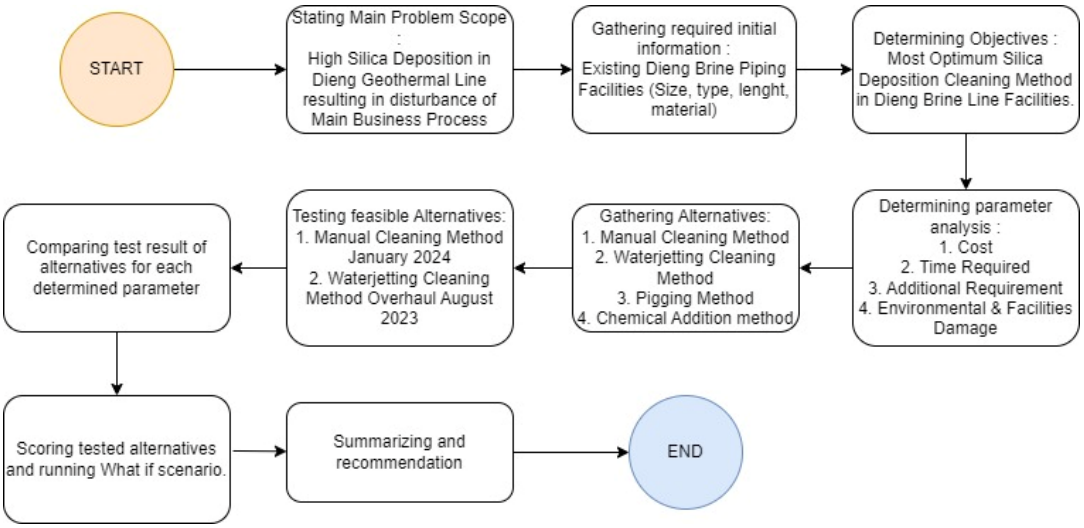

Figure 15: Comparative Analysis for Dieng Geothermal Brine Management & Reinjection System solution.

4. RESULT AND ANALYSIS

The main objective is to find the most suitable method in term of economical, safety, environmental and practical maintenance schedule to be applied to solve dieng geothermal deposition piping system. There are 4 potential alternatives which will be evaluated based on important parameters such as: 1) The total cost per meter of cleaning pipe, 2) The time required to complete pipe cleaning process, 3) The HSSE aspect including safety for the worker and surrounding and the effect to the environment. 4) The potential damage for piping facilities in the future. 5) the field feasibility.

Feasibility of each solutions should be assessed to eliminate any non-practical solution for current condition and objective. Based on 4 potential solution, the perquisites can be breakdown as below:

Table 7: Pre-Eliminary assessment of solution feasibility.

No	Cleaning Method	Compatibility of cleaning massive silica solid deposotion	Compatibility for non flowing condition	Result of Assessment
1	Manual Cleaning	V	V	Feasible
2	Water Jet Cleaning	V	V	Feasible
3	Pigging Method	V	X	Not Feasible
4	Chemical Addition Method	X	V	Not Feasible

Based on the assessment above, it was decided to continue with comparing the manual cleaning method and the water jet cleaning method.

4.1 Manual cleaning application for deposited silica pipeline system in Dieng Geothermal field.

Pipeline cleaning process using Manual Cleaning method is applied in 5 different scenarios in Dieng Geothermal pipeline system that prone to silica deposition problem. The cleaning process applied in full welded type of pipeline system as well as the mixed one with flanged type connection. The piping system is consisted of 8", 12" and 16" size of diameter. Manual cleaning application applied to brine line with hard silica deposition condition.

Table 8: Manual Cleaning Application Summary.

No.	Method	Total Cost	Pipe Connection	Pipe Size	Total Joint	Total Length (m)	Cost (Rp/m)	Time (hr)	AVG Speed (m/hr)	Silica Hardness Level	Safety & Environmental Aspects	Side Effect
1	Manual Cleaning	Rp 273.227.200	48% Flanged 52% Welded	8"	799	4794	Rp 56.993,58	255	18,8	Hard (Brine Line)	Labour Physical injury	Potential deformation on pipe body
2	Manual Cleaning	Rp 226.436.000	41% Flanged 59% Welded	8"	686	4116	Rp 55.013,61	172,5	23,9	Hard (Brine Line)	Labour Physical injury	Potential deformation on pipe body
3	Manual Cleaning	Rp 1.900.000.000	26% Flanged 74% Welded	8", 12", & 16"	4087	24522	Rp 77.481,45	1852,5	13,2	Hard (Brine Line)	Labour Physical injury	Potential deformation on pipe body
4	Manual Cleaning	Rp 116.882.500	Welded	8" & 16"	398	2388	Rp 48.945,77	105	22,7	Hard (Brine Line)	Labour Physical injury	Potential deformation on pipe body
5	Manual Cleaning	Rp 1.650.000.000	26% Flanged 74% Welded	8", 12", & 16"	2962	17772	Rp 92.842,67	1852,5	9,6	Hard (Brine Line)	Labour Physical injury	Potential deformation on pipe body

Total cost	total length (m)	cost Rp/m	Total Duration (hr)	Speed (m/hr)
Rp 4.166.545.700,00	53.592,00	Rp 77.745,67	4237,5	12,65

Table 9: Water jet Cleaning Application Summary.

No.	Method	Total Cost	Pipe Connection	Pipe Size	Total Joint	Total Length (m)	Cost (Rp/m)	Time (hr)	AVG Speed (m/hr)	Silica Hardness Level	Safety & Environmental Aspects	Side Effect
1	Water jet Cleaning	Rp 216.698.002	Flange to flange	10", 16", 18", & 20"	13	78	Rp 2.778.179,51	36	2,2	Very hard (2-phase)	Risk Pressure, Silica Scatter	Water Supply
2	Water jet Cleaning	Rp 390.000.000	Flange to flange	18" & 25"	24	146	Rp 2.671.232,88	46,2	3,2	Very hard (2-phase)	Risk Pressure, Silica Scatter	Water Supply

Total cost	total length (m)	cost Rp/m	Total Duration (hr)	Speed (m/hr)
Rp 606.698.002,00	224	Rp 2.708.473,22	82,2	2,7

A total of Rp 4.166.545.700 was required to clean a total 53.592 meters pipeline manually. This conclude the average cost of cleaning is Rp 77.745 per meter. The duration required is 4237,4 hrs thus the average speed of Manual cleaning process is 12,7 meters / hr.

The application of manual cleaning has side effects on both personnel safety and piping facilities. As the job is mainly hard labour, the potential risk of work is physical injuries due to falling objects and exhaustion. The piping

facilities suffers from hammering process could lead into deformation and lowering the strength in long run. Using manual cleaning on any line which operate in high temp and pressure could lead into early failure of the pipe.

The process is very simple that this method can be used for any brine line which very close to community farm, doesn't provide water supply and wide area to do work. While using manual cleaning can be flexible to do in any place, cleaning a very hard type of silica deposition on two phase line wellpad requires much longer time and can cause potential delay on business process.

4.2 Water Jet cleaning application for deposited silica pipeline system in Dieng Geothermal field.

Water Jet cleaning application is applied in 2 different scenarios in Dieng Geothermal Field piping system. The cleaning process is appied to full flanged pipe connection with varied diameter of 10", 16", 18", 20" and 25". The silica hardness level was very hard due to its located on two phase piping system.

A total of Rp 606.698.002 was required to clean a total 224 meters pipeline using Water Jet. This conclude the average cost of cleaning is Rp 2.708.473 per meter. The duration required is 82,2 hrs, thus the average speed of Water Jet cleaning process is 2,7 meters / hr.

The application of water jet cleaning has side effects on both personnel safety and environmental surrounding. As the job is pressurized water technique, the potential risk of work is injuries due to high pressure flow. The early precaution should be taken to make sure the job is done safely and eliminate the accident potential as much as possible. The surrounding environment suffers from scattering of silica. Housekeeping process should be included and additional rug needed to contain the silica.

The process is advanced that this method can be used to break down very hard silica such as in two phase line or any lower hardness silica. While using water jet cleaning can be flexible to do in any level of silica hardness, using this method requires a lot more equipment to begin with. The need of water supply and potential scattering of silica hinders this method to be used near community farm such as brine line. The use of this method can optimalized by several option such as; 1) Preparing a dedicated cleaning station which close to water supply and away from community. 2) a dedicated vehicle for transportation. 3) a full 100% flanged type connection of piping system as it align with speed of dismantling and practical re-assembly.

4.3 Water Jet cleaning and Manual Cleaning application comparison in Dieng Geothermal field.

Result of both cleaning method application on geothermal piping system can be measured by the cost and the speed of the process. The manual cleaning process proved to require less budget than using waterjet cleaning. This mainly caused due to its difference technology used. The cost of water jet equipment rent, skilled operator and personnel, water supply and power supply all resulted on high total cost to use Water Jet cleaning method. The ratio of cost between Manual Cleaning and Water Jet Cleaning is 1:35, which means that using water jet cleaning method to clean deposited silica pipeline is 35x more expensive than the manual cleaning.

Figure 16: Comparison of a) cost & b) speed of Manual dan Water Jet Cleaning method.

The result of speed conclude that manual cleaning is faster than water jet cleaning. The ratio is 1:5, which means cleaning manually is 5x faster than using water jet for given condition. This is related to the hardness level of silica scale target. The harder the silica deposition, the more power it required to detach from internal pipe diameter. Using manual cleaning method on brine line which has hard level of silica is proved faster than using Water Jet cleaning on very hard silica deposition at two phase line Wellpad. While speed and cost is used for

quantitatively evaluate both method characteristic, the field practice can be optimized by considering practical and future qualitative concern.

Table 10: Qualitative Comparison Manual dan Water Jet Cleaning method.

Cleaning Method	Accessibility	Area Footprint	Power	Personnel Risk	Environment Risk	Facilities Damage	Best Application
Manual	High Can easily reach brine line location	Small Only for personnel & hand tools	Low Limited to soft to hard silica deposit	Low Only manual labour and gravity	Low Silica fragment can be contained easily	High Physical Deformation	**Brine Line**, which : 1. Away from water supply 2. Soft to hard Silica 3. Low operating pressure line 4. Near civil community 5. Small area
Water Jet	Low Requires area with water supply	Large Require wide area for equpment placement	High Can easily clean very hard silica deposit	High Pressurized water	High Silica fragment scatters around	Low to N.A	**2-phase wellpad line**, which : 1. Equipped with water pond 2. Very hard silica deposit 3. High operating pressure line 4. Separated from community 5. Wide area

Considering accessibility, area, power, personnel risk, environment risk and facilities damage the use of most optimum cleaning method can be determined accordingly. Manual Cleaning method is best used on Brine line due to accessibility, soft to hard silica, low operating pressure line which lower the risk of physical deformation due to hammering, away from water supply, near people and small area of job.

While manual cleaning is best to be used on brine line, the Water jet cleaning is best use on Wellpad 2-phase line. The use of hammering on 2 phase line will very much damage the pipe body and potentially fail in the near future as it operate with extreme pressure and temperature. This risk can be easily eliminated by using water jet technique. The silica on two phase line Wellpad is closer to wellhead and usually deposit very hard silica on pipe, the use of manual cleaning requires too much duration to be applied on this case and potentially delay the upcoming maintenance schedule. This risk can also easily eliminated by using waterjet technique.

This conclude that to achieve best outcome of cleaning deposited silica in Dieng geothermal piping system, the use of both Manual Cleaning and Water Jet cleaning is required. Manual Cleaning can be used on Brine Line and Water Jet Cleaning should be used on 2 phase Wellpad line. By combining these two methods, piping system can be cleaned with most optimum budget, technical application, and environmental concern.

5. CONCLUSION

By combining Manual cleaning and water jet cleaning method on Dieng Geothermal Piping system, company can effectively and efficiently cleaned silica deposition on both Brine line and 2 phase line by considering cost, technical application, Safety, environment and facilities aspects. Manual cleaning method is best to be used on Brine line while Water Jet cleaning is best to be used on 2-phase line.

Manual cleaning method costs lower to operate than waterjet cleaning with 1:35 ratio. Manual cleaning needs Rp. 77.746 per meter cleaned, while Water Jet cleaning costs Rp 2.708.473 per meter cleaned. The speed of manual cleaning comparing to waterjet is 1:5 ratio for current Dieng existing facilities application.

For further research, Water Jet cleaning should be tested its application on Brine line deposited silica. Due to lower hardness of silica level on Brine line than 2-phase line, the use of waterjet technique on brine line should yield much faster speed.

The use of pigging and chemical addition method to clean deposited silica should be studied deeper to achieve practical level.

Keywords: TFT, NCG, Reservoir Surveillance, Geochemistry

ABSTRACT

The Sorik Marapi Geothermal Power (SMGP) field is a high enthalpy liquid dominated geothermal system which currently utilizes 15 production wells to support 160 MW gross capacity. A geochemistry surveillance program has been in place since the start of power generating operations in late 2019 monitoring the geochemical reservoir response in correlation with mass extraction and injection.

The geochemistry field monitoring consists of weekly geochemical measurements at production wells: gas/steam using a wet gas meter, and field measurements of chloride, silica, pH, and, conductivity for steam and brine monitoring. This field monitoring produces instant results as the measurements are done on site at Sorik Marapi. During the same time period, quarterly geochemiscal samples of produced fluids from each well are collected for more comprehensive laboratory analysis including non-condensable gas speciation of steam samples, and anion-cation , stable water isotope and total silica concentrations in brine. Mass flow rates measured at multiple-well separators and at the power plant inlets are supplemented with tracer flow test (TFT) data at individual wells and separators measuring steam and brine flow rates which produce, and enthalpy and total discharge data from calculations.

In this paper, we document how the geochemical surveillance programs captured reservoir changes over time and correlate these changes with production and injection data over the same period. Using temporal and spatial plots, the geochemistry data informs the evolution of the reservoir over time including; the development of a steam cap in portions of the reservoir, the impact of drilling activities, injection breakthrough, and related changes to the operational strategy. The interpretation from weekly monitoring is validated with quarterly sampling and the quality of weekly dataset and monitoring program is assessed in the context of other operational and geoscientific datasets providing a vital data set indicating real time reservoir response to production and injection which has been important for managing the reservoir.

1. INTRODUCTION

Sorik Marapi geothermal field license Area in northwestern Sumatera, located 650 km south-southeast of Medan. Sorik Marapi Geothermal Power (PT. SMGP) has geothermal concession that covers an 629 km2 area, The geothermal system was defined based on a generally N-S elongate magnetotelluric (MT) low resistivity anomaly (~6 km2) ad a wide distribution of warm to boiling hot springs and fumaroles primarily centered along the Sumateran Fault System (SFS) and extending west into the summit crater of Sorik Marapi Volcano (Figure 1) (Geologica, 2024).

The geothermal area lies within a depression zone which is a part of pull-apart basin caused by the displacement of Great Sumatran Fault Zone (GSFZ).

The active fault GSFZ appears to control the permeability, possible intrusive heat source and stratigraphy observed within the Sorik Marapi geothermal field. The stratigraphic sequence includes thick sequence of Quaternary volcanics overlying the older metamorphic, volcanic, metavolcanic and intrusive rocks which form the basement west of GSF. On the eastern side of GSFZ, the metasediments and sedimentary rocks are present shallower than on the western side. Existing fractures based on identification of feed zones within the wells appear to be related to displacement along the GSFZ. The presence of this range of geologic and geophysical features and the high number of surface manifestations and mass discharged from these features is a strong indication of a high temperature fault-controlled geothermal system (Hinz et al., 2021).

There are more than 40 wells drilled in the Sorik Marapi concession. Providing steam and hot brine for the power plants, SMGP drilled from Pad A (7 wells), pad T (10 wells), pad AA (3 wells), pad AAE (6 wells), and the most

recent pad V (3 wells). The primarily injection is provided from pad P (4 wells including one with multilateral wells), Pad C (5 wells) and Pad D (3 wells) (Figure 2)

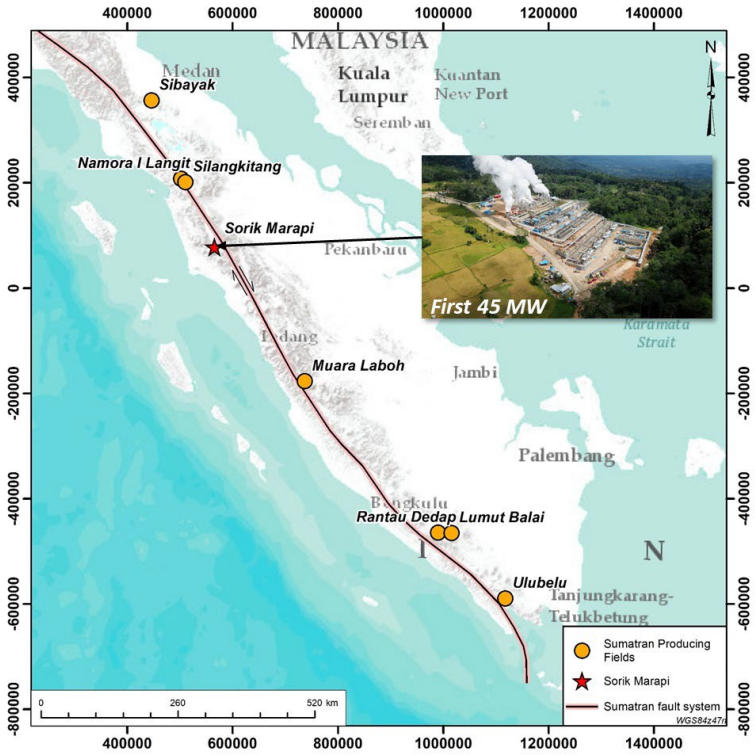

Figure 1: Sorik Marapi Location on Sumatera relative to other geothermal fields.

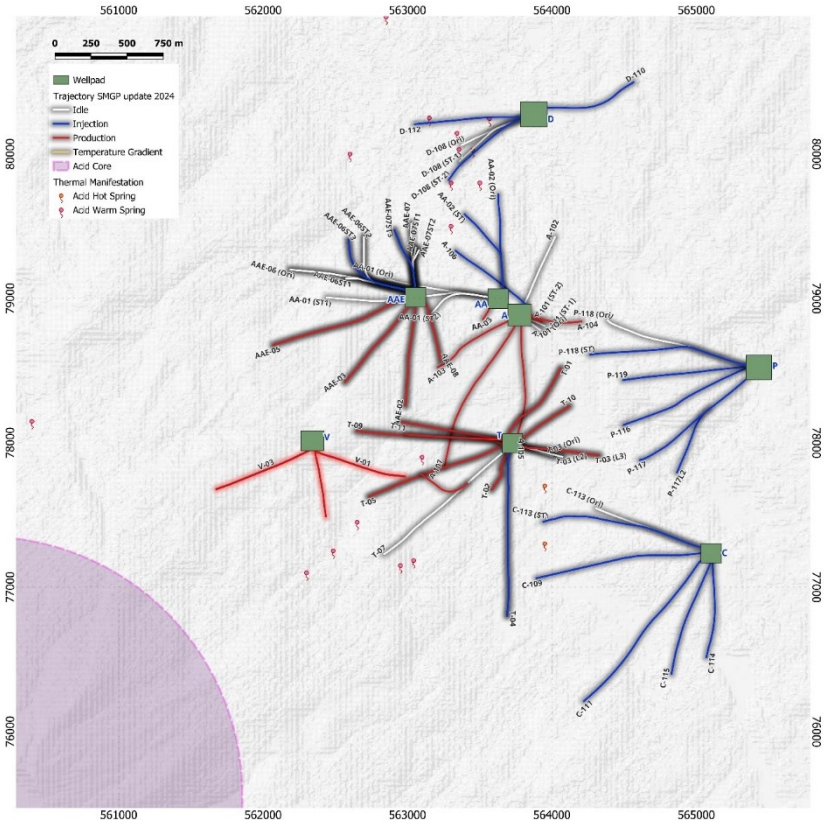

Figure 2: Production and Injection wells with feed zones drilled within the currently developed Sorik Marapi Geothermal Reservoir.

Geothermal brine and steam samples a from production wells have been sampled every 2 weeks and analyzed for gas/steam (steam sample) and pH, electrical conductivity, silica (SiO_2) and chloride (Cl) (brine sample) as a part of reservoir surveillance to understand reservoir conditions. Additional geochemical surveillance programs such as quarterly sampling and tracer flow testing (TFT) (Hirtz, 2001), full non-condensible gas (NCG) analysis of steam, full anion-cation analysis of brine, and stable water isotope analysis were established to validate and supplement weekly monitoring (Figure 3). TFT data allows the geochemistry of the total discharge (representing the reservoir fluids averaged over multiple feed zones if they exist) to be calculated for individual wells and enables comparison of geochemical monitoring and individual well performance.

Figure 4: Bi-weekly Chemistry Analysis at SMGP .

2. SURVEILLENCE PROGRAMS

2.1 Bi-weekly

The geochemical monitoring at SMGP consists of bi-weekly field measurements of steam and brine: gas/steam (G/S) using a wet gas meter in steam samples, and field measurements of chloride, silica, pH, and, conductivity in brine samples collected at operating production wells (Pad A, Pad T, Pad AA, Pad AAE). Initially, weekly samples were collected at steam and brine outlets of high pressure separators which combined flows from one or two wells, in order to use the separator flows to estimated total enthalpy and correct to reservoir conditions. Subsequently, sampling was changed to wellheads using a small sampling separator.

Figure 4 shows the problem identification within SMGP bi-weekly chemistry monitoring program. To confirm trends indicated by bi-weekly monitoring, quarterly geochemical sampling and analysis of brine and steam and TFT from individual wells is performed. This approach is applicable in Sorik Marapi field and might be similar with the other water dominated field.

The silica concentration in brine is important for controlling brine treatment for silica scale control in geothermal power plants or reinjection line/wells with low discharge temperatures, especially in high-temperature volcanic geothermal settings. The basis of chemical brine treatment for silica scale mitigation depends on silica concentration, pH and brine flowrates.

2.2 Quarterly geochemical sampling, analysis and TFT

More comprehensive quarterly geochemical monitoring includes tracer flow test (TFT) (Hirtz, 2001) measurements of enthalpy and steam and brine flow, laboratory analyses of non-condensable gas primary species concentrations in steam samples, anion-cation laboratory analysis of brine, and stable isotope analysis of steam and brine at the new wells (Figure 3) The data are collected and stored in a geochemical database for evaluation over time and comparison with baseline or initial fluid chemistry. While bi-weekly monitoring data are primarily used as measured to evaluate trends, quarterly laboratory analyses are corrected to reservoir conditions based on sampling conditions and reservoir enthalpy of the individual well. The main purpose of quarterly geochemistry sampling and analysis is to confirm and further explore the reservoir behavior indicated by the bi-weekly chemistry, validate trends and assess additional reservoir conditions related to production and injection from the more detailed chemistry.

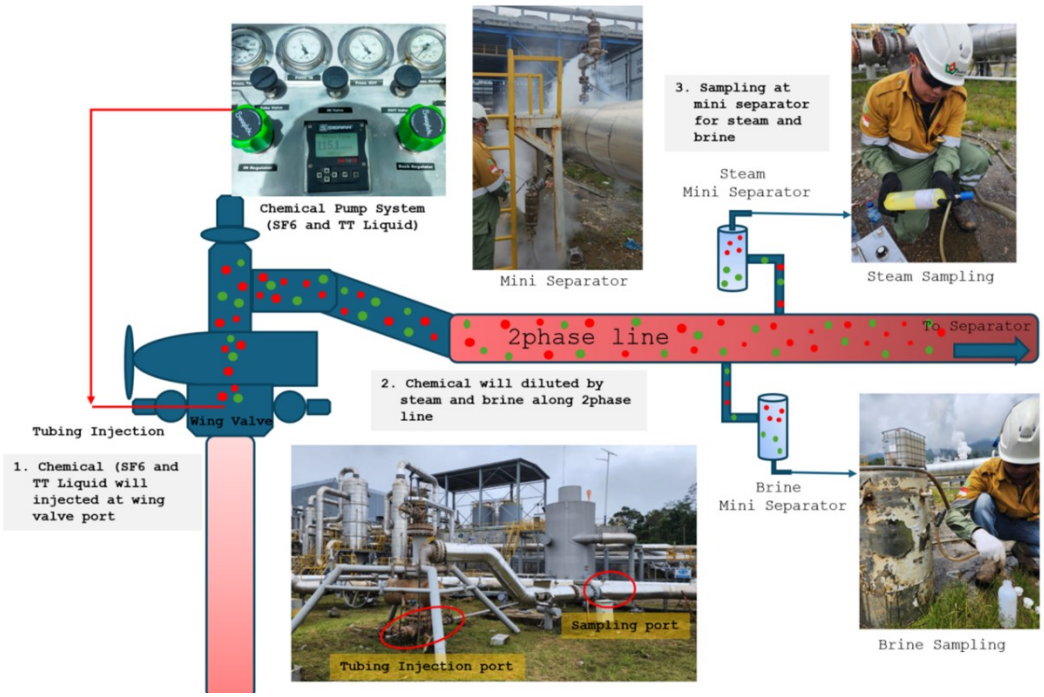

Figure 5: TFT field sampling.

During TFT testing (Figure 5), the injection of chemical in two-phase line allows the determination of steam and brine mass by the dilution of tracer chemical injected. This method is performed without disrupting the production conditions, thus the generation is not effected. TFT allows measurement of the individual well performance of mass flow of steam and brine at specific pressures and temperatures from which enthalpy and total mass flow are calculated. TFT testing frequency has varied from lower frequency (once a year) to higher frequency (3-4 times a years). Current plans include conducting more TFT tests as a part of reservoir monitoring, as a comparison with installed metering, and to allow construction of output curves and Pressure-Temperature- Spinner (PTS) analysis at specific flow rates. The enthalpy data from TFT results were used to interpret geochemical data by calculating the chemistry of the reservoir fluid before boiling (to calculate the chemistry of the total discharge).

There are three main step to conducting he TFT and quarterly geochemical sampling and analysis programs; sampling preparation, field sampling, and laboratories analysis. The sampling preparation includes giggenbach bottle preparationand tracer liquid calibration.

Field sampling requires a chemical injection location, chemical dilution, and sampling at specific, documented conditions. In SMGP, the tracer is injected into the wing valve. 3/8” tubing is inserted into the middle of pipe for ensuring the chemical injection. The minimum distance between injection port and sampling port is 20 pipe diameters to achieve proper mixing. The steam is sampled from a vertical port at the top of the line and the brine is sampled from a port at a 45^{o} from the bottom of the pipe The mini separator is installed at each port to separate steam and brine, then each fluid is cooled in a dedicated condenser/cooler to ensure that there is no flashing and then sampled.

The specific of tracer flow test at Sorik Marapi was the sampling location were less than 20 pipe diameters and located before FCV, thus, to operate this TFT equipment and result need more calibration data. The sampling strategy was to take as many data, then select the result based on data distribution.

Production and injection monitoring data of SMGP are documented in daily production and daily injection reports These reports record wellhead pressure (WHP), wellhead temperature (WHT), flow control valve position (FCV%) for each production well, separator steam mass flows, brine mass flows, separator temperature and pressure, and total mass flow (TMF) and temperature and pressure for injection wells. One or multiple wells flow to each high-pressure separator. Some wells which have a lower flowing wellhead pressure flow to low pressure separators. Therefore, TMF and enthalpy for production are measured as steam flow and brine flow at a separator pressure, which can be combined to estimate total production. For example, flow from wells A-105 and A-107 combine into separator HP-105 and the steam flow and brine flow from this separator is measured continuously but not the individual wells. Mass flow rates measured at the separators have been supplemented with TFT data which may include steam rate, brine rate, and enthalpy data for total discharge calculation. Based on the production and injection monitoring data, the timing of major operational changes, such as changes in injection, can be identified. Major changes in operations can be compared with geochemical monitoring data over time to identify potential changes in the reservoir, indicated by chemistry.

3. STUDY CASE SORIK MARAPI

3.1 Baseline Geochemical Condition

Initial well testing and production indicated the SMGP wellfield produced fluids over a range of flow rates (~100-500 tph) from a reservoir between <260 ˚C and 290˚C (enthalpy from ~1100 to ~1300 kJ/kg) primarily from Quaternary to Tertiary volcanics and intrusives and older metasediments. Later drilling produced higher flow rates to over 600 tph and enthalpies to nearly 1500 kJ/kg. Analysis of baseline (initial well tests 2017 – 2020) samples indicate that all Sorik Marapi wells, except those on Pad D from which there is no well test data, produce a Na-Cl type fluid with relatively low noncondensable gas (NCG) of ~400 mg/kg (corrected to reservoir conditions) from a single geothermal system. Initial reservoir fluid concentrations include ~500 – 600 mg/kg Cl (reservoir corrected), Cl/B ratio ~23, and clustering of data points on cation and anion trilinear plots (Figure 6 and figure 7). Note that hotter and cooler wells group close together, especially in cations controlled by temperature-sensitive reactions.

Initially, produced fluids from wells in the hottest portion of the Sorik Marapi reservoir (i.e., likely to be closest to the upflow, Pad T) are characterized by higher SiO_2 ~630 mg/kg versus field-wide average of 530 mg/kg, and higher NCG, ~960 mg/kg (reservoir corrected), but about the same concentration of Cl (650 mg/kg in upflow zone and 670 mg/kg field-wide average. Groupings of wells with deeper, hotter feedzones (mostly on Pad T) can be seen in cation and anion trilinear plots of baseline chemistry (6 and 7). The anion and cation concentrations of all wells plot in a group suggesting that under baseline conditions, anion concentrations (Cl, HCO_3 and SO_4) as well as cation Na, Ca and K concentrations (but to a lesser extent) were similar in wells of different temperatures, with the exception of wells adjacent to the upflow near Pad T, and therefore lower temperatures were initially unlikely to be related to unequilibrated mixing with cold meteoric water.

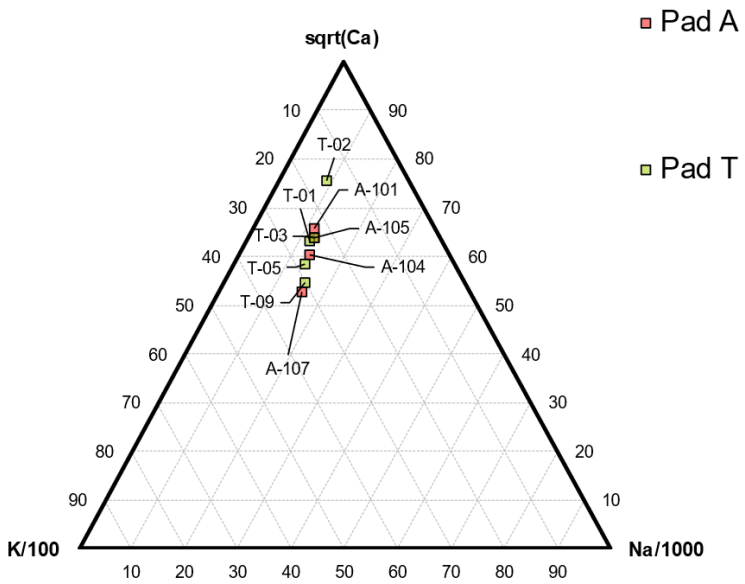

Figure 6: Cation trilinear plot of baseline (2017 – 2020) Pad A and Pad T geochemical samples. Note the temperature dependent mixing trend with T-09 and A-107 as the hot end members.

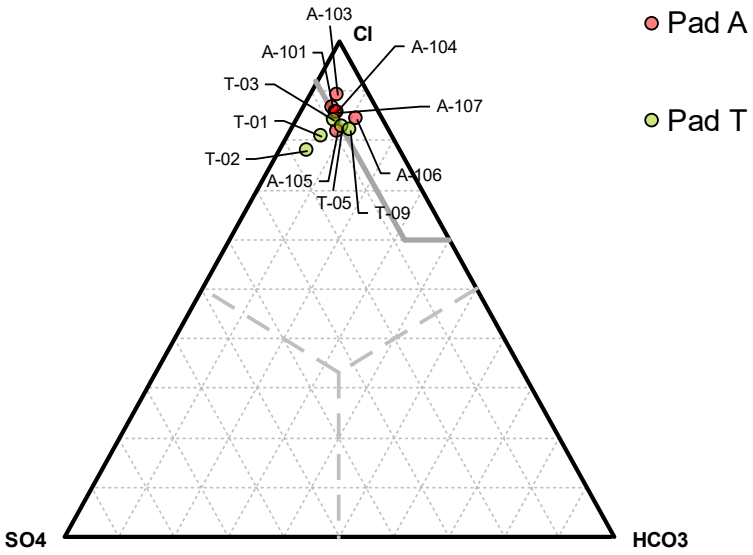

Figure 7: Anion trilinear plot of baseline (2017 – 2020) Pad A and Pad T geochemical samples.

Baseline laboratory gas analyses indicate reservoir NCG concentrations range from ~400 – 1000 mg/kg, with an average ~428 mg/kg NCG in the total fluid (reservoir corrected). Baseline NCG concentrations show two groups: One group has > ~600 mg/kg and while the other has < ~600 mg/kg. Wells with higher NCG concentrations (T-09, A-107, T-05 average >800 mg/kg) are characterized by higher H_2S (T-09, A-107, T-05 average ~200 mg/kg H_2S whereas the fieldwide average is ~100 mg/kg in the reservoir). Wells with higher NCG and H_2S, deeper feedzones, higher measured temperatures, and are likely to be closer to the upflow.

3.2 Geochemical trends, Interpretation, and Operational Impact

Temporal geochemical trends in Sorik Marapi production fluid shows the fluid chemistry and reservoir condition have changed over the last ~4 years of production and injection operations. As in other liquid-dominated geothermal fields under exploitation, chloride (Cl) and non-condensable gas (NCG) can vary between production and injection. In this paper, we will only discuss pad A production wells. Pad A has 5 production wells: A-101, A-103, A-104, A-105, and A-107 (Fig 8) and A-106 as backup injector wells.

3.3.1 Injection Tracking

Geochemical and enthalpy changes indicate that in-field waste brine injection at A-106 lead to chemical and possible thermal injection breakthrough to production wells at SMGP. While the greatest effects are observed in Pad A wells our analysis indicates that the impact of injection on production is widespread. Laboratory analyses suggested fluid geochemistry from Pad A wells was initially relatively stable until mid-2021 (8). Increasing Cl and decreasing NCG in Pad A wells occurred after March 2021 to early-2022, concurrent with high rates of injection into well A-106. After A-106 injection was reduced and eventually ceased in mid-2022, Cl concentrations declined or stabilized to mid-2023. Changes in bi-weekly field measurements of geochemical parameters (Cl, G/S (G/S representsNCG), SiO_2) in A (and T pad) wells appear to coincide with injection into A-106, which began in late May 2021 and increased through June 2021, then decreased in mid-2022 and was reduced to zero by the end of July 2022

Observed geochemical changes in production wells do not correlate directly with injection into other wells on C, T, and P Pads, and the overall injection rates into these wells (e.g., C-111, C-114, P-116, P-118, P-119, T-04, and T-07) are much less than A-106 injection rates during the same time period. Comparing laboratory Cl data from A pad wells to injection flow rates at SMGP over time prior to June 2021, indicates limited correlation between injected and produced fluid until A-106 injection began in June 2021.

Magnesium (Mg) concentrations decreased from an average ~0.023 to 0.004 mg/kg with many wells having concentrations too low for laboratory detection, indicating it is unlikely that meteoric waters (typically, high in HCO3 and Mg) are currently being pulled into the geothermal reservoir. Consistent with Cl increases, NCG concentrations in Pad A wells decreased over the same time period; both indicative of injection breakthrough. After A-106 injection was decreased and discontinued, NCG concentrations in most wells recovered to pre-A-106 levels.

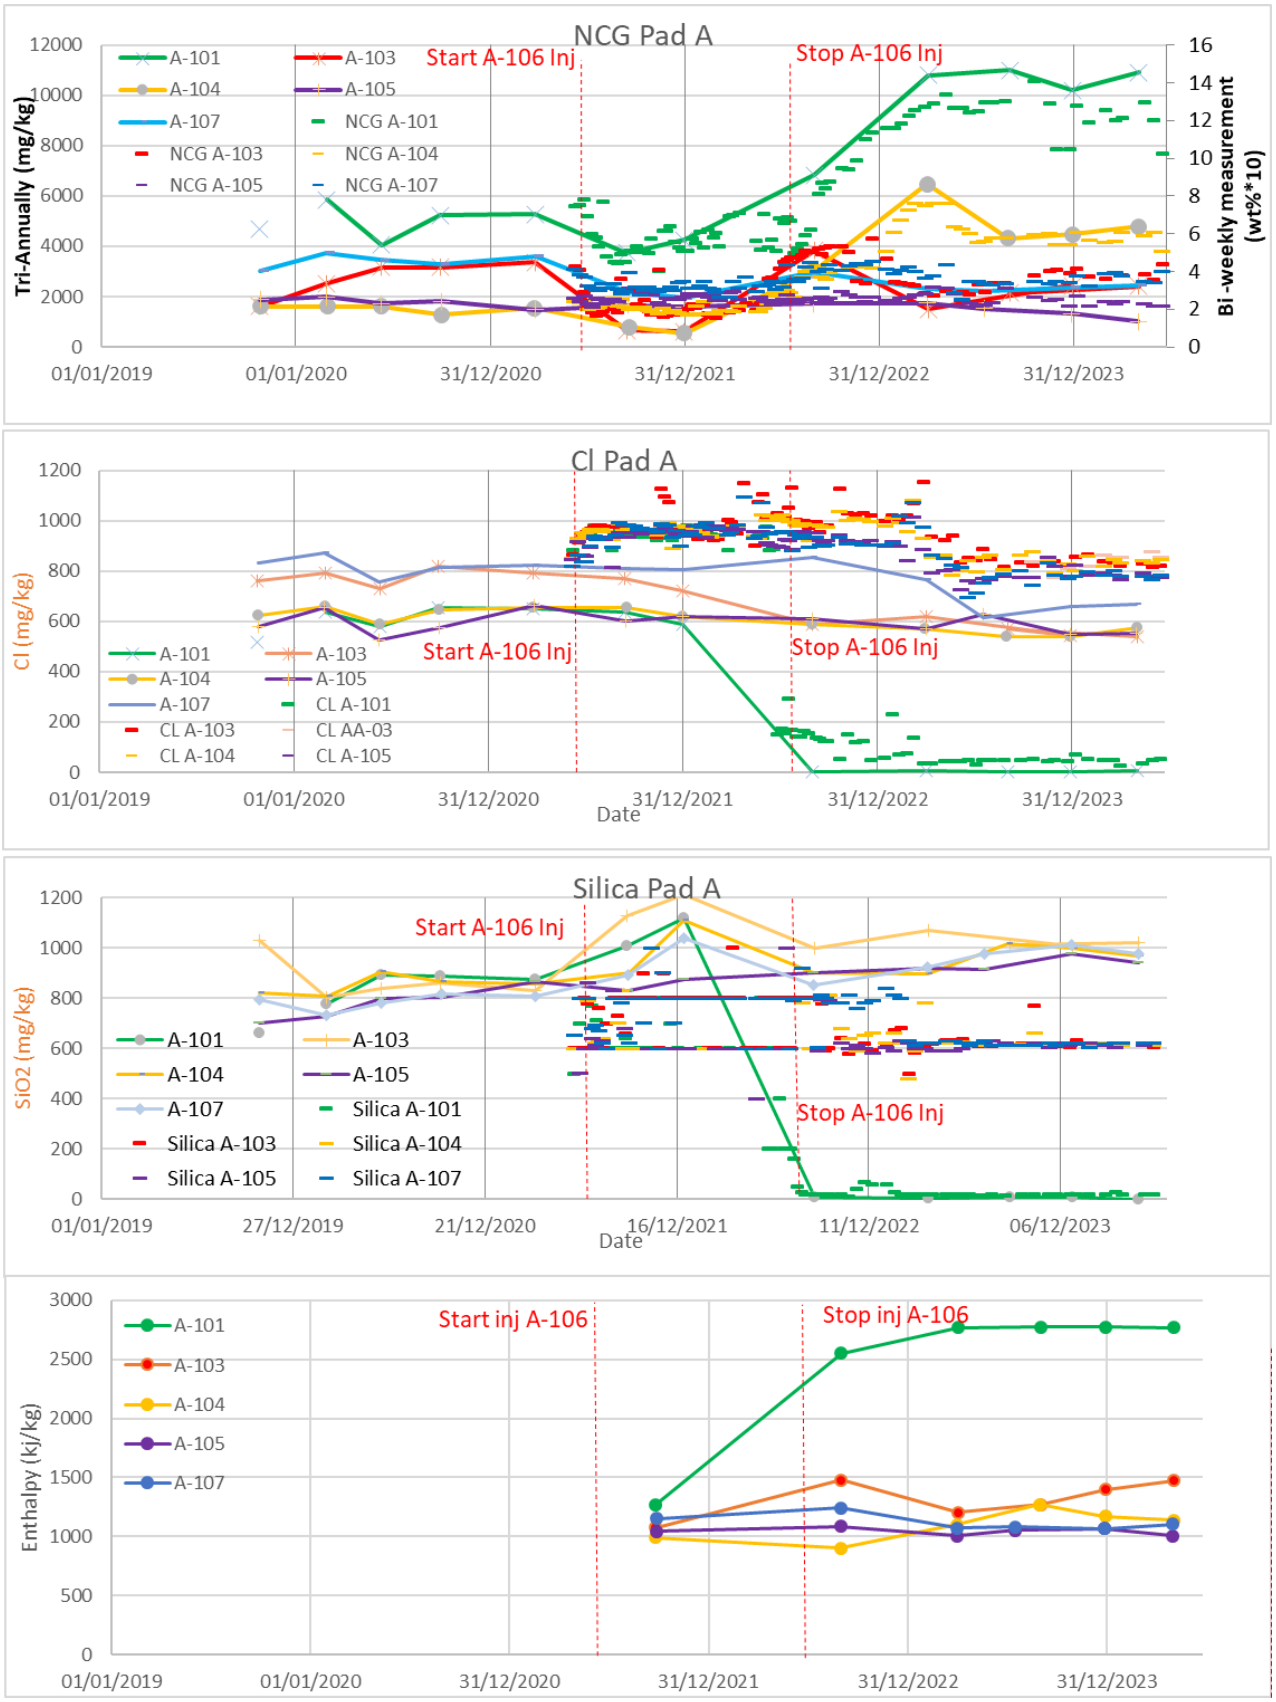

Figure 8: Bi-weekly sampling compared with Quarterly sampling.

3.3.2 Boiling, Excess Steam and Development of a Steam Cap

After recovering from being suppressed by injection breakthrough, total NCG concentrations increased from 2022 to 2023 with especially high increases in A-101 and A-104, and a slight increase in A-103 (Figure 8). Field geochemical data for A-101 indicates a large increase in NCG concentrations and sharp declines in Cl and SiO2 beginning in mid-2022 which correlate with the changes observed in laboratory geochemical data (8). The increases in NCG correlate with increases in enthalpy (from TFT) at A-101, and to a lesser extent A-103 and A-104 since injection into A-106 was curtailed. It appears that A-101 has begun producing near 100% steam since mid-2022 (when A-106 injection stopped) with a high flowing enthalpy of ~2500 kJ/kg. The original pressure-temperature surveys from initial flow tests from this well also indicated a possible steam zone. Liquid samples from this well, when collected, appear to be steam condensate (very low Cl and SiO2 concentrations). A-101 has the shallowest fluid entry of pad A wells and while the increases in NCG and enthalpy suggest development of a steam cap, the recent stabilization in A-104 suggests the steam cap may be limited. Note that one Pad A well, A-105, showed no decrease or increase in NCG or enthalpy.

4. CONCLUSION

The geochemical monitoring program at Sorik Marapi Geothermal field successfully monitoring key reservoir processes such as injection breakthrough and development of a steam zone in some wells and stabilization in other wells. While the quarterly geochemical monitoring with enthalpy measurements using TFT confirmed the field data, the field monitoring allowed for real time results enabling reservoir management to address issues including modification of injection strategy. After modifying injection strategy, the SMGP geochemical monitoring program was able to confirm recovery of production wells from the adverse impacts of injection breakthrough.

Sorik Marapi geochemistry programs was designed for a geothermal liquid dominated field with double flash brine ORC; the field chemistry used differences in Cl (higher concentration in injecton) and NCG (lower concentration in injection) between production and injection due to the flash system and steam loss. These program, especially the field measurements, should be adapted to the field as needed for different types of surface facilities The Bi-weekly field monitoring may be modified if the surface facilities change, wellfield production and injection strategies change and the parameters differentiating production and injection fluids change

ABSTRACT

Ngā Tamariki geothermal field is located in the Taupo Volcanic Zone (TVZ), New Zealand, with current electricity production of 85 MWe from four binary units. To minimise the carbon emission, non-condensable gas (NCG) from one of their units has been injected back into the reservoir through reinjection wells.

Ngā Tamariki is operated with 100% reinjection distributed across north and south reinjection areas. A 1D radial multiple interacting continua (MINC) model was set up using TOUGHREACT v.4.13 to simulate chemical and mineralogical reactions occurring in the reservoir near the north reinjection area. The model calibration process aimed to simulate the reinjection history of the well using integrated geochemical and flow modelling. The model focuses on the reservoir rock near the NM9 reinjection well, which receives the most NCG injections, extending to the nearest production well (NM7), which is located ~1 – 1.5 km to the southeast. Several scenarios, ranging from 0% to 50% NCG reinjection rates, were investigated. The analysis included diagnostics for assessing mineral dissolution and precipitation and their overall effect on the reservoir porosity and permeability.

The 1D-radial model shows porosity-permeability increases near the reinjection well and decreases in the outer part. This trend was mainly due to the dissolution and precipitation trends of calcite and anhydrite. Different NCG reinjection scenarios show variations in calcite dissolution. A higher amount of NCG reinjection gives a higher dissolution of calcite near the wellbore due to the lower pH of the injection fluid. The porosity, permeability, and volume fraction of other minerals did not show any significant changes within different NCG reinjection scenarios.

1. INTRODUCTION

Geothermal is considered a clean source of energy, particularly when compared to fossil fuels. The average operational emission intensity of geothermal power plants in New Zealand is 76 $gCO_{2\text{-}eq}$/kWh. This is significantly lower than natural gas power plants, which release 390 $gCO_{2\text{-}eq}$/kWh (combined cycle) and 525 $gCO_{2\text{-}eq}$/kWh (open cycle), and coal power plants, which release 955 $gCO_{2\text{-}eq}$/kWh (Mclean & Richardson, 2019). Geothermal power plants emit various gases known as non-condensable gases (NCGs), of which CO2 is the main component. These NCG emissions from geothermal operations can be decreased by injecting them back into the reservoir. NCG reinjection could give positive impacts such as reservoir recharge, pressure support, steam production improvement, and permeability enhancement. However, it could also give negative impacts, such as a porosity and permeability decrease, NCG breakthrough to nearby production wells, and NCG leakage to the surface (Kaya & Zarrouk, 2017).

Several geothermal fields in the world have implemented NCG reinjection, including Hellisheidi (Aradóttir et al., 2015; Ratouis et al., 2022), Kızıldere (Erol et al., 2022), Umurlu (Yücetaş et al., 2018), Hijiori (Yanagisawa, 2010), Ogachi (Kaieda et al., 2009), and Coso (Kolar et al., 2015). In New Zealand, NCG reinjection has also been applied at Te Huka (Ruiz et al., 2021), Ngāwhā (Mclean et al., 2023), and Ngā Tamariki (Abd Ghafar et al., 2022). Te Huka and Ngāwhā have been reinjected with 100% of the NCG, while Ngā Tamariki has been reinjected with 25% of it (Mclean et al., 2023). While most of the fields have found no problems, several NCG reinjection projects have encountered issues, including scaling in production lines in Hijiori (Yanagisawa et al., 2007), CO_2 increases in the produced fluid in Ogachi (Pistone et al., 2011; Kaieda et al., 2009), and increases in operational costs in Coso (Kolar et al., 2015).

The Ngā Tamariki geothermal field is located in the Taupo Volcanic Zone (TVZ), New Zealand, producing 85 MWe from four binary units (Figure 1). Ngā Tamariki has a deep and hot reservoir (260-285°C), near-neutral fluid, high content of chloride (900-1000 mg/kg), with domination of meteoric water (Chambefort et al., 2016). There are three production wells and four reinjection wells. The reinjection wells are located in the south and north of the field, while the production wells are located in the centre of the field.

NCG reinjection has been implemented in Ngā Tamariki since mid-October 2021 (Abd Ghafar et al., 2022). NCG from one of the binary units, which constitutes 25% of the total NCG of the plants, is injected mainly into NM9, located in the northern part of the field. The NCG is dissolved together with the brine before the reinjection well. Abd Ghafar et al. (2022) reported that there were no issues found in Ngā Tamariki after almost one year of NCG reinjection. While the effect on the reservoir remains uncertain, a reactive transport model could provide a clearer understanding of how mineral solubility, porosity, and permeability in the reservoir might be affected. This paper will focus on the results of the 1D-radial model.

2. METHODOLOGY

2.1 Reactive Transport Model

The reactive transport model in this research was created using TOUGHREACT v.4.13 (Sonnenthal et al., 2021). TOUGHREACT is a programme for conducting numerical simulations that can simulate chemically reactive non-isothermal multiphase flow fluids in porous and fractured rock formations (Xu et al., 2006). It was developed by incorporating thermal-physical-geochemical conditions into the TOUGH2 simulator, enhancing its capability to model the interactions between fluids and rock matrices in complex geological systems under reservoir conditions. Numerous subsurface thermophysical and chemical processes are considered across a broad range of temperature, pressure, ionic strength, water saturation, pH, and Eh conditions. Mineral and fluid interaction can occur under equilibrium conditions or with kinetic rates. The simulation can be used to predict how the porosity and permeability of the formation change over time based on the precipitation and dissolution processes.

Additional chemistry calculations were also conducted using a separate programme called PHREEQC (Parkhurst & Appelo, 2013), a programme by the U.S. Geological Survey (USGS). PyTOUGH (Croucher, 2023) was used to create the model's grid, while TIM (Yeh et al., 2013) was used to visualise the grid structure.

2.2 Model Setup and Parameters

2.2.1 Model setup

A 1D-radial model of the first and major feedzone (FZ#1 in Figure 2) of the NM9 reinjection well was created to understand the chemical and mineralogical (volume fraction change) response of the reservoir to the NCG reinjection implementation. Figure 2 shows the stratigraphy, pressure and temperature (PT) data, and production casing depth with the location of the feedzones. The parameters used in the 1D-radial model followed the feedzone parameters, namely a thickness of 29.6 metres (rounded up to 30 metres) and pressure and temperature of the feedzone following the PT data. The model was constructed with two parts: the reservoir and the outer parts

(Figure 2). The reservoir part was created using multiple interacting continua (MINC) for a radius of 3 km. The outer part was created using a single porosity approach with a total radius of 50 km to prevent boundary effects. The injection rate followed the daily injection rate data of NM9, proportionate to the contribution of the feedzone.

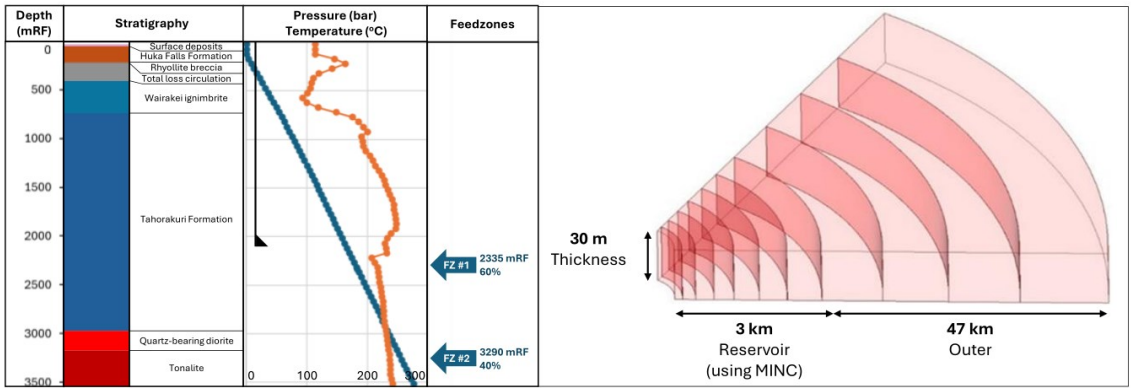

Figure 2: Left: NM9 stratigraphy log with PT data, production casing depth, and feedzone depth (compiled from Lewis et al. (2013) and Mercury (personal communication, February 2, 2024)); Right: An unscaled illustration of the 1D-radial model.

2.2.2 Fluid chemistry

The fluid chemistry used in the model was the reservoir and injection chemistry. The reservoir fluid chemistry data was obtained from the produced fluid chemistry of the nearest production well, NM7. This data was corrected to reflect the reservoir conditions using quartz geothermometer calculations. The pH of the reservoir chemistry was calculated using PHREEQC. The injected fluid chemistry consists of a mixture of brine and condensate, and the NCG chemistry data were calculated using the mass balance calculations. Furthermore, the bicarbonate (HCO_3^-) concentration was recalculated following the field pH measurements using PHREEQC. The fluid and NCG chemistry data are then combined and input into PHREEQC to get the pH for each model scenario. The reservoir and injected fluid chemistry used in this model can be seen in Tables 1 and 2, respectively.

Table 1: Reservoir-corrected produced fluid chemistry of NM7 (Mercury, personal communication, February 2, 2024).

	Concentration (ppm)	
Date	1/15/2019	8/2/2021
Fluid		
pH	6.119	6.149
Na^+	504.6	485.8
Cl^-	842.0	837.4
HCO_3^-	38.2	34.3
Ca^{2+}	2.6	2.6
SO_4^{2-}	7.4	9.0
Mg^{2+}	0.01	0.01
Fe^{2+}	0.01	0.02
K^+	112.6	108.1
$SiO_{2(aq)}$	623.1	642.3
AlO_2^-	0.3	0.2
Gas		
CO_2	2013.5	1904.7
H_2S	38.2	70.4
CH_4	21.5	18.3
H_2	0.1	0.1

2.2.3 Volume fraction of minerals

The volume fraction of minerals was determined following analysis by Sewell (2022) and from the NM9 geological report by Lewis et al. (2013) at the depth location of the feedzone. Table 3 shows the volume fraction of minerals used in the model. Although some of the minerals are initially not found in the mineralogy data, namely amorphous silica, chalcedony, smectite, and montmorillonite, they were still input into the model with a volume fraction of 0% to know the precipitation possibility of these minerals.

Table 2: Injected fluid chemistry. Besides the recalculated pH and bicarbonate, the chemistry data was obtained from Mercury (personal communication, February 2, 2024).

	Concentration (ppm)		
	0%	**25%**	**50%**
Fluid			
pH	5.52	5.23	5.08
Na^+	501.0	501.0	501.0
Cl^-	931.0	931.0	931.0
HCO_3^-	101.9	101.9	101.9
Ca^{2+}	2.9	2.9	2.9
SO_4^{2-}	10.3	10.3	10.3
Mg^{2+}	0.0	0.0	0.0
Fe^{2+}	0.5	0.5	0.5
K^+	107.0	107.0	107.0
$SiO_{2(aq)}$	688.0	688.0	688.0
AlO_2^-	0.8	0.8	0.8
Gas			
CO_2	533.2	928.6	1324.1
H_2S	66.2	75.1	84.0
CH_4	4.0	8.1	12.2
H_2	0.00001	0.00001	0.00001

2.2.4 Reactive surface area (RSA) of minerals

The RSA of the minerals was calculated using the same methodology reported in the TOUGHREACT module (Sonnenthal et al., 2021), which was calculated for each mineral for the fracture and matrix domains. The result of the calculation and the RSA used in the model can be seen in Table 3.

Table 3: Volume fraction and calculated RSA for each mineral.

Minerals	**Volume fraction**	**RSA (m^2/m^3)**	**RSA/1000**
Quartz	50%	1.414E+02	1.414E-01
Albite	2%	5.655E+00	5.655E-03
Calcite	7%	1.979E+01	1.979E-02
Chlorite	2%	5.655E+00	5.655E-03
Pyrite	2%	5.655E+00	5.655E-03
Illite	12%	3.393E+01	3.393E-02
Kaolinite	7%	1.979E+01	1.979E-02
Anhydrite	5%	1.414E+01	1.414E-02

Montmorillonite	0%	3.142E+02	3.142E-01
Matrix	-	4.440E+03	-

2.2.5 Chemical reaction of minerals

The chemical reaction of minerals, with their related parameters, could affect the behaviour of the minerals. All minerals were assigned with kinetic reactions in this model. Table 4 shows the rate constants, activation energies, and rate laws for each mineral, which were mainly sourced from Altar & Kaya (2020), Palandri & Kharaka (2004), and Xu et al. (2007).

In the thermodynamic database of TOUGHREACT, the dissolution reaction of each mineral was also input. These chemical reactions were beneficial in determining which chemical species would affect the behaviour of minerals. Table 5 shows the summary of the chemical species associated with the minerals.

Table 4: Kinetic reaction parameters for minerals consisted of rate constants, activation energies, and rate laws (Altar & Kaya, 2020; Xu et al., 2007; and Palandri & Kharaka, 2004).

Mineral	Dissolution			Precipitation		
	Log k_{25}	E_a	Rate law	Log k_{25}	E_a	Rate law
Quartz	-13.99	87.7		-9.42	49.8	$a_{SiO_{2(aq)}}$
Albite	-10.16	65.0	$a_{H^+}^{0.457}$			
	-12.56	69.8				
	-15.60	71.0	$a_{H^+}^{-0.527}$			
Calcite	-0.30	14.4	$a_{H^+}^{\square}$	-2.15	51.9	$a_{Ca^{2+}}^{\square} a_{HCO_3^-}^{\square}$
	-5.81	23.5				
Chlorite	-11.11	88.0	$a_{H^+}^{0.5}$			
Pyrite	-4.55	56.9				
Illite	-12.60	14.0				
Kaolinite	-13.18	22.2				
Smectite	-12.78	35.0				
Montmorillonite	-14.41	48.0				
Anhydrite	-3.19	14.3				
Pyrophyllite	-12.40	29.0				
Amorphous silica				-9.42	49.8	$a_{SiO_{2(aq)}}$
Chalcedony				-9.42	49.8	$a_{SiO_{2(aq)}}$

Table 5: Summary of chemical species of each mineral's chemical reaction.

Mineral	Chemical species
Albite	Na^+, $SiO_{2(aq)}$, AlO_2^-
Calcite	H^+, Ca^{2+}, HCO_3^-
Chlorite	H^+, $SiO_{2(aq)}$, Fe^{2+}, Mg^{2+}, H_2O, AlO_2^-
Pyrite	$H_{2(aq)}$, H^+, Fe^{2+}, $H_2S_{(aq)}$
Illite	H^+, Mg^{2+}, K^+, $SiO_{2(aq)}$, H_2O, AlO_2^-
Kaolinite	H^+, $SiO_{2(aq)}$, H_2O, AlO_2^-
Anhydrite	Ca^{2+}, SO_4^{2-}
Pyrophyllite	H^+, $SiO_{2(aq)}$, AlO_2^-
Quartz	$SiO_{2(aq)}$
Am-silica	$SiO_{2(aq)}$
Chalcedony	$SiO_{2(aq)}$
Smectite	H_2O, Ca^{2+}, H^+, Mg^{2+}, $SiO_{2(aq)}$, AlO_2^-
Montmorillonite	H^+, Ca^{2+}, K^+, Na^+, Mg^{2+}, H_2O, $SiO_{2(aq)}$, AlO_2^-

2.3 Model scenarios

This research aims to investigate the differences between several NCG reinjection scenarios, namely 0% NCG reinjection, 25% NCG reinjection, and 50% NCG reinjection. The modelling period covers three periods: before NCG reinjection (2013-2021), current NCG

reinjection (2021-2024), and future NCG reinjection (2024-2034). A summary of the scenarios used in the model can be seen in Table 6.

Table 6: Scenarios that are being used in the model.

Period	Scenario 1: 0% NCG reinjection	Scenario 2: 25% NCG reinjection	Scenario 3: 50% NCG reinjection
Before NCG reinjection (2013-2021)	No additional NCG injection (only passive)	No additional NCG injection	No additional NCG injection
Current NCG reinjection (2021-2024)		25% NCG injection	25% NCG injection
Future NCG reinjection (2024-2034)			50% NCG injection

3. RESULTS AND DISCUSSION

3.1 Calibration Results

Calibration was conducted to ensure the model's parameters accurately represented field conditions. This was conducted by comparing the model results with measured parameters, e.g. pressure and chemistry concentration trends.

3.1.1 Pressure calibration

The initial pressure from the model was very high compared to the pressure from PT data. This high-pressure result was attributed to the thin layer thickness and the low permeability of the fracture. Modifications to the layer thickness or permeability were necessary to mitigate this pressure difference. It was decided not to change the thickness as it would differ from the condition of the feedzone being modelled. Instead, the permeability was modified to a higher value. This is a reasonable approach as the permeability data provided by Mercury (personal communication, February 2, 2024) represented the permeability of the rock medium in the reservoir, whereas only the feedzone being modelled is expected to have a much higher permeability. Therefore, the permeability values were increased by a factor of 5.5.

The pressure comparison can be seen in Figure 3. The model's result from the first grid of the radial model shows a close alignment with the pressure from PT data. The comparison between the model's results with wellhead pressure (WHP) also shows a similar trend, although not entirely identical. It was difficult to achieve a similar trend with WHP as the model represents only one feedzone group, while WHP is affected by all of the feedzones and processes inside the wellbore as well as from the potential connection to nearby production and reinjection wells.

The pressure data in Figure 3 also shows that the PT data and WHP do not change dramatically over time, which may indicate that there is no significant permeability loss or precipitation around the wellbore. This is valid even when the injection rate increased in early 2021. It seems that there is no significant injectivity loss in this well.

3.1.2 Chemistry calibration

Chemistry calibration was also conducted by comparing several chemical species, namely chloride (Cl^-), sulphate (SO_4^{2-}), and bicarbonate (HCO_3^-). Chemical concentrations from the grid corresponding to the location of NM7 were compared with chemical concentrations from field data under reservoir conditions. The grid of NM7 was chosen by using the closest distance between the modelled feedzone of NM9 to the NM7 well, measured using TIM for visualising the well's trajectories.

The model gives a chloride value of around 910 ppm, which closely matches the field value of around 850 ppm. Sulphate concentration from the model was relatively high, at around 300 ppm, while the field data is only around 10 ppm. Bicarbonate concentration from the model also shows a higher value, around 150 ppm, which is higher than the field data of 40 ppm. Introducing a natural flux with a rate of 3.5E-5 kg/s.m2 and water enthalpy at reservoir temperature was considered to observe its effect on the model's sulphate and bicarbonate value. After a natural flux was introduced, the sulphate and bicarbonate concentrations from the model decreased to around 40 ppm and 90 ppm, respectively. The comparison of the chemical concentrations can be seen in Figure 4.

Further reducing these concentrations would require reducing the injection rate and increasing the natural flux rate. However, these adjustments were not conducted to prevent further deviation of the model from the reservoir conditions and potential interference with other chemistry calibrations. Notably, minerals associated with sulphate and bicarbonate, such as anhydrite and calcite, are more likely to be overestimated. This difference between model and field data could be due to the distance between NM9 and NM7. They may have been too close for choosing the grid. Using a longer distance would result in lower concentrations.

3.2 Effects on the volume fraction of minerals

Each mineral demonstrates unique behaviour depending on its chemical reaction parameters, including the kinetic rate constant, activation energy, assigned reactive surface area, and reaction with different chemical species. Different NCG reinjection scenarios were also expected to give distinct results because of variations in their injection chemistry, particularly in gas composition and pH (Table 2).

This section will discuss the trends in several minerals within the radial distance at the end of the simulations with all scenarios. The focus will be on the changes in each mineral's volume fraction in the fracture domain. Therefore, the results in Figure 5 represent the mineral's volume fraction in the fracture.

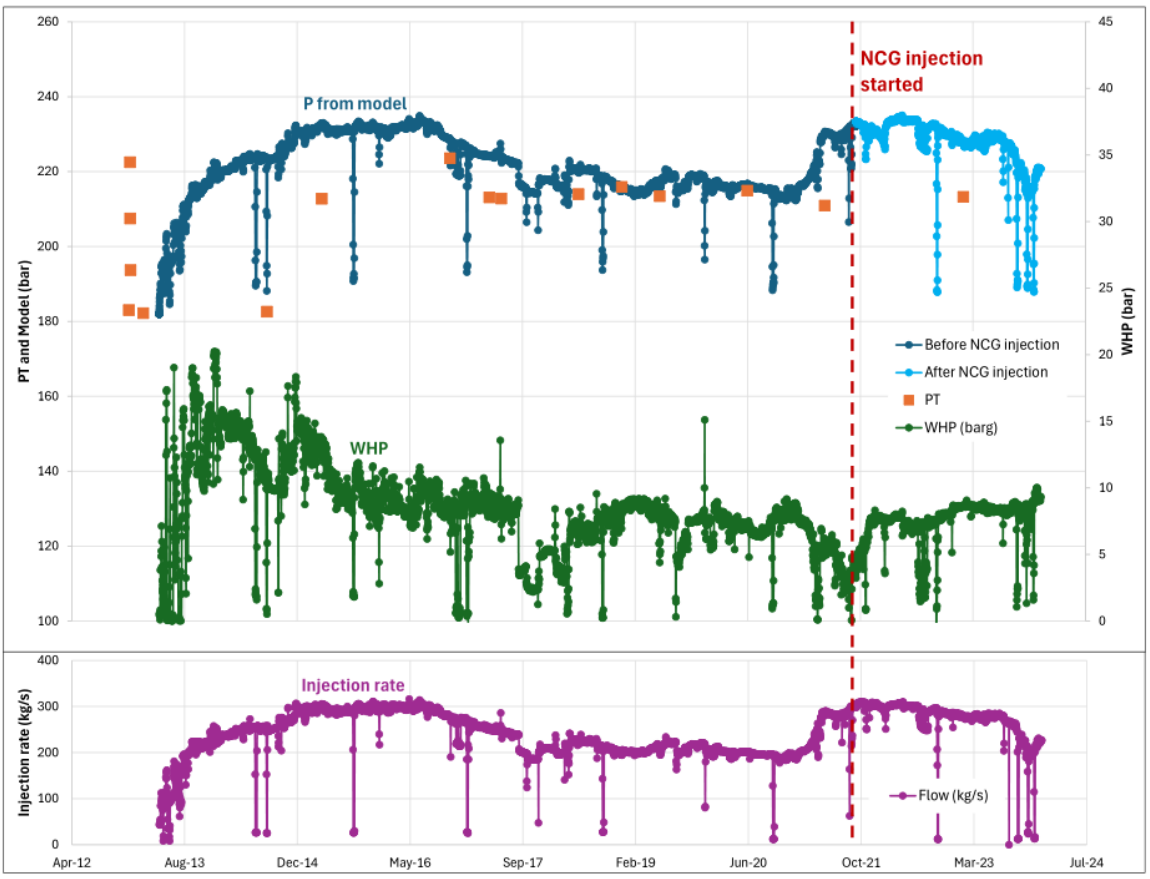

Figure 3: Pressure comparison between the model's result, PT logging data, and WHP with injection rate plotted below the pressure comparison.

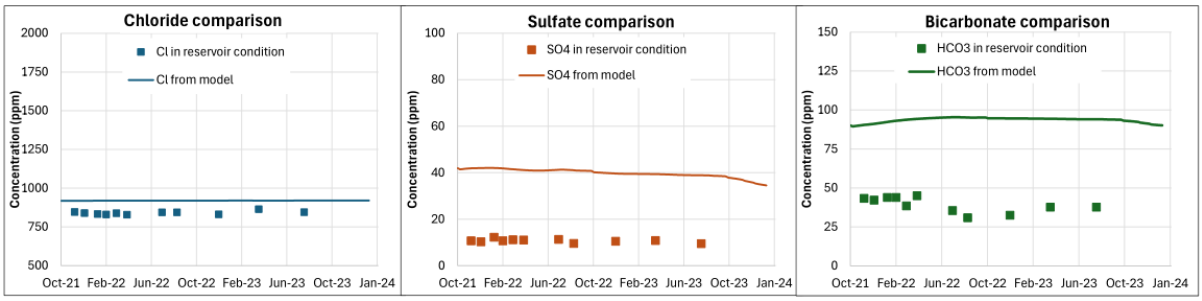

Figure 4: Chemical concentration comparison between the model's result and field data in reservoir condition.

The result of calcite is given in Figure 5A. Calcite shows a dissolving trend within around 1000 m near the wellbore, as indicated by a decrease in its volume fraction. Beyond 1000 m, calcite shows minimal precipitation to no change. This precipitation was due to the presence of calcium ions in both the injected fluid and the reservoir. The comparison between different NCG reinjection scenarios shows that only calcite gives different results with different NCG reinjection scenarios (Figure 5A). An increase in the NCG reinjection amount leads to higher CO2 and subsequently lowers the pH (Table 2). The lower pH promotes calcite dissolution in the near wellbore area, contributing to an increase in porosity and permeability.

Anhydrite shows a dissolving trend around 800 m from the injection well (Figure 5B). After 800 m, anhydrite shows a precipitation trend. The precipitation's magnitude is much higher than the calcite's precipitation trend. This trend of anhydrite shows that the dissolved anhydrite in the near wellbore is precipitating in the outer area. This anhydrite precipitation also aligns with the evidence of anhydrite scaling found in the adjacent monitoring well NM2 (Buscarlet et al., 2016). Anhydrite shows similar results across different NCG reinjection scenarios (Figure 5B). Despite variations in H2S concentrations among different NCG reinjection scenarios (Table 6), it does not appear to affect the anhydrite precipitation. Anhydrite formation requires calcium (Ca2+) and sulphate (SO42-). According to the reaction in Equation (1) below, H2S would need to be oxidised to become SO42-. This

reaction was input into the model's thermodynamic database. Due to the field's closed system without any contact with the atmosphere, no oxygen was found in the system.

$$H_2S + 2O_2 = SO_4^{2-} + 2H^+ \quad (1)$$

Pyrite only shows precipitation near the wellbore (Figure 5C). Different NCG reinjection scenarios yield similar results, as the variation in H2S injection is very small (Table 2). Amorphous silica shows slight precipitation (Figure 5D), while quartz does not change significantly despite its high-volume fraction. It shows insignificant dissolution in the near wellbore and precipitation in the outer area. This slow change was due to its low rate constant (Table 4). Clay minerals, namely kaolinite and smectite, show a precipitation trend near the wellbore. Some minerals do not show any or minimal changes in the model (below 0.01% of change), namely albite, chalcedony, chlorite, pyrophyllite, illite, and montmorillonite. Although if looked at closely, some of the minerals show a precipitation trend near the wellbore, such as chalcedony, illite, and montmorillonite, and some others show a dissolution trend, such as albite and chlorite, it was decided to neglect it as the changes were not significant. Pyrophyllite, on the other hand, shows no change in its volume fraction.

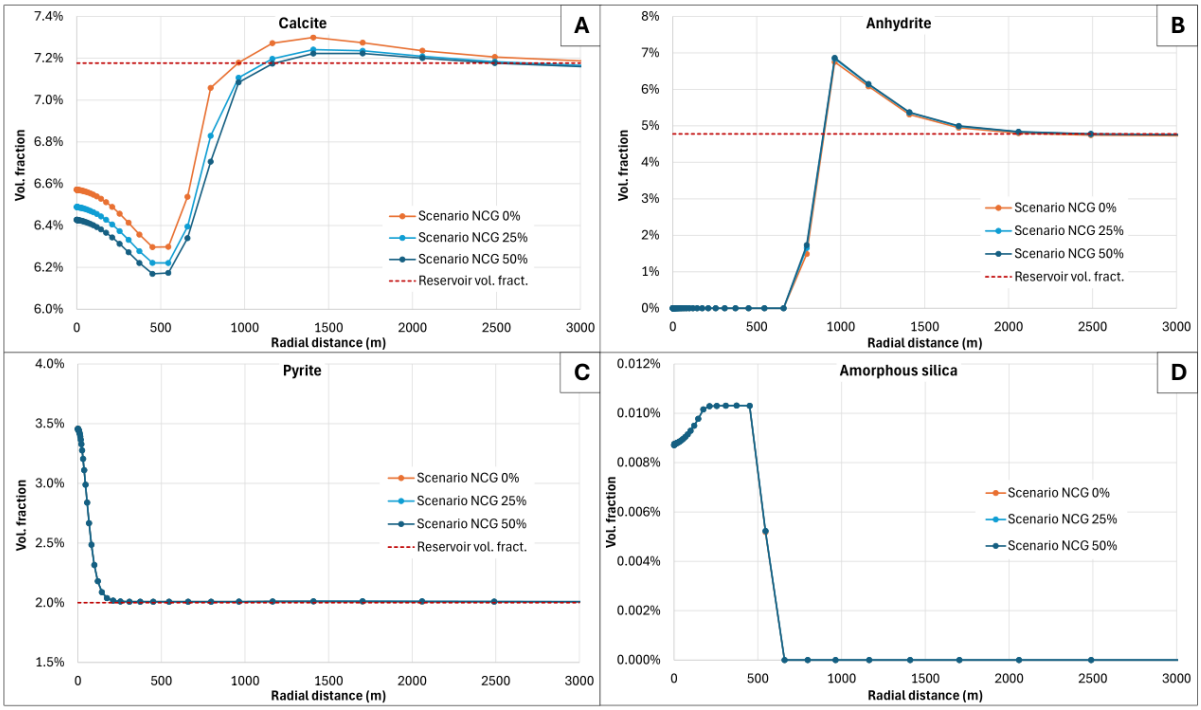

Figure 5: Volume fraction change within radial distance of calcite, anhydrite, pyrite, and amorphous silica at the end of the model's running time in 2034.

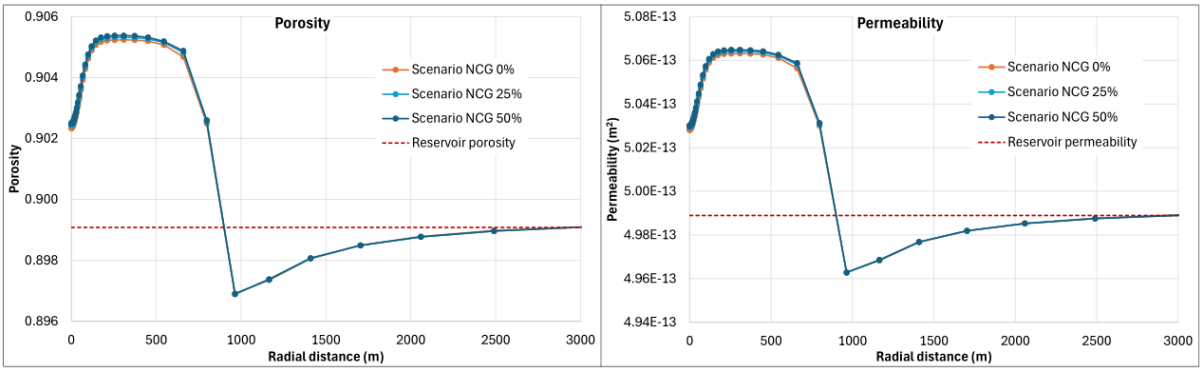

Figure 6: Porosity (left) and permeability (right) value within the radial distance at the end of the model's running time in 2034.

3.3 Effects on porosity and permeability

Changes in the mineral volume fraction contribute to the porosity and permeability of the rock. Porosity and permeability within the radial distance at the end of the model's run time in 2034 can be seen in Figure 6. Both porosity and permeability show a similar trend, increasing from the wellbore to around 900 m and decreasing in

the later part. Calcite and anhydrite are two main minerals affecting porosity and permeability trends. The dissolution of calcite and anhydrite in the near wellbore area increases the porosity and permeability. In the outer area, anhydrite precipitation decreases the porosity and permeability.

3.4 Effects on chemical concentration

The chemical concentration and minerals' volume fractions influence each other. A high concentration of specific chemical species may result in the deposition of certain minerals and, subsequently, a decrease in the chemical concentration. The dissolution of minerals can lead to an increase in some chemical concentrations. The relationship between chemical concentrations and minerals'volume fraction is governed by the mineral's kinetic reaction parameters (Table 4) and the chemical reactions (Table 5). This section will further discuss several key minerals undergoing significant changes, such as calcite, anhydrite, and pyrite, and their interactions with chemical concentrations (Figure 7).

3.4.1 Calcite

Calcite is mainly affected by pH, bicarbonate, carbon dioxide, and calcium concentration. This is because the chemical reaction of calcite was affected by these components in their kinetic reactions (Table 4) and chemical reactions (Table 5). pH, bicarbonate, and carbon dioxide are interrelated through the equilibrium reaction of Equation (2). The calcite dissolution reaction is shown in Equation (3). Both equations are input into the thermodynamic database of TOUGHREACT.

$$CO_{2(aq)} + H_2O \rightleftharpoons H^+ + HCO_3^- \quad (2)$$

$$Calcite + H^+ \rightleftharpoons Ca^{2+} + HCO_3^- \quad (3)$$

Figure 7 shows the relation between calcite and related chemical concentrations. According to the equilibrium reaction of dissolved carbon dioxide and bicarbonate (Equation 2), an increase in dissolved carbon dioxide would decrease the pH, favouring calcite dissolution. The dissolution of calcite, in turn, would increase the calcium and bicarbonate concentration. Due to the increase of bicarbonate, the dissolved carbon dioxide would decrease to fulfil the equilibrium condition of Equation (2). Dreybrodt et al. (1997) mentioned that the reaction described in Equation (2) limits the precipitation rate of calcite due to its slow kinetics.

The bicarbonate concentration increases until saturation conditions are reached, at this point, calcite dissolution stops, followed by a small precipitation of calcite. Due to its retrograde solubility (Zarrouk & McLean, 2019), calcite precipitation is also affected by the temperatures, which will increase towards the outer parts of the wellbore. The solubility of calcite was assigned in the thermodynamic database. Calcite precipitation is also followed by a decrease in bicarbonate and calcium concentrations, following Equation (3).

3.4.2 Anhydrite

Anhydrite is affected by calcium and sulphate concentrations, as detailed in its kinetic reaction (Table 4) and chemical reaction (Table 5). Figure 7 is plotted to better understand the relationship between anhydrite and related chemical concentrations. According to Equation (4), anhydrite dissolves and increases calcium and sulphate concentrations near the wellbore. This increase continues until calcium and sulphate reach oversaturation, at which point anhydrite precipitates. Temperature also affects the precipitation of anhydrite, following the retrograde solubility of anhydrite (Zarrouk & McLean, 2019).

$$Anhydrite \rightleftharpoons Ca^{2+} + SO_4^{2-} \quad (4)$$

As explained in section 3.2, different NCG reinjection scenarios with varying hydrogen sulphide concentrations do not affect the precipitation of anhydrite. This is due to the need for oxygen to oxidise the hydrogen sulphide into sulphate that is needed to form anhydrite (Equation 1).

3.4.3 Pyrite

According to its chemical reaction, Pyrite is affected mainly by iron and hydrogen sulphide (Table 5 and Equation 5). Due to its fast kinetic rate (Table 4), pyrite only precipitates near the wellbore, followed by the decreasing trend of iron and hydrogen sulphide (Figure 7).

$$Pyrite + H_{2(aq)} + 2H^+ \rightleftharpoons Fe^{2+} + H_2S_{(aq)} \quad (5)$$

3.5 Effects throughout times

To better understand how each NCG reinjection scenario affects the overall volume fraction, the net change through time for the future model at NM9 (first grid) and at the estimation of NM7 were plotted (Figure 8). Based on the charts, an increase in net volume fraction happened in both NM9 and NM7 wells, with a slightly higher increase in NM7. Different NCG reinjection scenarios gave different results only in NM9, where increased NCG would lower the net volume fraction increase.

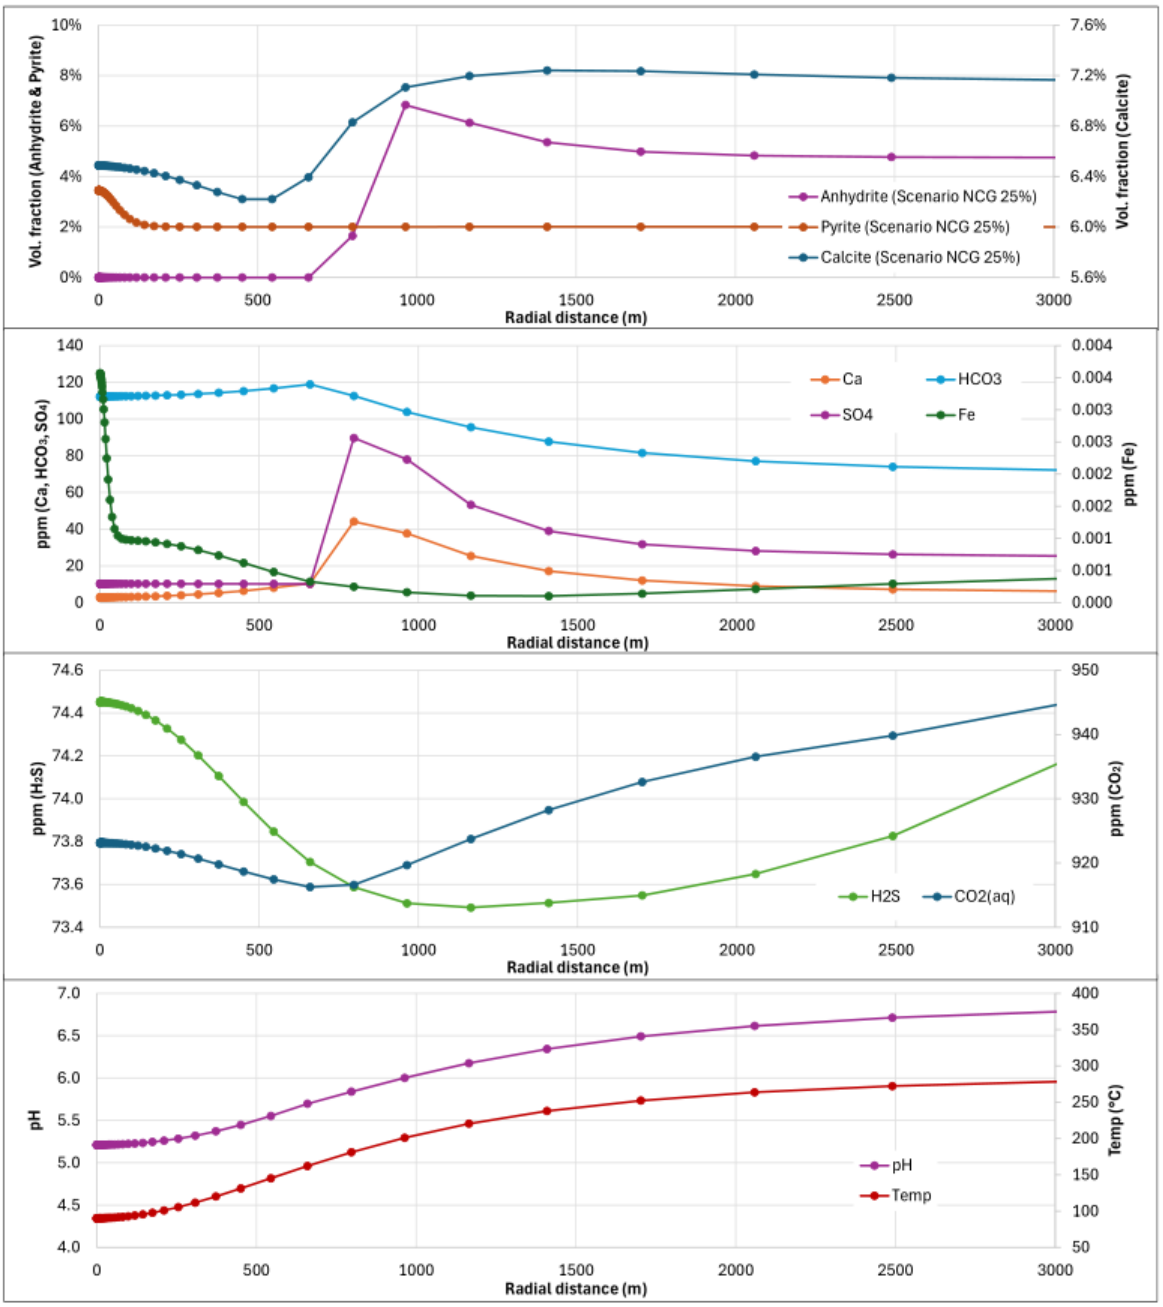

Figure 7: Volume fraction trend of calcite, anhydrite, and pyrite with related chemical species concentrations (Ca, HCO3-, SO42-, Fe, H2S, and CO2), pH, and temperature within the radial distance from the wellbore.

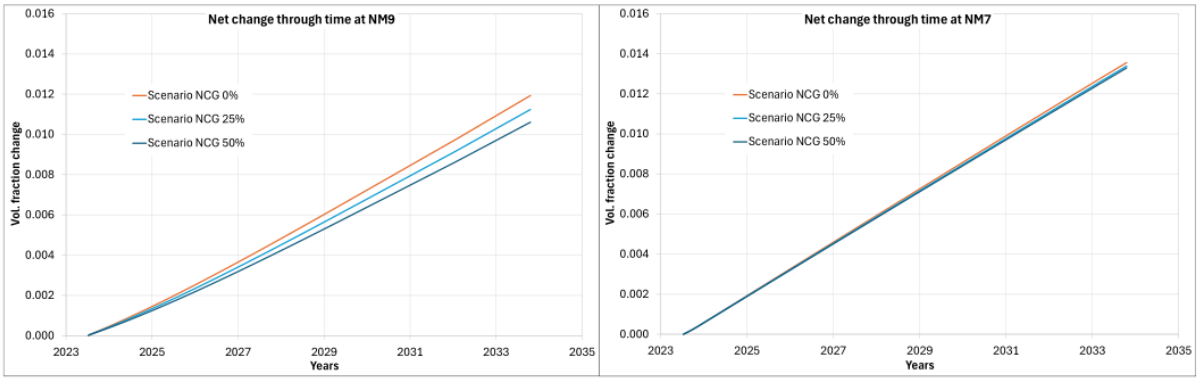

Figure 8: Left: net change through time at NM9; Right: net change through time at NM7.

4. CONCLUSION

The reactive transport models presented in this work evaluate the effects of the NCG reinjection on the Ngā Tamariki reservoir. The NCG is mainly reinjected to NM9 reinjection well located in the northern part of the Ngā Tamariki geothermal field. The nearest production well, NM7, was also included in the model to evaluate whether NCG reinjection has any influence on production.

The 1D-radial model shows a varying trend of porosity and permeability along the radial distance. Near the NM9 wellbore, porosity and permeability increase, mainly due to the dissolution of calcite and anhydrite. Conversely, the porosity and permeability decrease in the outer region due to anhydrite precipitation. Different NCG reinjection scenarios of 0%, 25%, and 50% of NCG reinjection were also modelled. These scenarios did not show significant differences in porosity and permeability. However, calcite dissolution showed differences for each scenario. Higher amounts of NCG reinjection resulted in increased calcite dissolution in the vicinity of the wellbore due to the lower pH of the injection fluid. On the other hand, anhydrite distribution did not show any significant variations across the different NCG reinjection scenarios. The increase of H2S concentrations did not affect the precipitation of anhydrite as the additional H2S is not oxidised to SO42- due to anoxic conditions in the reservoir.

ACKNOWLEDGEMENT

The authors would like to thank Mercury NZ Ltd. for the provision of field data, permission to publish, and for the support and discussions during this research. We also thank the NZ Ministry of Business, Innovation and Employment for funding the work through the MBIE Research Programme: UOAX2211 “Reversing Carbon Emissions in the Geothermal Energy Industry: Template for Emission-Intensive Industries” projects.

Transient Heat Conduction Modelling for Slim and Large Diameter Geothermal Well: A Case Study from Okuaizu Field, Tohoku, Japan

Ken Prabowo

Baker Hughes

Keywords: Transient Heat Conduction, Geothermal Well Modelling, Pressure and Temperature Survey (PTS), Thermal Conductivity Calibration

ABSTRACT

Japan is set to triple its geothermal power generation to 1.6 GW by 2030. Due to the Strategic Energy Plan and emergence of Advanced Geothermal System, there has been increasing focus on small-scale plants (<7.5 MW) that offers shorter development timeline and minimum environmental impact assessment. Unlike the traditional focus on high temperature sources, the situation may require past exploration well to be revisited. Amongst the data are pressure and temperature profiles that plays a pivotal role in locating & characterizing potential feed zones, designing well & facility and most importantly determining project feasibility. However, geological complexity of the island poses a challenge in terms of acquiring and apprehending the temperature profile.

This paper is meant to show how transient heat conduction modelling is able to be utilized to better understand the temperature gradient from PTS survey both in slim hole and large diameter well. The slim holes have measurement from different time and meant to calibrate the heat conduction parameters including the bottom hole temperature and formation heat transmissivity. The selected larger hole diameter wellbore has fluctuations in the PTS survey and the transient temperature modelling is meant to eliminate the conducted heat and give insight into other possible heat transmission mechanism such as convection.

The result shows the workflow can match the temperature in shallow T-1 and deeper OA-1 by a margin of <5%. While in larger diameter wellbore such as N-17t and N-18t, the temperature profile was able to match the trend especially in the shallow section while the lower zones seem to be influenced by convection that increases the temperature beyond the temperature conduction model. The convection zones could be further matched by increasing the thermal conductivity to represent heat exchange through fluid. In conclusion, the workflow could be further utilized to better understand PTS survey and bring more insight that ultimately would help in developing the geothermal fields.

1. INTRODUCTION

Pressure and temperature survey or PTS are performed frequently in a geothermal operation. From time to time, measurement with fluctuating gradient that deviates from the linear geothermal gradient are encountered. More than often, these “fluctuations” are ignored even though the subsurface temperature distribution has a far-reaching consequence to exploration and development strategy of a geothermal asset. Heat conduction modelling could be utilized to gain better understanding of the temperature gradient and this paper is meant to evaluate and showcase how this near wellbore physics could be utilized to improve our understanding on wellbore dynamics.

2. METHODOLOGY

The basis of thermal flux is based on one dimensional Fourier’s Law that could be formulated as below.

$$\frac{Q}{\Delta t} = -kA\frac{\Delta T}{\Delta x}$$

Q is the net heat (energy) transfer, Δt is the time taken, ΔT is the difference in temperature between the cold and hot sides, Δx is the thickness of the material conducting heat (distance between hot and cold sides), k is the thermal conductivity, and A is the surface area of the surface emitting heat.

The paper utilize in house software that has adapted the heat flux equation to wellbore condition. Surface emitting heat is calculated based on the inputted wellbore schematics and thermal conductivities of each heat conducting material are defined separately as shown in Figure 1.

Overall wellbore simulation could be illustrated in Figure 2. Geothermal gradient are assumed to be constant leaving the fluid temperature in the wellbore to be solved through the iterations. For this exercise, transient simulation would be performed for maximum duration of 5 days.

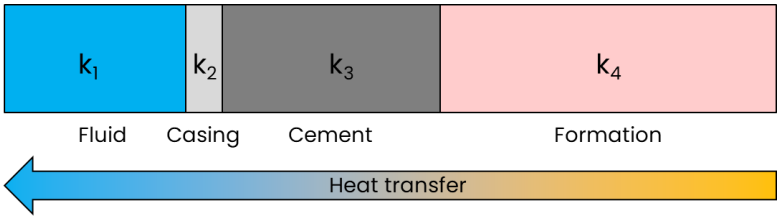

Figure 1: Heat flow patch from formation to wellbore with different heat conductivity.

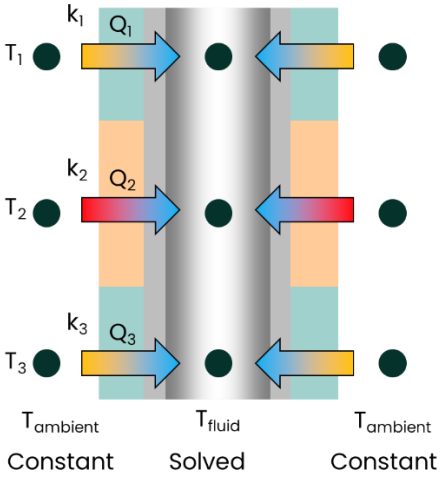

Figure 2: Illustration of 1D heat flux model with constant temperature and fluid temperature to be solved.

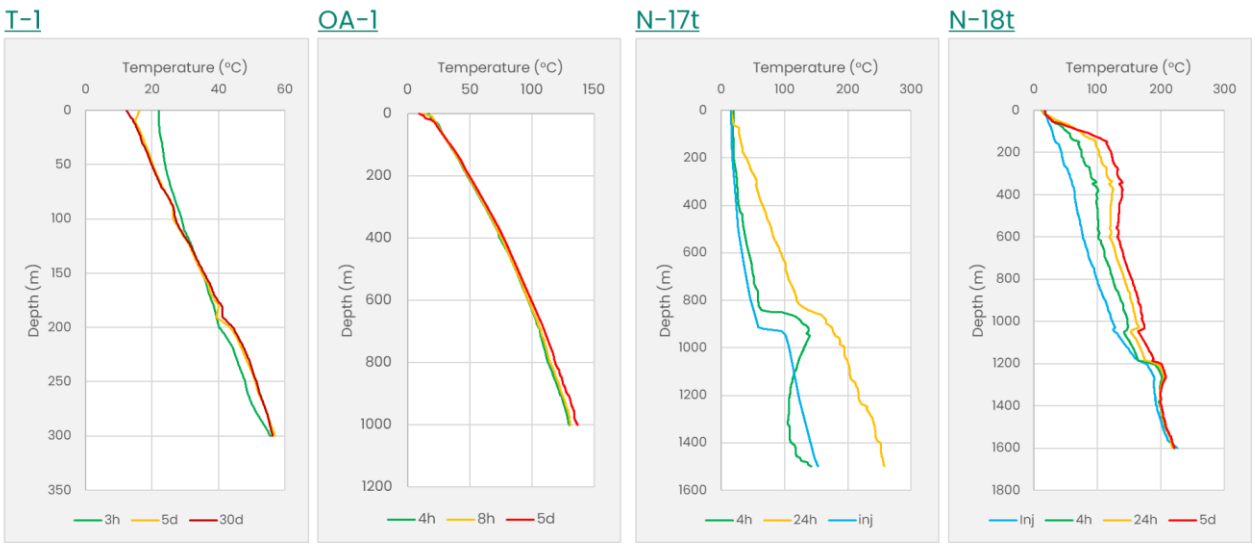

Figure 3: PTS surveys from T-1, OA-1, N-17t and N-18t.

3. OKAIZU FIELD OVERVIEW

The Okuaizu Geothermal Field is located approximately 35 km southwest of the active volcano Mt. Bandai. The field has been extensively studied since 1974. The commercial power station has started operation on 1995 with capacity of 65 MW. There are publicly available and suitable dataset for this research. The dataset includes completion, well trajectory, stratigraphy & production/injection history. There are four well that has been selected based on the hole size and distinct pressure measurement: slim hole: T-1 & OA-1 and large diameter wellbore: N-17t & N-18t. The digitized PTS surveys from Garg & Combs (2002) are shown in Figure 3. PTS surveys from these well would be used to calibrate the heat flux model.

4. RESULT

4.1 T-1 Slim Hole

T-1 is a slim hole with a depth of 300 meter. Available PTS survey are done within 3 hours, 5 days and 30 days. The trend indicates a single linear geothermal gradient. Measured temperature can be matched using default thermal conductivity of 1.3 BTU/(hr.ft.°F). Surface or near surface temperature initially comes from the injection inlet and it shifted to geothermal gradient after the operation stops. The temperature stabilized after approximately 12 hours. Prior to reaching state of equilibrium (such as measurement in the third hours), temperature in wellbore has not reflected the geothermal gradient of the formation.

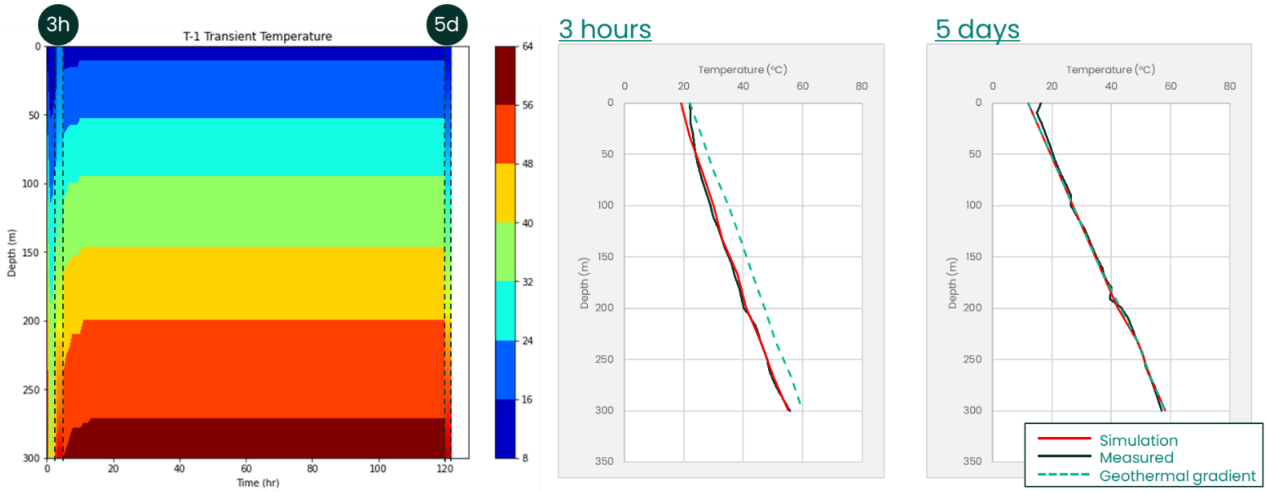

Figure 4: Transient temperature result for T-1.

4.2 OA-1 Slim Hole

OA-1 is a slim hole with a depth of 1,000 meter. Available PTS survey was done in 4 hours, 8 hours and 5 days. The curving temperature along the wellbore indicates changes in geothermal gradient. The measure temperature could be matched by using default thermal conductivity and three different temperature gradients. The temperature stabilized after approximately 100 hours.

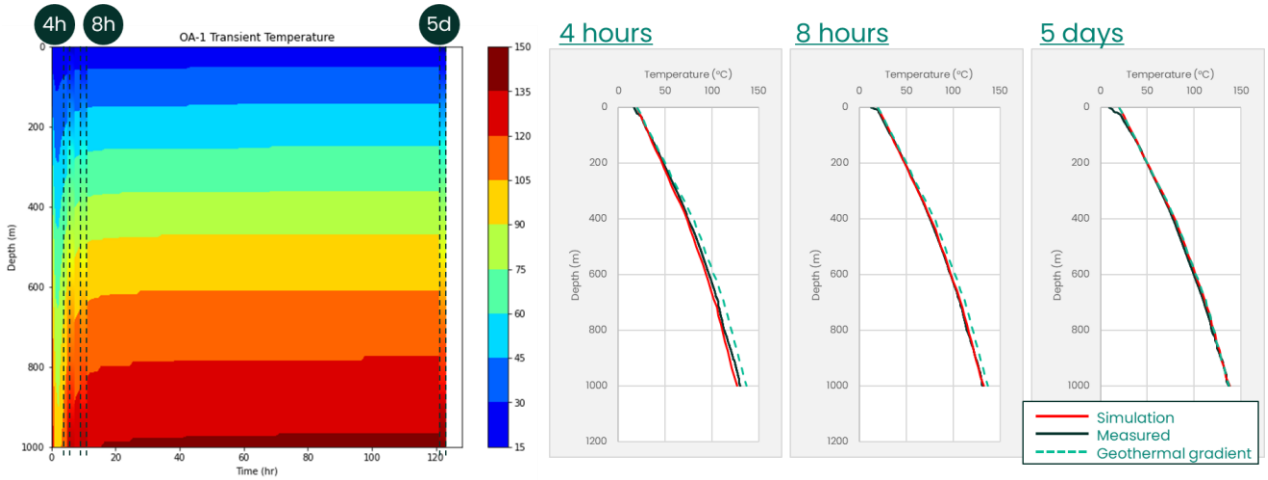

Figure 5: Transient temperature result for OA-1.

4.3 N-17t Large Hole

N-17t is a large diameter deviated well with a depth of 1,500 meter. Available PTS survey is done during injection, 4 hours and 24 hours. Abrupt shift in the bottom section of the well indicates convection. In order to match the measured temperature, the thermal conductivity was increased to 50 BTU/(hr.ft.°F) and the initial geothermal gradient was split into two different gradients. The temperature has yet to be stabilized after approximately 24 hours of shut in.

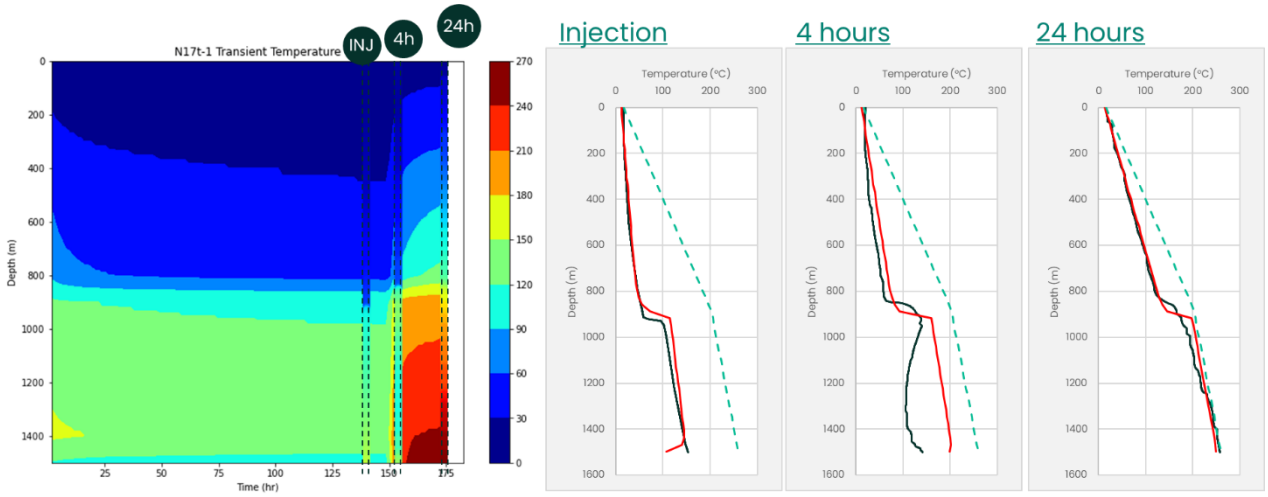

Figure 6: Transient temperature result for N-17t.

4.4 N-18t Large Hole

N-18t is a large diameter deviated well with a depth of 1,600 meter. Available PTS survey is done during injection, 8 hours, 24 hours, 60 hours and 5 days. Fluctuating temperature in the top and bottom section of the well indicates changes in geothermal gradient. The top temperature could be matched by adjusting the geothermal gradient to match the curve shape. In order to calibrate the temperature during injection and shut in, the thermal conductivity also needed to be increased to be at least 50 BTU/(hr.ft.°F) in the concave sections.

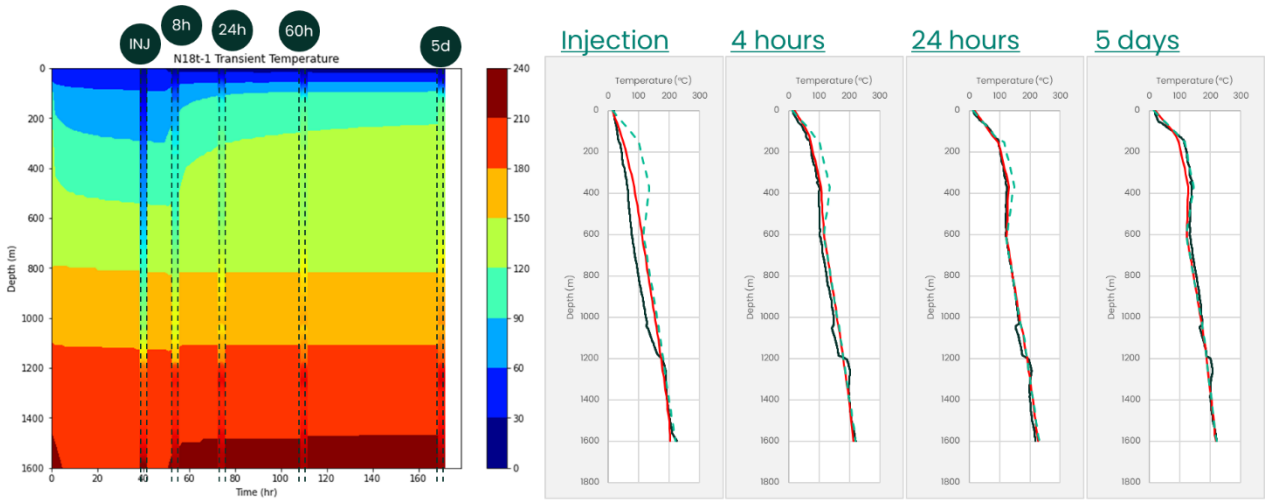

Figure 7: Transient temperature result for N-18t.

5. CONCLUSION

1. The heat conductivity model is based 1D Fourier's Law.
2. Okaizu geothermal field in Japan is selected due to widely available dataset.
3. Four wells were selected to be digitized and used for this exercise:
   - Slim hole: T-1 & OA-1
   - Large diameter wellbore: N-17t & N-18t
4. The simulation was able to simulate and match the measured temperature in slim hole that has minimum fluid movement (heat conduction dominated).
5. The large wellbore in this exercise indicates presence of convection. The thermal conductivity of the fluctuating interval was increased to better match the measured temperature.
6. Benefits of deploying this workflow:
   - Accurately estimate true geothermal gradient from short shut-in time or even shallow slim hole.
   - Strategically plan PTS survey interval.
   - Better understanding of full wellbore dynamics and its operating envelope.
   - Gain better insight on formation properties specifically thermal conductivity and storativity.

The Advantages of Simple 3D Numerical Modeling in Characterizing a Localized Reservoir Boundary for New Wellpad Development in Wayang Windu

Stefano Pentury, Mulyadi, Deoky Pandu Dewanto, and Meiyanto Joko Purnomo

Star Energy Geothermal Wayang Windu, Jakarta

stefano.pentury@starenergy.co.id

Keywords: geothermal reservoir characterization,reservoir simulation, TOUGH2 simulator

ABSTRACT

The Wayang Windu field has maintained its steam supply above the power plant demand from the start of commercial operations in 2000 until the present time. There are currently 32 active producers, five of which are new wells drilled in 2021. Those new wells were drilled from three distinct well pads within the proven reservoir area, with one steam well located at a new well pad in the northern reservoir sector, known as MBI-X well. Despite its good performance, MBI-X has exhibited a relatively higher pressure decline than its neighbor wells. As a result, MBI-X might be associated with a distinct reservoir localized area that is relatively less connected to the adjacent higher production wells. An analytical pressure transient analysis confirmed that MBI-X lies in a confined boundary configuration resembling an intersecting fault, ranging approximately 200-300 m in distance. Despite this, pressure transient analysis could not determine which intersect faults confine the reservoir. To provide some insight, a simple 3D numerical process model has been developed using TOUGH2 simulator with a dimension of 1600x1600x1600 m, involving MBI-X as well as the other two most nearby wells, WWQ-X and MBD-X. Expectedly, this approach can assist earth scientists and engineers during the well targeting process for new make-up wells (MUW), especially within MBI's pad, where there will be plenty of make-up wells to drill in the upcoming Wayang Windu drilling campaign.

1. INTRODUCTION

Located approximately 40 km south of Bandung, Wayang Windu field has consistently been one of the largest geothermal producer in Indonesia for more than 20 years, providing up to 230.5 MW of electricity. The Wayang Windu reservoir is a high-terrain geothermal system that has relatively high temperature (250-320 degC) which has been described as a transitional zone between vapor dominated system from the top of reservoir at 1200 mASL until 400 mASL and liquid dominated system that follows. Wayang Windu has maintained its strong steam production, with an extraction primarily sourced from the steam cap northern area, followed by the central liquid area; meanwhile the injection wells have strategically been placed in the southern area. Up to this point, not much exploitation has been executed in the north-west part of the field, although microgravity survey indicates a reduction in gravity which might imply for strong connection to the main extraction area. In 2021, there were six wells located in four different wellpads drilled in the Wayang Windu field, bringing the total number of wells to 65, of which 32 are active producers. Amongst of the four wellpads, there is a new well pad called MBI located in the north-west, which consists of only 1 well, named MBI-X. As there will be additional wells to drill in the next drilling campaign, the objective of this paper is to perform reservoir characterization including the MBI region. This MBI pad is important because it represents the new beginning to explore more productive zone on the way to the westside.Furthermore, the Pressure Temperature Spinner (PTS) analysis and drilling breaks indicate that MBI-X has three feed zones (FZ) at about 990, 906, and 880 mASL.. With a total depth (TD) no greater than the field's average liquid level at about 400 mASL, MBI-X ought to be a steam (vapor dominated) well. Therefore, based on Figure 1, it is verified that the liquid beneath ~800 mASL in the 2021 PT profile (left graph) is water dead leg; an accumulated colder injected fluid that is not flashing since there is no productive FZ below that depth. This also corresponds to the evidence of no spinner change below 800 mASL.

On the other hand, although MBI-X has showed a decent initial performance, it is underperformed shown by a more accelerated decline compared to the most nearby wells, MBD-X and WWQ-X that have been actively produced for 5 years and 8 years, respectively. Figure 2 shows the production performance of MBI-X in comparison to MBD-X and WWQ-X. To make the comparison more apparent, the steam rate has been normalized to 12 bar of wellhead pressure and initial value is set to 100 kg/s. According to figure 2, MBD-X and WWQ-X have both been able to maintain productions at 2% and 5% annually, respectively. MBI-X, on the other hand, experiences a sharper decline with a rate of 8 %/year in the first year of production, then it accelerated to 13.4 %/year afterwards.

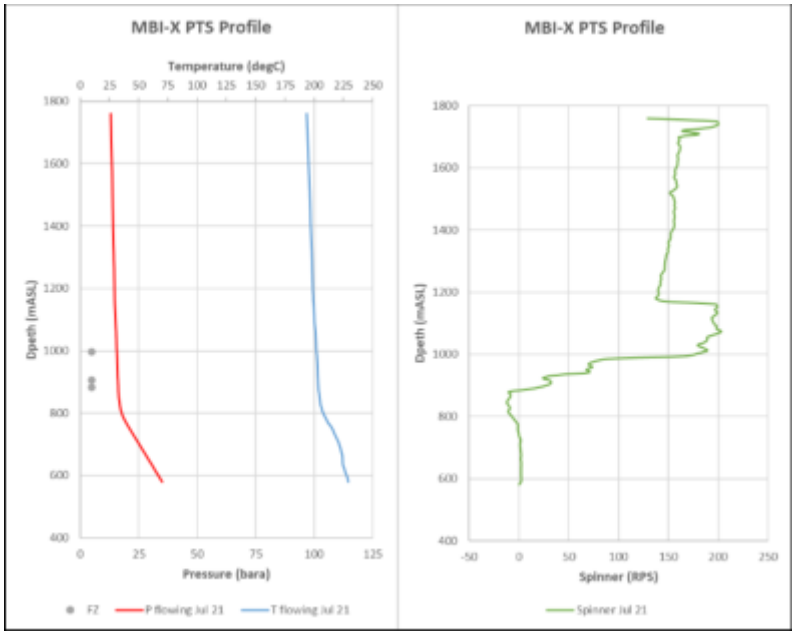

Figure 1: MBI-X PTS profile and FZ information.

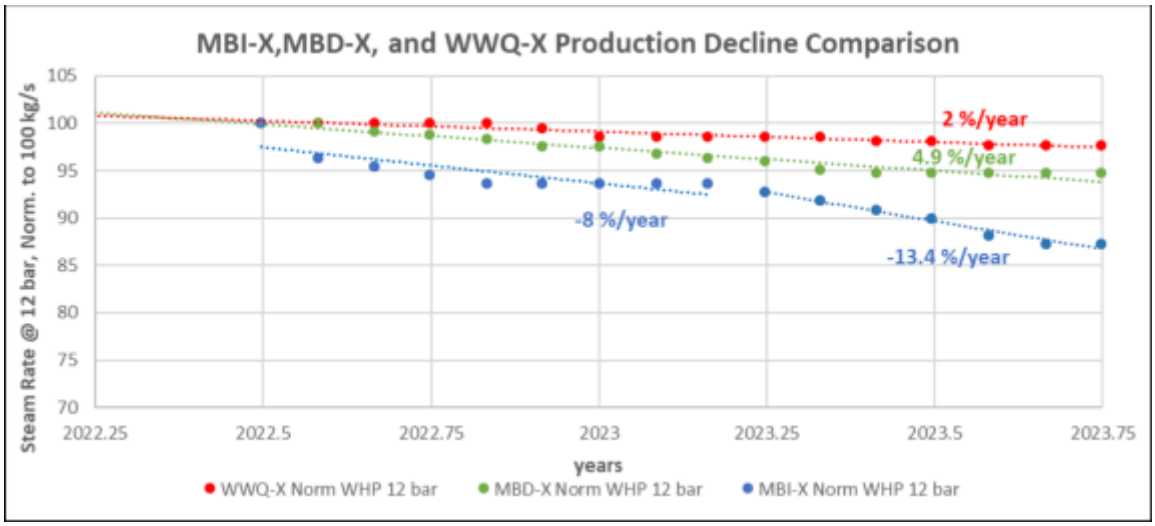

Figure 2: Production Performance of MBI-X comparing to its nearby wells.

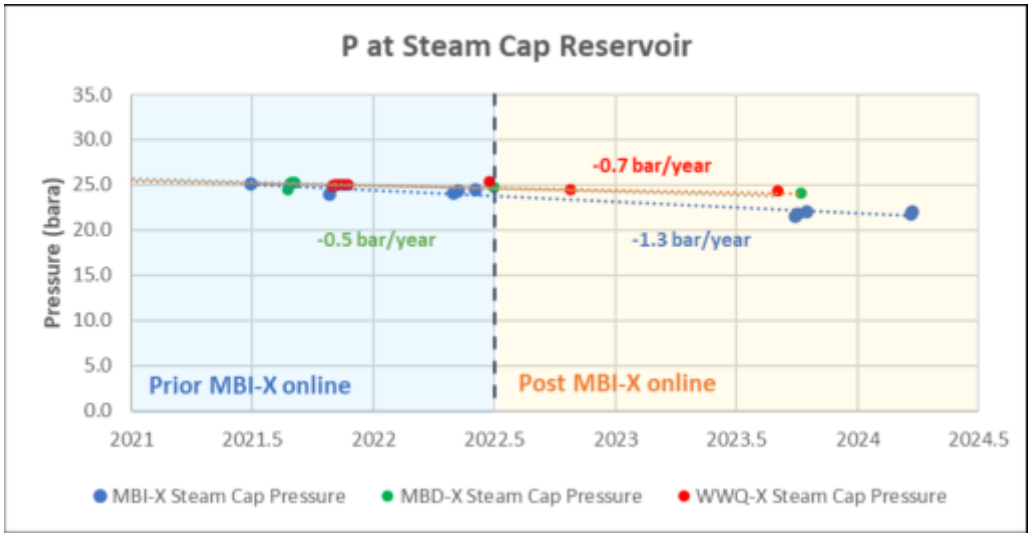

Figure 3: Pressure Response of MBI-X comparing to its nearby wells.

Meanwhile for the reservoir pressure within the steam cap area, MBI, WWQ, and MBD wells tends to have similar magnitude in the beginning. Corresponding to the higher production decline of MBI-X than MBD-X and WWQ-X, the pressure of this well also shows a larger pressure drop overtime, lying at 1.3 bar/year. Figure 3 shows how distinct the pressure of MBI-X performs against MBD-X and WWQ-X.

Due to a different steam production and reservoir pressure response with only short FZ distance to its neighbor wells ranging from ~274 to 627 m, MBI-X might be located in a local confined reservoir area that is separated from MBD-X and WWQ-X reservoir. Despite that, prior to the online of MBI-X on July 2022, the reservoir pressure still shows the same declining trend as MBD-X and WWQ-X for a year of monitoring. Therefore, it is most likely that MBI-X still has a weak connection toward MBD-X and WWQ-X and does not separate completely. Given that, an initiative to assess MBI-X's boundary condition through Pressure Transient Analysis (PTA) has been implemented.

PTA is a powerful tool that can be used to identify crucial parameters including reservoir boundary type alongside with the distance approximation. The reservoir boundary type can be identified through the derivative pressure and differential pressure curve extracted by various well-testing pressure responses such as build-up test, injection test, fall-off test, or production test. Nevertheless, it is essential that the response duration must be long enough just to ensure that it reaches the reservoir boundary, in conjunction with the good pressure response quality for better interpretation. The huff and puff program was executed in October 2023 consists of series of well tests including build-up test, injection test, and fall-off test that can be used for pressure transient analysis. Among of those series of well tests, it appears that there were 1 build-up (before 1st cycle) and 1 injection test (during 1st cycle) that had a sufficient duration and quite good quality data. Even though there was no direct measurement of the bottom hole pressure during huff and puff, the well head pressure was monitored continuously and could represent steam cap pressure properly. After doing pressure transient analysis with various sensitivities and trial and errors on the well-head pressure profiles, the best model that fit was either homogeneous or dual porosity slab with boundary type of intersecting faults. For instance, figure 4 shows the pressure transient analysis result of the build-up test pre-1st cycle.

Figure 4 shows an uptrend profile of both the derivative curve and the differential pressure curve at the late period, indicating that MBI-X has a limited reservoir boundary. Both Homogeneous and Dual Porosity model conclude the reservoir boundary to be as intersecting faults with similar distance at around ~200 m from the MBI-X's feedzones. Corresponding to the previously developed structure interpretation, the confined boundary that restricts MBI-X's area might be resulting from the damaged zone of Bedil-Gambung Fault and Cibitung Splay Fault, which propagated with a buffer of 100 m outwards, linear with the green dots shown in figure 5.

Therefore, the structural interpretation in figure 5 will be used as a guide to create the 3D static model; the aim of this model is to validate the local compartment of MBI-X and to provide a clear picture on how the key static properties distribute throughout the region.

2. MODEL SETUP

A simple 3D numerical process model has been created using TOUGH2 simulator; which is a widely used numerical simulator in the geothermal industry for modelling subsurface fluid and heat flow processes in porous and fractured media. The model was created with a simple dimension of 1600x1600x1600 m that covers MBI-X alongside with its two neighboring wells, MBD-X and WWQ-X. The grid size should be as small as possible in the focus area to create a more refined profile; with finer size focusing in MBI-X area (50 m in distance) and more coarser outward with a distance ranging from 200 m to 300 m in size as shown by figure 6.

Majority of static properties had been set referring to the Wayang Windu full field model developed by Pasikki et al (2020), which was properly calibrated to the measured data. The uppermost model is expected to represent the top of reservoir at the elevation of 1200 mASL, connected to the atmosphere with a distance of 537 meters from the interface (based on average actual topography). While the bottom part of the model is at an elevation of -400 mASL, which is linked to a 300 degC hot plate at a distance of 2200 m. An upflow with rate of 5 kg/s and enthalpy of 1500 kJ/kg is attached at the bottom part of the model, then, a deliverability outflow with PI of 1e-12 m3 is attached at the middle side of the model. These configurations for the upflow and outflow were determined through several trial and errors. In the meantime, the summarized of the initial rock properties is shown in Table 1 and illustrated in Figure 7.

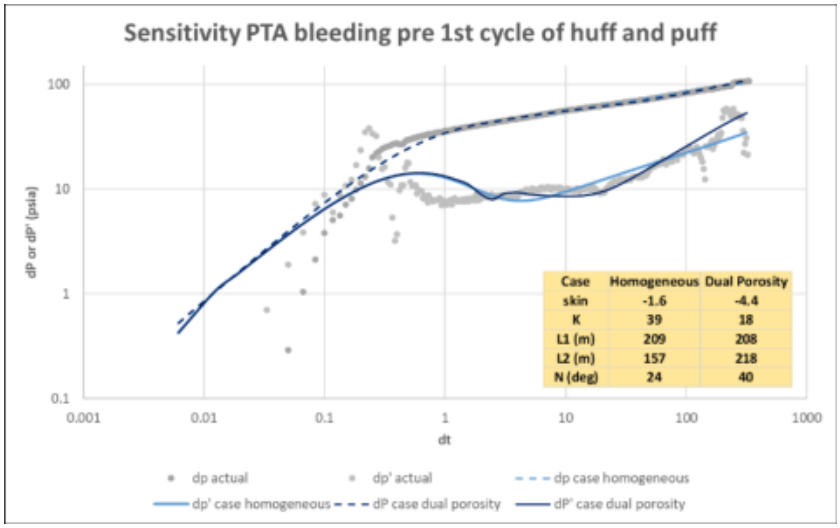

Figure 4: PTA MBI-X Analaytical Result.

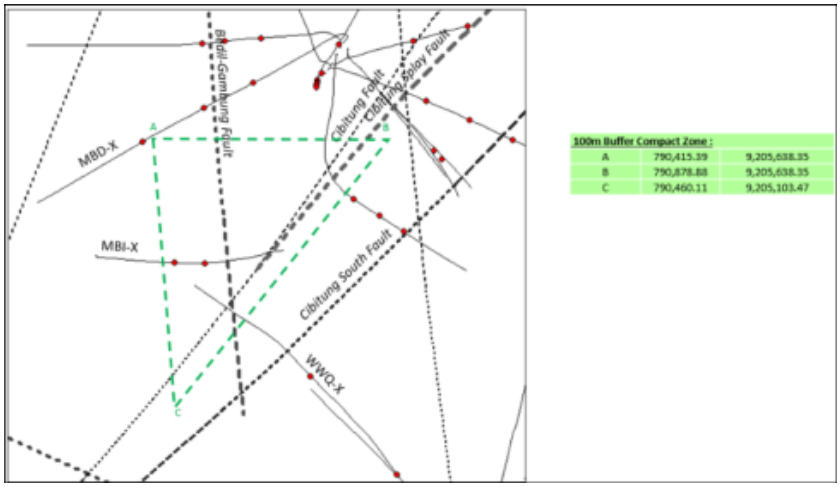

Figure 5: Structural Interpretation of the Localized area.

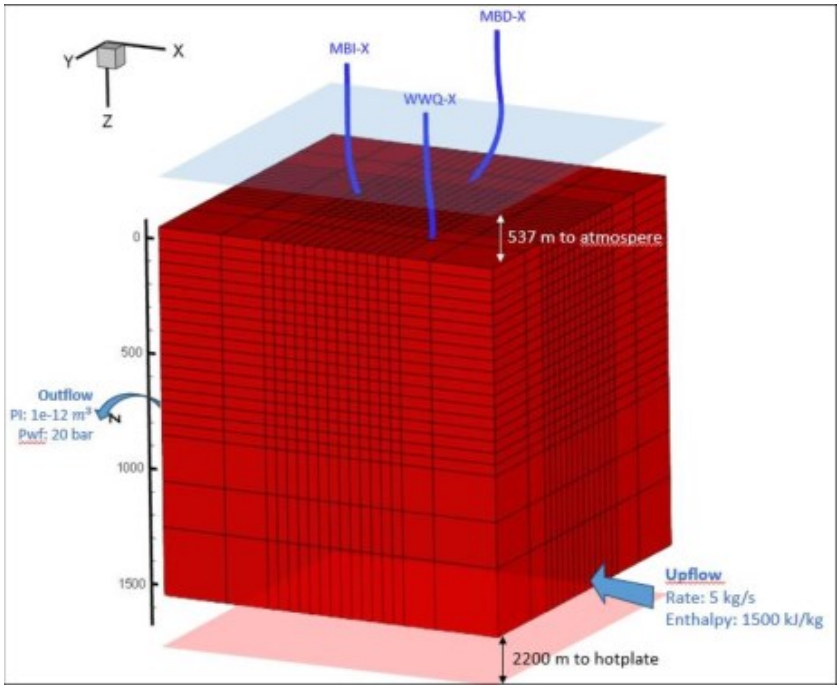

Figure 6: Model Geometry and Boundary Information.

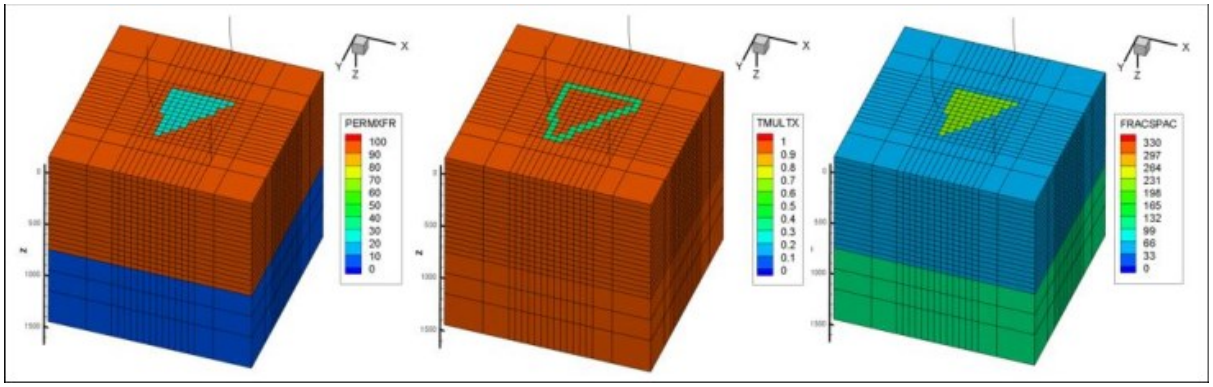

Figure 7: Reservoir Properties of the 3D model.

Table 1: Initial Rock Properties of the Model.

Static Properties	Value	Remarks
Fracture Permeability X,Y,Z	• Within MBI-X: 30 mD • Outward MBI-X: 100 mD	• Refer to PI" formula and PTA calculation • Based on Wayang Windu full field model
Transmissivity multiplier X,Y,Z	Surrounding MBI-X: 0.3	Create it as if a barrier capturing smaller volume; The barrier is not fully closed leaving a fraction of 30%.
Fracture spacing	• Within MBI-X: 220 m • Outward MBI-X steam cap area: 50 m • Outward MBI-X liquid area: 110 m	• To make the MBI-X to have a smaller fracture-matrix interaction • Based on Wayang Windu full field model • Based on Wayang Windu full field model
Matrix Permeability X,Y,Z	5 µD	Based on Wayang Windu full field model
Fracture Porosity	50% with 2% bulk volume	
Matrix Porosity	7% with 98% bulk volume	

In particular, the local area of MBI-X is differentiated by three parameters, such as fracture permeability, transmissivity multiplier, and fracture spacing; where the distribution itself refers to the structure interpretation as discussed in the previous section. Moreover, the faults confined the area of MBI-X is assumed to have 0-degree dip angle due to several uncertainties that can occur in the actual condition. At the same time, the applied fracture permeability refers to the Darcy equation with corrected PI toward enthalpy and pressure corresponds to the thermodynamic state, published by Pasikki et al (2017). Using equation (1) and with parameters of; total calibrated PI" of MBI-X at 4.83E-12 m3, well radius (rw) based on actual condition at 0.26 m, drainage radius (re) to be assumed at 500 m, and the thickness (h) is assumed as the height between the top of liner (TOL) and the deepest feedzone at 213 m, a fracture permeability (k) about ~30 mD is obtained. This is the fracture permeability used for MBI-X's local area in the model.

$$k = PI" \; x \; \frac{\ln\left(\frac{re}{rw}\right) - \frac{1}{2}}{2\pi h} \qquad (1)$$

Likewise, the transmissivity multiplier is set to be modest, assumed to be 30% in this case, to indicate a weak connection between MBI-X to MBD-X and WWQ-X.

3. SIMULATION RESULTS

3.1. Initial State Model

The fundamental step in reservoir modeling is to ensure that the model is aligned with the actual initial condition, which can be achieved by changing the configuration of boundary condition to match the model's pressure and temperature throughout the elevation. In this case, the actual initial condition to be matched refers to the first stabilized PT static survey of MBI-X that took place after completion of drilling campaign in June 2021. By setting the start-time of the model as entirely liquid, the model is run for 47500 years to reach pseudo-steady state

condition. Figure 8 exhibits the matching result between the model and the actual measured data with respect to MBI-X, MBD-X, and WWQ-X.

In overall, the initial state model shows good match in term of pressure and temperature with the actual data of MBI-X and the two nearby wells. The higher actual liquid column in MBI-X is more caused by the existence of a non-evaporated fluid post-drilling (water dead leg).

3.2. History Matching Model

The history matching procedure is used for an additional calibration once the initial state model has been verified to fit the real data. The history matching process is carried out in a separate model using INCON (initial condition) corresponds to the end time of the initial state model, and run until early of 2024. The historical shut-in well head pressure (SI WHP) or the steam cap reservoir pressure is the parameter to be matched; The simulated SI WHP can be calculated by using exponential regression from the reservoir pressure of the steam cap block, with a slope of -4.9718 x 10-5 bar/m referencing to the study of Acuna and Pasaribu (2010). Thus, since the wells have been operated dynamically with variety of WHP throughout the time, the pressure response from the model that will be looked at only occurs while shut-in condition which can be represented by the peak of solid line seen in figure 9.

Initially, the applied static properties shown in table 1 does not give a proper match in the history matching, given that the MBI-X pressure decline in the model is still not sharp enough comparing to the actual measured data. This indicates that the recharge for MBI-X is still large enough to maintain its pressure overtime. Hence, the transmissivity multiplier must be further reduced to minimize the lateral recharge from the surroundings, as well as increasing the fracture spacing to limit the recharge from the matrix. On contrary, the fracture permeability does not significantly impact the pressure decline overtime but has a stronger effect on the pressure drawdown and build-up during the dynamic changes of the wells.

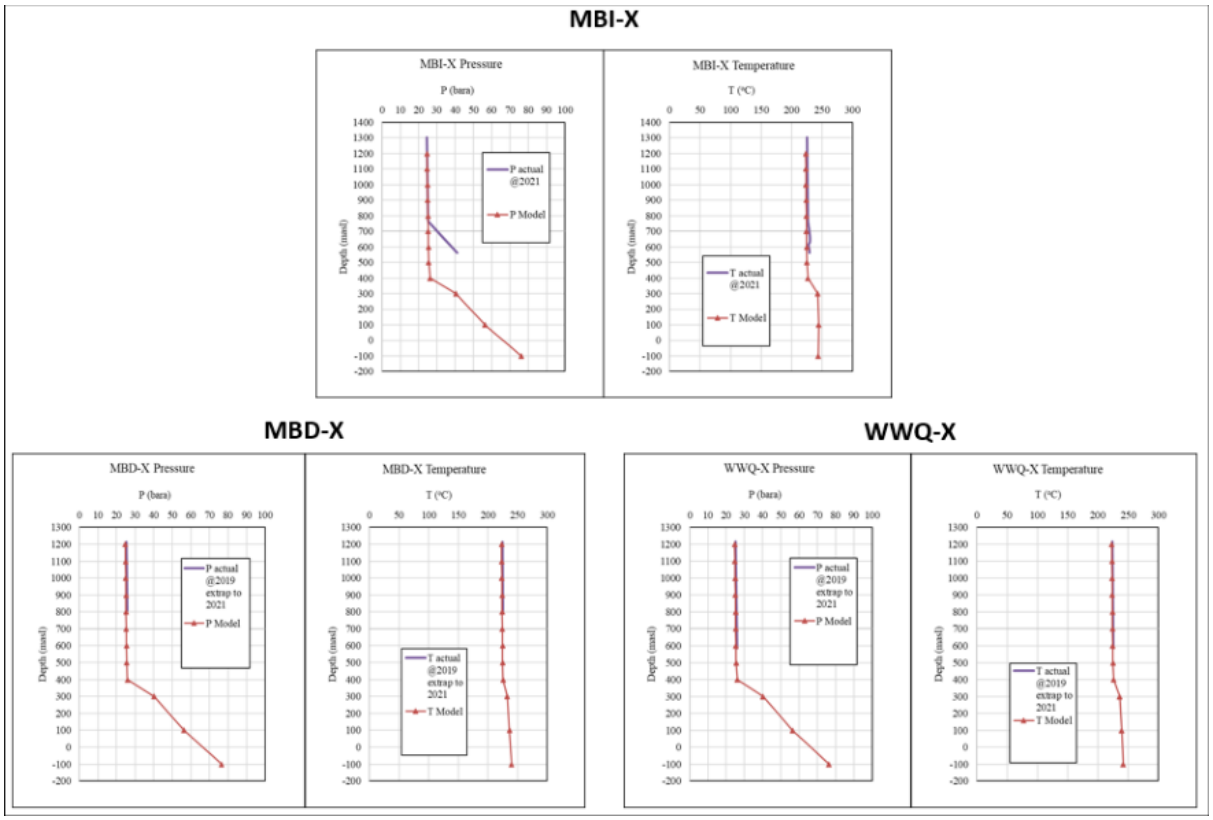

Figure 8: Initial State Model Result.

Figure 9 illustrates how a model with new transmissivity multiplier and fracture spacing given in table 2 produces the best results for MBI-X after several trials to match the actual data. However, in comparison to MBI-X's result, the WWQ-X and MBD-X results still show less accuracy in the history matching. This might be because the model only partially accounts for their two reservoirs.

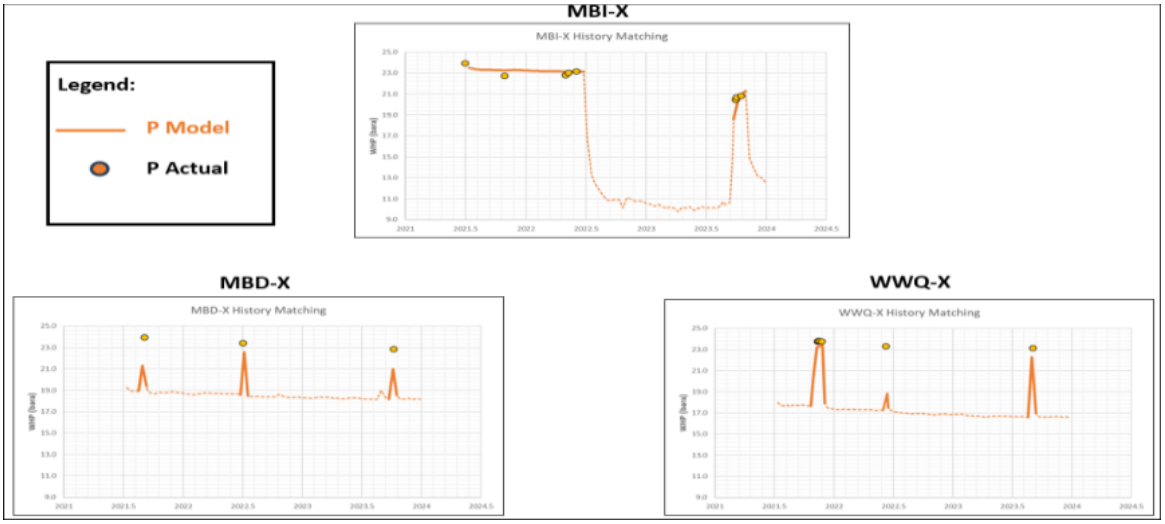

Figure 9: History Matching Model Result.

Table 2: Final Rock Properties of the Model.

Static Properties	Value	Remarks
Fracture Permeability X,Y,Z	• Within MBI-X: 30 mD • Outward MBI-X: 100 mD	The same as Initial Properties in Table 1
Transmissivity multiplier X,Y,Z	Surrounding MBI-X: 1%	Reduced from 30% to 1%
Fracture spacing	• Within MBI-X: 330 m • Outward MBI-X steam cap area: 50 m • Outward MBI-X liquid area: 110 m	Only increasing within MBI-X from 220 to 330 m
Matrix Permeability X,Y,Z	5 µD	The same as Initial Properties in Table 1
Fracture Porosity	50% with 2% bulk volume	
Matrix Porosity	7% with 98% bulk volume	

To gain a better understanding on how several parameters affect the pressure response over time, sensitivity analysis is developed and explained in detail. The sensitivity analysis focusses to see the effect of parameters that have a control in the mass transfer and heat transfer both on the intra block (i.e., fracture spacing) and on the inter block (i.e., fracture permeability and transmissivity multiplier). Furthermore, the sensitivity analysis will give a conclusion which of these parameters that have the biggest impact in the history matching process.

3.2.1 Transmissivity multiplier sensitivity analysis

Transmissivity multiplier is responsible in controlling both anisotropic permeability and the thickness in a specified block, meaning that the lower transmissivity multiplier can create a more flow restriction throughout the porous medium. Usually, this parameter is used to apply reservoir heterogeneity such as making local compartment areas and barriers. In this model, it is designed to enclose the MBI-X area as if it has its own localized bounded reservoir with lower drainage volume as shown in figure 7. Corresponding to figure 10, the smaller the transmissivity multiplier, the weaker the connection between MBI-X to MBD-X's and WWQ-X's reservoir. It causes more pressure drop during production and less pressure rebound during shut in as impact of less pressure support from the surrounding reservoir.

3.2.2 Fracture spacing sensitivity analysis

In contrast, fracture spacing is one parameter that can control the intra-block mass and heat transfer between the fracture and the matrix. The larger the fracture spacing, the less plentiful the series of fractures throughout the block, allowing for minor matrix-fracture mass and heat exchange, which creates less recharge coming from the matrix. Thus, the reservoir pressure should have become less sustainable in the long run. According to Lippman et al (1985), fracture spacing can be varied and can reach a value up to 1640 ft or 500 m. Since fracture spacing

of 330 m is sufficiently large, the other two parameter that is used for the sensitivity analysis are less, which are 60 m and 220 m. Figure 11 proves by applying smaller fracture spacing within MBI-X area, it gives MBI-X's pressure to decline more gradually as time passes.

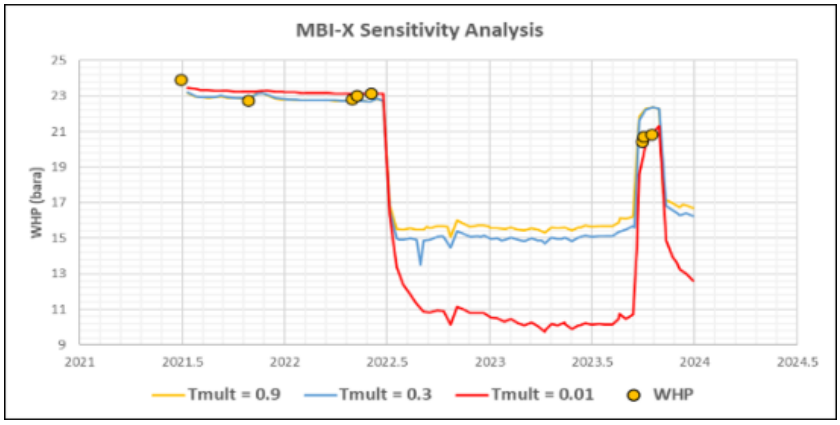

Figure 10: Transmissivity multiplier Sensitivity Analysis.

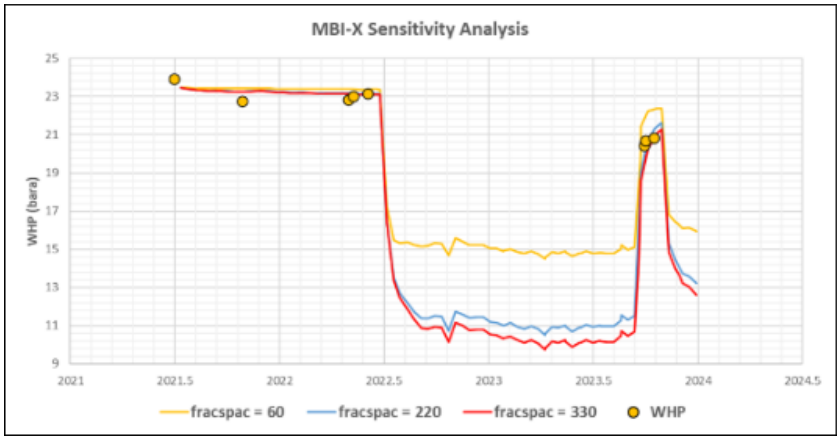

Figure 11: Fracture spacing Sensitivity Analysis.

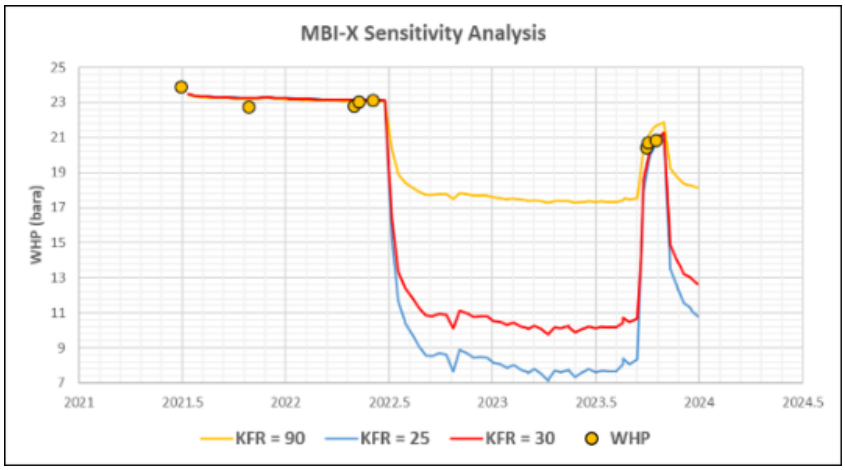

Figure 12: Fracture Permeability Sensitivity Analysis.

3.2.3 Fracture Permeability sensitivity analysis

Furthermore, fracture permeability manages to control the ability for a fluid between fractures internally. Even though, there is also an interaction between fracture and matrix, the fluid movement between these two is dominantly controlled by the matrix permeabilities, especially when the fracture has only 2% of the bulk volume. Figure 12 shows the sensitivity analysis in fracture permeability from 25 to 90 mD. Based on figure 12, it is clear that adjusting fracture permeability affects the pressure drawdown and build up during flowing and shut-in periods, respectively, instead of pressure decline over time itself. The small effect on the pressure over time is due to insignificant contribution of the fracture properties toward the intrablock fracture-matrix along with the

continuously limited recharge between inter-blocks due to the very small transmissivity that surrounds the drainage volume of MBI-X.

Therefore, amongst these three parameters, transmissivity multiplier and fracture spacing are the two parameters that give the most impact in the pressure decline while shut-in overtime. However both parameters must be combined in order to get the best match with the actual data. Eventually, it can give a sense that MBI-X reservoir tends to have a local enclosed reservoir with lesser series of fractures.

4. CONCLUSION

Amidst the tremendous performance of Wayang Windu field over 20 years of production, there is one newly drilled well, MBI-X whose performance differs to the neighboring wells (MBD-X and WWQ-X) despite relatively close distance. This has been proven from the pressure and production response of MBI-X that has declined more promptly compared with the two nearby wells. In addition, Pressure Transient Analysis (PTA) is carried out and can confirm that MBI-X's reservoir is finite, constrained by impermeable faults with approximately 200 meters in distance. However, PTA could not give a clear insight where these faults are located.

Reservoir Simulation has some advantages in tackling those uncertainties; not only it can confirm that one well MBI-X is located in a local finite area, but it can also give an insight on how the structure looks like. The outcome of this simulation has a crucial role to plot the next MUW in the upcoming drilling campaigns, especially at the surroundings of MBI-X since it has a prospective connectivity to the main production area according to various kinds of surveillance activity. After conducting a sensitivity analysis on numerous parameters in the numerical model, it is validated that MBI-X has a lower drainage volume after applying very low transmissivity multiplier in every corner of the area, and has fewer series of fractures by increasing the fracture spacing. Although lower fracture permeability may contribute to a slight effect in the reservoir pressure, the model suggests that the variance in MBI-X performance is primarily driven by changes in the reservoir volume and the counts of fracture.

In conclusion, validation through this simple process model can bring a valuable guidance for well targeting to not go toward the area. Based on this analysis, the area needs to avoid can be approximately up to ~124,000 m2 which is within the 100 m buffer damaged zone from Bedil-Gambung and Cibitung Splay Fault. However, in terms of the elevation, the confined boundary can only be confirmed in the steam cap zone with 0 degrees of dip angle due to the unavailability data in the liquid zone. Yet, this result is not definitive, and future make-up well (MUW) campaign must also contribute to validate the local compartment area. Continued data monitoring must be done to get the model closer to an imitation of the actual condition, especially on the lateral extension; this can be supported by kinds of activities such as drilling more brine toward that area and gathering more geochemistry and geophysical data.

Keywords: Pressure Transient Analysis, reservoir simulation, TOUGH2 simulator, fall off tests

ABSTRACT

Pressure transient analysis (PTA) is a very powerful tool in the oil and gas industry that allows us to acquire reservoir parameters such as permeability, reservoir boundary, and skin factor in a more efficient manner. This valuable information serves as a guide for assessing the extent of drainage areas, providing initial structural insights, and informing decisions related to well stimulation. However, the common analytical method for PTA is designed more for an isothermal well, which means that it might not be reliable in non-isothermal wells like geothermal wells. Hence, in this study, alternatives of creating a 2D or 3D numerical model that incorporates phase changes and heat flow is applied, with the model is created radially using logarithmically spaced radius with the TOUGH2 simulator. While the common analytical method can also be utilized in geothermal wells in the end, the results can be deviating as it does not involve the effect of temperature that amends the PVT data of the fluid (e.g density and viscosity). This is proven from this study as the skin factor often overestimated, potentially leading to misinterpretations in the degree of scale that damages the reservoir. On the other hand, this numerical method can also be more versatile while it comes to non-ideal data inputs, such as when encountering pressure bumps resembling of steam inflow during the early of fall of test. By that reason, this study also shows the example to overcome such a challenge.

1. INTRODUCTION

1.1 Background

In the oil and gas industry, PTA has been trusted for many years as one of the fastest methods to identify some reservoir parameters such as skin factor, reservoir permeability, and reservoir boundary or the drainage area. Two main inputs for PTA are the profile of pressure and flow/mass rate while changing the wellbore condition. The well condition changes can be varying such as changing from production to shut-in (build-up test), shut-in to production (drawdown test), shut-in to injection (injection test), and injection to shut-in (fall-off test). The profile used for the analysis can be in a form of single test, changing from 1 condition to another or by including several multi-rate tests or what it is so called as the superposition. The application is mostly done through analytical approaches involving mathematical correlations, with semi-log curve and log-log derivative type curve being the two most widely used approaches. The concept in either approaches is mainly the same, where the pressure as the time flow/mass rate changes, have been converted into a semi-log or log-log curve in particular ways, then it gives several variables (e.g. slope, or Pd, td, Cd, etc) that can be used to calculate the reservoir parameter such as skin factor and permeability. However, in some contexts, the reservoir condition can be complex such as having a finite boundary in a specific geometry, more heterogeneous, or fuggy which need more advanced formulation. But, the PTA on those cases can be easily done nowadays with an analytical PTA software.

Despite of the widely used of analytical PTA software in the oil and gas reservoir, this software might not be reliable in the geothermal reservoir. The reason is simply because all the mathematical correlations provided in this software is only applicable in an isothermal condition as it does not accommodate the fluid properties changes (e.g. density, viscosity, etc) due to the thermal changes. Kaya et al (2019) demonstrate that performing PTA using analytical PTA software can lead to a significant overestimation of reservoir properties, particularly the skin factor. This overestimation can mislead interpretations regarding the presence and scale of skin in the reservoir.This must be carefully taken into account, as positive skin factor ($s>0$) can lead the decision to conduct several types of workover project that can costs up to thousands or even million of dollars. With this condition, expertise such as McLean and Zarrouk (2016), have found a new approach through a numerical modeling so the PTA can be done in the geothermal reservoir with more accurate and reliable results. The numerical modeling is executed using a simulator that involves the thermal changes or thermodynamic conditions that is called as TOUGH2; as the model is created radially with 1 layer starting from a block size with the smallest radius in the middle, considered as the well, and becomes logarithmically larger toward the reservoir for a smaller running time.

Wayang Windu field, located in South Bandung, Indonesia, is one of the largest geothermal producers in the world. As of 2024, it generates electricity with a capacity of up to 230.5 MW and plans to expand its generation capacity in the coming years.In this study, one until two wells with different condition is used to conduct PTA, especially with numerical approach along with the assessment to its reliability compared to the analytical approach. The study starts from showing how the numerical model has been set up, showing the results and sensitivity analysis, and the comparison to the analytical approach. In addition, one from the two wells used, has a unique condition where there is an anomaly pressure bump due to the presence of steam inflow at the fall-off test profile; thus, this study also shows the application of numerical PTA in this non-ideal condition.

1.2 Study Case

For geothermal reservoir, sometimes fall off test and injection test are the two out of four tests that are more suitable, as the build up test and drawdown test can let the steam inflow to set the pressure profile apart from ideal. Thus, for this study, it uses fall off test for as the input of the model. There are two cases used for numerical PTA with TOUGH2, which are MBA-X with an ideal pressure profile where there is no any disturbance during the data acquisition, and WWA-X with a non-ideal pressure profile due to the presence of steam inflow; the study in MBA-X is more robust which includes sensitivity of several variables, while WWA-X only acts as an additional case showing on how to handle with non-ideal input. Before setting up the model for each case, a brief background on MBA-X and WWA-X is provided in the following section.

MBA-X is one of the steam wells that is located in the northern main production area with a current production and initial production at 7 kg/s and 13 kg/s, respectively. The drilling of this well had been completed on Jan 2019 with a total depth (TD) of 1480 mMD. However, after being produced for several years, the maximum clearance depth (MCD) got shallower which is now lying at 1220 m. Preliminary assessment suggests the shallowing MCD is due to rubble formation build-up and it can be the main reason for the production to drop ~6 kg/s. By this reason, an initiative to do PTA in this well has been carried out to see if there is also a flow assurance issue within the reservoir aside the one that takes place in the wellbore as result of the rubble formation. Fall off test along with PTS injection have been conducted on Dec 2022 (injection rate: 48 kg/s). According to the PTS injection result, there are two inflows observed at 1160 m and 970 m above sea level, indicated by the temperature and spinner response. In addition, inferring the steam inflow can disturb the ideal fall-off test pressure profile, the pressure at the logging hanging depth closed to the MCD has no steam inflow (injection pressure > shut-in pressure); so, there is no issue to start the fall-off test in that particular depth. Figure 1 and 2 shows the MBA-X's PTS profile. On the other hand, figure 2 shows the MBA-X's Fall Off Test Profile, started from injecting a condensate at 48 kg/s, then it stopped letting the pressure to fall off until it reaches the reservoir (shut-in) pressure. This Fall Off test profile, which is the one that will be used to calibrate the model.

In another scenario, WWA-X production also tends to drop quite promptly 10 months after the well online from the start. Although the production transient effect might be the main cause here, conducting PTA to see the flow assurance issue within the reservoir can be one good solution, especially to WWA-X as one of the biggest two-phase producers in Wayang Windu field (current production 25 kg/s). The same as MBA-X, the PTA is executed through the data from Fall Off test and it takes place on September 2022 alongside PTS injection.

However, during the implementation of PTS injection, the temperature response still shows a gradual increase as it goes deeper towards the MCD, meaning there is still a possibility of steam inflow to exists and can disturb the Fall Off test pressure response (see figure 3). Consequently, the steam inflow did disturb the Fall Off Test and the profile can be seen in figure 3. Last but not least, in terms of the testing period, the fall off test is still at the early stage (wellbore storage) since it can be continued due to the steam inflow and an operational issue.

2. DESIGN STRUCTURE

2.1 MBA-X numerical design structure

For MBA-X, referencing from the study of McLean and Zarrouk (2016), a single-layer radial model has been developed, with a block of smaller radius representing the well located in the center of the model, which then spatially extends logarithmically towards the reservoir. The case has been done in two discrete models; one that is the condition changes from shut-in to injection (injection test) with a period about 1 day, the other is when it changes from the injection to shut-in (fall-off test) for 4 days. In addition, the grids are classified into three lithologies as each lithology has its own properties, which are the well, the skin (near-wellbore) area, and the reservoir area as can be seen in figure 4.

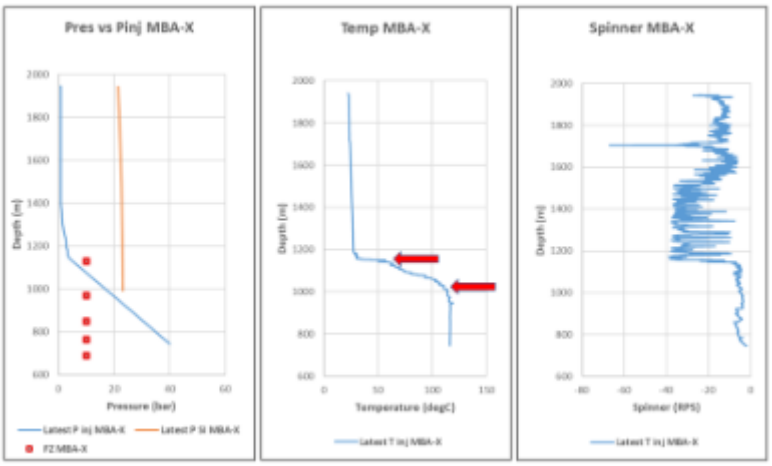

Figure 1: MBA-X's PTS profile.

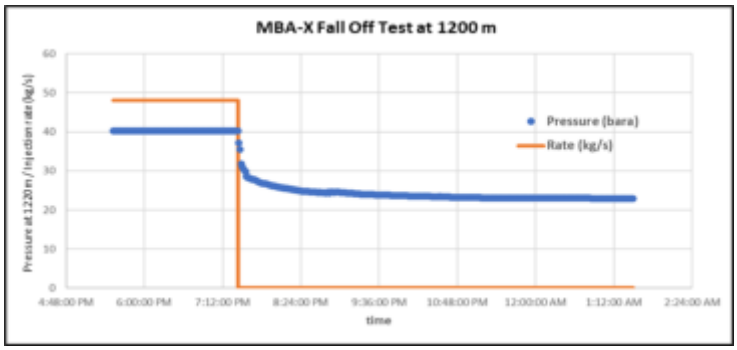

Figure 2: MBA-X's Fall Off Test Profile.

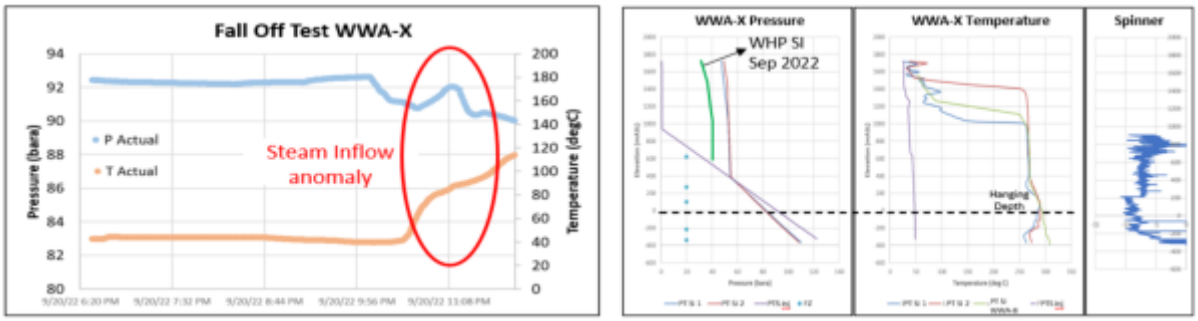

Figure 3. WWA-X's Fall Off Test Profile (left) and PTS profile (right).

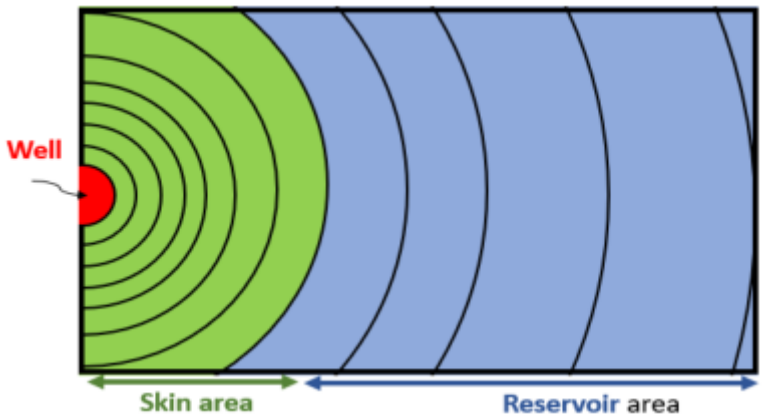

Figure 4: the grid model of PTA MBA-X numerical model.

In addition, since there is no any boundary seen in the pressure profile, the radius of reservoir is designed spatially large with no impermeable boundary in the end; meanwhile the skin does not extend far from the wellbore lying at 4 m in radius. The model has a total of 100 blocks consists of 15 blocks up to the end of the skin area, and 85 blocks applied on the rest of the reservoir. Although in an ideal case, the porosity of a well must be 100%, it can create instability in the TOUGH2 simulator; so, the porosity is applied with a high number as possible, such as 90%. The permeability assigned in the model will act as the MBA-X's true permeability which will then be compared to the analytical PTA. On the other hand, by knowing both skin permeability and reservoir permeability, the skin factor can be estimated simply with a common skin factor formula that is derived from mathematical models describing fluid flow in porous media as follows:

$$s = \left(\frac{kres}{ksin} - 1\right)\ln\left(\frac{rskin}{rwell}\right) \quad (1)$$

The well block is also being applied with a rock compressibility or can be called a well compressibility to accommodate the wellbore storage effect in the wellbore. The compressibility of the well, as well as the skin and reservoir permeability, incorporates values determined through extensive calibration or sensitivity analysis to align with the pressure derivative type curve created; the sensitivity study is also provided in later section. In summary, table 1 shows the detailed inputs of the reservoir model including the reservoir parameters after sensitivity study.

Table 1: MBA-X's assigned reservoir parameters and injection parameters.

Properties	Value	Remarks
h (thickness) | Depth reference @ 1200 m	300 m	Based on actual thickness from TOL to MCD
well radius (rw)	0.22 m	Based on actual
skin radius (rs)	4 m	Logarithmically spaced radius that consists of 14 blocks
reservoir radius (rres)	100,000 m	Logarithmically spaced radius that consists of 85 blocks
Ø Reservoir	10% (single porosity)	
Ø Well	90%	
Well Compressibility (Ct)	9 x 10^{-8} Pa^{-1}	For capture wellbore storage
Initial P reservoir	22.88 bar	From PT Shut-in
Initial T reservoir	219 degC	From PT Shut-in
Calibrated skin permeability	16 mD	Based on calibration/sensitivity study
Calibrated res permeabiliy	10 mD	Based on calibration/sensitivity study
Injection rate	48 kg/s	
Enthalpy of Mass in	546 kJ/kg	Refer to the T mixture during Fall-off test

2.2 WWA-X numerical design structure

WWA-X's model framework is much more complex than MBA-X as the radial model must be created in 3D, containing at least three layers to accommodate several zones such as steam zone, boiling zone, and brine zone. In this model, 5 layers are created as the first two layer act as the steam zone with thickness of 400 m, then the following 2 layers as the boiling zone thickens at 300 m, and finally the rest 200 m layer as liquid zone as can be seen in figure 5.

The concept WWA-X radial model is generally the same as MBA-X, but only it is built more in a 3D model consisting more than 1 layer. The way the water being injected into the model is also treated different to MBA-X's model, where the water at 30 kg/s is injected through an extra cell that will go down quite straightly toward the three well blocks underneath. Whereas for the steam zone blocks (400 meters at the top of the model), it is made to have higher lateral permeability so it can go straight to the liquid zone through the well blocks that have higher Z permeability. To simulate the steam to entering the liquid layer can be a challenge and full of uncertainty; the concept that previously discussed is just one way to make the steam so it can enter the liquid zone. The details of the assigned properties can be seen in the table 2.

Unlike the well testing in MBA-X that use a single test, WWA-X well testing consists of several multi-rate injection tests before implementing the fall off test. Those multi-rate tests are included as the field data to be matched with the model; the well testing in WWA-X can be seen in figure 6. Lastly, the depth reference to extract the injection and fall-off test pressure refers to -16 mASL, which is the deepest layer corresponds to the model.

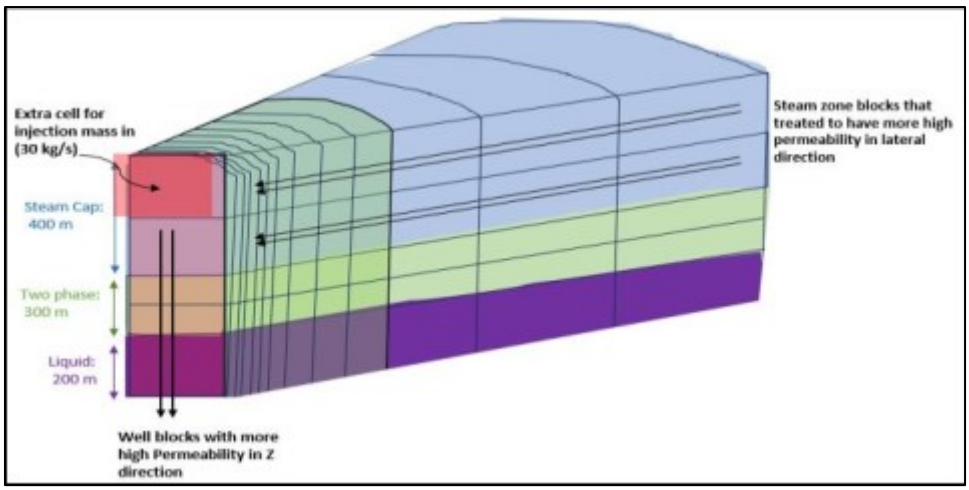

Figure 5. the grid model of PTA WWA-X Model (Additional Case).

Table 2: WWA-X's assigned reservoir parameters and injection parameters.

Properties	Value	Remarks
h (thickness)	900 m (400 m of steam cap, 300 m of boiling, and 200 m of liquid)	Based on actual thickness and PT SI survey
r skin (steam cap, boiling, liquid)	14 m, 24 m, 24 m	
Ø Reservoir	20% (single porosity)	
Ø Well	90%	
Well Compressibility (Ct)	6 x 10-8 Pa-1	For capture wellbore storage
Initial P reservoir (layers: 2 steam cap, 1 boiling, 1 liquid)	54, 54, 61, 71, 85 bara	From PT Shut-in
Initial T reservoir (layers: 2 steam cap, 1 boiling, 1 liquid)	269, 270, 276, 286, 288 degC	From PT Shut-in
Calibrated skin permeability (layers: 2 steam cap, 1 boiling, 1 liquid)	250 mD for all	Based on calibration/sensitivity study
Calibrated res permeabiliy (layers: 2 steam cap, 1 boiling, 1 liquid)	50, 50, 30, 10, 10 mD	Based on calibration/sensitivity study
Injection rate	30 kg/s	
Enthalpy of Mass in	159 kJ/kg	Refer to the T mixture during Fall-off test

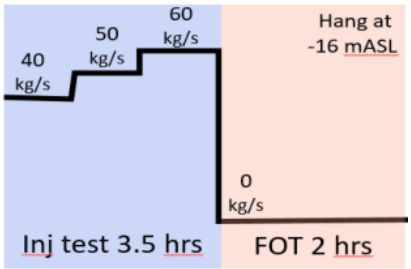

Figure 6: WWA-X multi-rate tests and fall-off test.

2.3 Analytical PTA

Furthermore, for the analytical PTA, the pressure derivative curve that is once created by the model is then being used as the same derivative curve to estimate the skin factor and the permeability through the analytical PTA software. However, the reservoir distance will not be the parameter to be compared in this case, as the pressure profile still shows an infinite acting behavior for MBA-X, and it is even still in the wellbore storage stage for WWA-X. Ideally, the fluid properties of water should have changed as the temperature changes. One complexity in the analytical PTA is that the temperature is a fixed parameter, meaning the viscosity and density will also be fixed. Figure 9 shows the relationship of both viscosity and density vs temperature developed by Alambra (2022).

As a result of figure 7, it creates a confusion which temperature should be chosen in the analytical PTA since MBA-X has a temperature ranging from 129 degC (injected) to 220 degC (reservoir temperature). Thus, in order to be more moderate, the temperature applied is the average between the two which is ~170 deg C, creating the viscosity to be ~0.2 cP according to figure 7.

3. RESULTS AND ANALYSIS

3.1 Final Result of PTA MBA-X

After doing sensitivity study of several parameters, the best match is the model with well's grid rock compressibility of 9 x 10^{-8} Pa^{-1}, alongside with skin permeability and reservoir permeability of 18 mD and 11 mD, respectively, similarly what is showed in table 1 in the previous section. By using those permeabilities and formula 1 as described in the section 2, it gives an approximate skin factor of -1.1; this confirms MBA-X does not have a wellbore damage in the reservoir and no need to be stimulated (s<0). Figure 7 illustrates the comparison between the model and field data in regards of the pressure profile, temperature profile, and the derivative pressure curve.

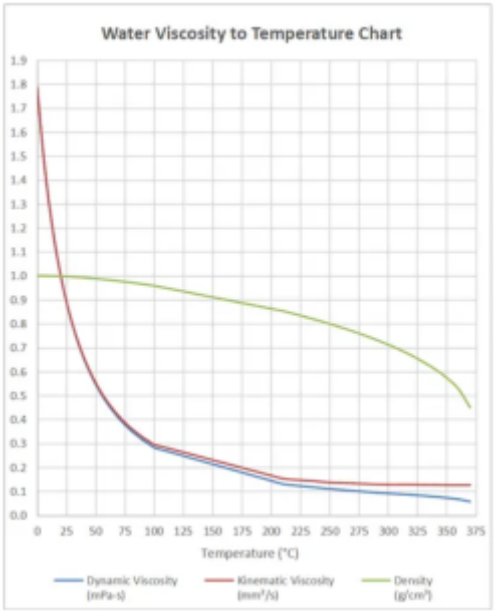

Figure 7: Relationship of water viscosity and density vs Temperature, Alambra (2022).

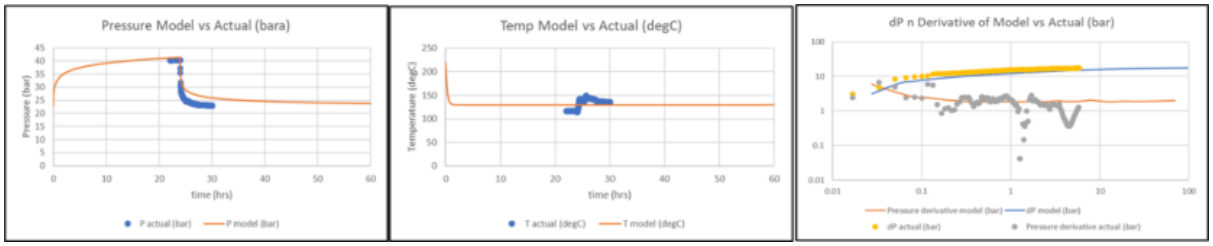

Figure 8: PTA MBA-X Model vs Actual Results.

According to figure 8, the pressure and temperature of the model generally matches the measured data. Since the 1 layered model has no mass outs such as outflow in a form of extra cell or production, it barely covers the heated-up temperature (temperature increase) corresponding to the temperature field data during fall-off test as seen in figure 8. Due to that reason, the enthalpy of injection is set to be the water enthalpy that has been mixed with steam inflow during the fall-off test (546 kJ/kg), creating it is much more matched with the late-time temperature. The conversion from pressure profile to the derivative curve and pressure drop on the right graph of figure 8, which is the orange line and blue line, respectively, is supported by the conversion feature in a PTA analytical software; those two graphs resulting a satisfactory match with the measured data. The good match of this comes after making several adjustments/sensitivities in the well compressibility, and skin factor. Thus, the next sub-section will discuss the effect of well compressibility and skin factor changes alongside with the other parameters.

3.2 Sensitivity Study of PTA MBA-X

The parameters used for the sensitivity analysis are layer thickness, well-block compressibility, temperature injection, well radius, and skin factor, where every one of them can be illustrated in figure 9. Transmissivity or the overall flow capacity which is denoted as k.h is one of the most important parameters to be monitored. Thus, when thickness (h) decreases for a given permeability, it surely decreases the flow capacity allowing the pressure drop to be larger alongside with the increase of the derivative curve. On the other hand, in the dynamic sense, higher well block compressibility (considered as wellbore storage) allows a higher compression into the fluid resulting it to move slower in response. This makes the pressure drop and derivative curve become delayed and shifted more to the right side. Similarly to the reservoir thickness, the well radius is also the other parameter that controls the volume. But, unlike the reservoir thickness that covers the entire reservoir, well radius only covers the small part within the well-block. This creates the result of sensitivity is the same with thickness where the higher the wellbore radius, the larger the pressure drop and derivative curve, but only it has insignificant effect. The skin factor and injection/mixing temperature are two important parameters that show a similar response in the sensitivity analysis. Both, the increase of skin factor and the decrease of mixing temperature, produces a higher hump at the early stage of the derivative curve profile.

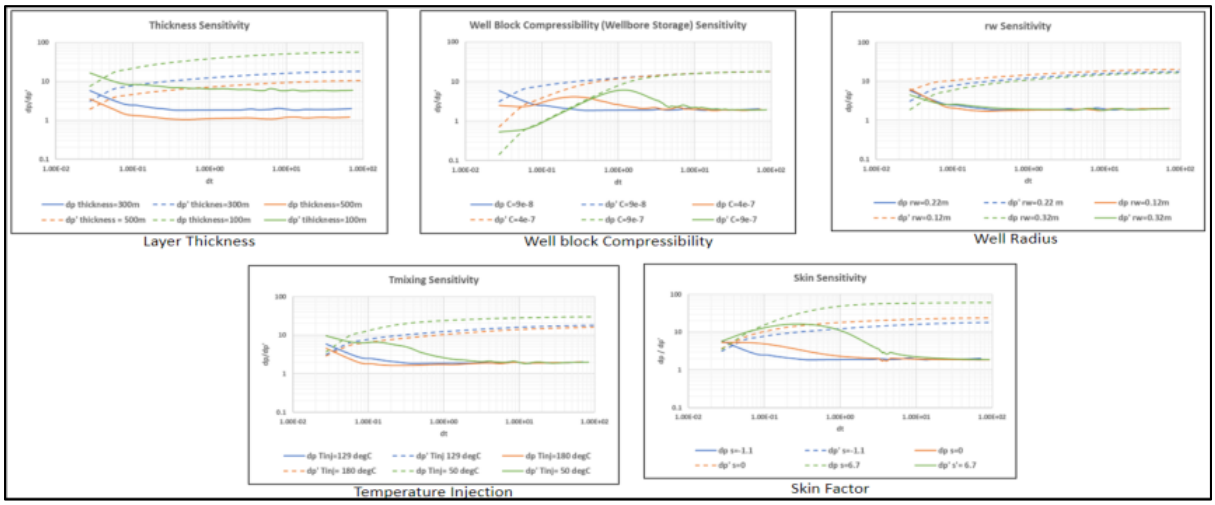

Figure 9: PTA MBA-X Model Sensitivity Analysis.

Table 3: Skin Sensitivity Analysis of MBA-X Model.

Numerical skin factor	Analytical skin factor	Numerical K (mD)	Numerical K (mD)
-1.1 (matched)	0.2	10	16.8
0	1.5	10	15.5
6.7	7	10	9.4

Table 4: Temperature Sensitivity Analysis of MBA-X Model.

Model Temp (degC)	Model skin factor	Analytical skin factor	Model K (mD)	Analytical K (mD)
129 (matched)	-1.1	0.2	10	16.8
50	-1.1	3	10	15.3
180	-1.1	-0.5	10	16.8

Table 3 and table 4 shows the comparison results between the numerical model and analytical approach with respect of the skin factor and the injection temperature, respectively.

Based on the three scenarios of skin sensitivity analysis (-1.1, 0, and 6.7), all the three shows an overestimation of skin factor. On the other hand, the slight difference of the permeability is more derived from the uncertainty of the applied viscosity in the analytical approach.

Moreover, since the decrease of injection/mixing temperature also makes a higher hump at the early stage of the pressure derivative curve, it can mislead the analytical PTA interpretating as an increase in the skin factor. This is proven from the table 4, especially when the mixing temperature being 50 degC, the analytical PTA concludes a positive skin factor even though it should have been a clean formation.

3.3 Final Result of PTA WWA-X (Additional Case)

Different to MBA-X, WWA-X does not have analytical PTA to be matched with as the very early time response in the pressure profile can produce a lot of uncertainty while determining the results.

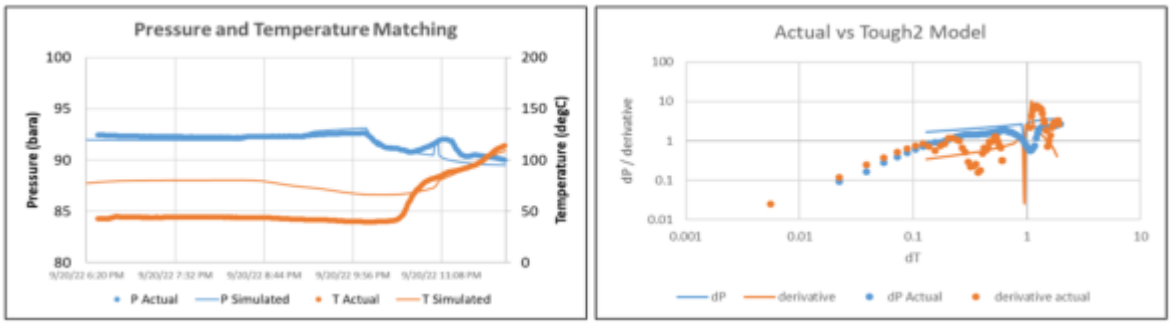

Figure 10: PTA WWA-X Model vs Actual Results.

To have a limited fall-off test pressure response (stopped at the early stage) together with acquiring a pressure bump due to steam inflow anomaly, makes the numerical modeling be somewhat more challenging. Moreover, creating a model with multiple layers may prevent pressure and temperature stabilization. Corresponding to the result seen in figure 10, the pressure overall shows a good match with the measured data. The model also depicts the pressure bump due to the steam inflow with the right timing, yet not the duration which is possibly due to the instability in TOUGH2 when it comes to an extremely low temperature or vacuum condition. This pressure bump has heavily been controlled by the reservoir permeability in the steam cap and it is also responsible to the slightly overmatch of the temperature profile; where the increase of steam cap reservoir's permeability allows the pressure bump to be more seen, yet the temperature becomes larger. Then, with those permeabilities, it creates a skin factor as -4.5 (clean formation) with derivative curve as can be seen on the figure 10.

4. CONCLUSION AND RECOMMENDATION

4.1 Conclusion

This paper shows the application of numerical PTA in a couple of Wayang Windu wells with one well whose result is compared with the common analytical approach. As a result, application of PTA using numerical and process model is something that will be high interest for geothermal reservoir since it has accommodated the thermodynamic system or the changing of fluid properties due to thermal change. Based on this study, also consistent with the study of Kaya et al (2019), the skin factor calculated by the analytical approach is mostly overestimated in every case which surely can mislead the decision of workover that can spend thousands of dollars or more. For example, as lowering the injection/mixing temperature has the same response as the increase of skin, it can conclude the reservoir to have a wellbore damage in a form of scale/skin regardless how clean the reservoir is. In addition, numerical PTA at times can be more versatile than the analytical approach for geothermal reservoir. To put it another way, it can be used to match a non-ideal pressure profile such as having a pressure bump due to the presence of steam inflow at the early stage of the fall-off test in particular two-phase well. However, in this context, it must be made by at least 3 layers that consists of steam cap, boiling, and liquid zone, where the pressure and temperature might not be stabilized as the initial state condition.

4.2 Recommendation

Implementing Fall-Off Test in a geothermal well must be extremely careful, especially when it deals with a steam well or well whose feedzone/series of fractures is many. Thus, it needs a deeper assessment while setting the hanging depth, such as ensuring there is no inflow indicated by comparison between injection pressure and shut-in pressure, or set it at a point where it has stabletemperature profile. In addition, in spite of the more reliable result from the simplified PTA numerical model in this study, the thermal effect is only responsible to the change of fluid properties. Meanwhile, on an actual case, the thermal effect can affect the rock properties such as rock matrix expansion that can reduce the pore size. Therefore, it is suggested to consider this for a more accurate and representative results in the future.

Keywords: 3D Conceptual Model, Geothermal Reservoir Modelling, Natural State Simulation, Maritaing

ABSTRACT

Maritaing is one of the potential geothermal areas in the eastern part of Indonesia, located in Alor Island, East Nusa Tenggara. Previous studies indicate that the green field has 17 MW of hypothetical resources. This study aims to create a conceptual model of the geothermal prospect area by combining geology, geophysics, and geochemistry data. The model is built based on a digitalized conceptual model using Leapfrog and a natural state model through numerical modelling using AUTOUGH2. Furthermore, the natural state model is calibrated by matching the temperature of the top of the reservoir from geothermometer data and surface manifestations. In accordance with the parameters obtained from the numerical modelling, a new conceptual model of the Maritaing geothermal prospect area successfully represents the heat and mass flow of the system.

1. INTRODUCTION

The Maritaing geothermal area is one of the potential fields that is situated on Alor Island, East Nusa Tenggara province. The field is located at 800 km from the Ulumbu field and about 700 km from the Maritaing area. The field is about 5 km away from the port. Preliminary studies have been conducted regarding its geology, geophysics and geochemistry (Rahadinata et al., 2017; Setiawan et al., 2015; Supriyadi et al., 2015). The system was confirmed to have a chloride-content hot spring, which is presumed to be in the up-flow zone. There are also several warm springs spread around the eastern and southern parts of the field (Supriyadi et al., 2015). The prospect area is 3 km^2 and the temperature of the reservoir is estimated to be 200°C.

This paper objective is to present an updated conceptual model of Maritaing reservoir through calibrating a natural state numerical model using AUTOUGH2 that tightly coupled with 3D digital conceptual model of the Maritaing field in Leapfrog Geothermal. The 3D digital conceptual model was based on previous tentative conceptual model and involving data of geological, geophysical surveys and geochemical studies. Several steps were conducted to build the 3D conceptual model including set up the structures, rock types, alteration rock, and surface features. This 3D conceptual model was used as the basis for the numerical reservoir model. The calibration of the natural state model was according to the geothermometer and surface features data.

2. FIELD INFORMATION

2.1 Geological Setting

The study by Setiawan et al. (2015) highlights the fact that the Maritaing geothermal field mainly consists of surface deposits, volcanic rocks and sedimentary rocks. Surface deposits which formed in this field are alluvium and lake deposits. The volcanic rocks mainly consist of andesite lava and pyroclastic flows. Conglomerates and limestone are the sedimentary rocks in the field. According to Noya et al. (1997), the Alor formation is composed of lavas and breccia, interspersed with tuff. The lavas include hornblende andesite, biotite hornblende andesite,

hyalo andesite, and pyroxene basalt. Strong alteration, mineralization, and sheeting joint structures are evident in specific areas.

The sequence of stratigraphic layers, starting from the oldest and going through to the youngest formation, including Katuwusi andesite lava, Katuwusi pyroclastics, Worakena andesite lava, Koya-Koya andesite lava, Koya-Koya pyroclastic, Inukamang andesite lava, Pakmana andesite lava, Meriaka andesite lava, Kunatena pyroclastic, Bulamaka andesite lava, Karitemang dacite lava, lake deposit, Karitemang pyroclastic-1, Karitemang pyroclastic-2, conglomerate, limestone and alluvium (Setiawan et al., 2015). Figure 2 depicts the distribution of rock formations on a geological map.

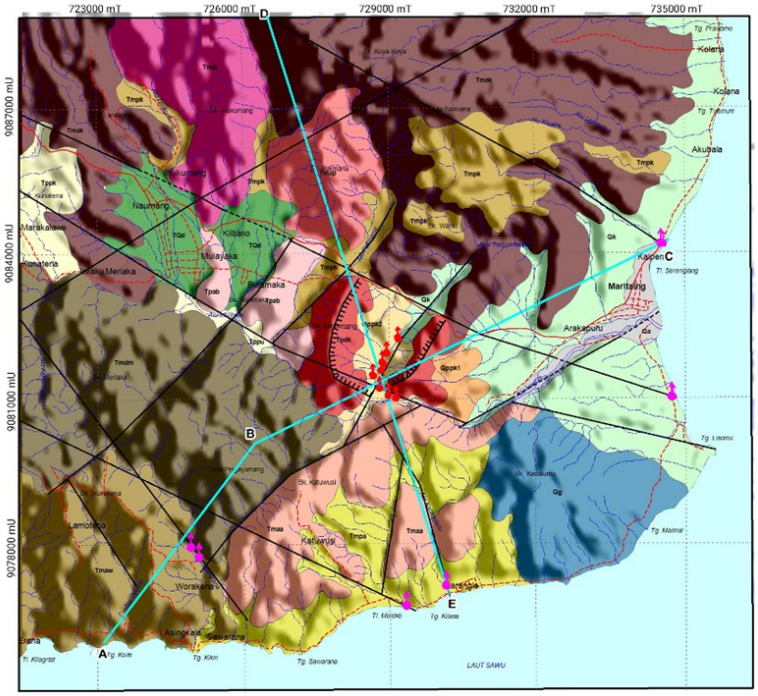

Figure 2: Geological map of the Maritaing geothermal field (Setiawan et al., 2015).

2.2 Geophysical Surveys

Various resistivity and gravity measurements have been carried out to determine the prospect areas (Rahadinata et al., 2017; Supriyadi et al., 2015). Gravity measurements were conducted in a closed polygon manner where each measurement always begins and ends with a measurement at the base point. The method has the ability to provide structural information in prospect areas. The Audio Magnetotelluric (AMT) measuring the response of the electric field and magnetic field to natural variations in the electromagnetic field with a frequency range from 0.1 Hz to 10 kHz was also applied. Low resistance values in a geothermal system identify zones of altered rock which serve as a caprock to prevent hot fluids from reaching the surface (Supriyadi et al., 2015).

Recent Magnetotelluric (MT) and Time Domain Electromagnetics (TDEM) surveys conducted by Rahadinata et al. (2017) aimed to gain subsurface data with more focus on the surrounding geothermal prospect area. TDEM and MT measurements were conducted at 42 points, which covers the entire estimated potential area. The TDEM distribution points were designed to be utilised for MT data correction. The distributions of resistivity values at different depths are shown in Figure 3.

At depths of 100 m and 250 m, conductive zones with resistivity <10 Ohm·m observed around the Maritaing hot spring location. They form a closed and extensive southwest-northeast pattern that corresponds with the geological structure presumed to control manifestations in the survey area. This conductive zone is believed to act as the cap rock layer for the Maritaing geothermal system. In comparison, low resistivity values in the south and east at 250 m depth are expected due to the sedimentary rocks that are not revealed at the ground surface. At 500 m depth, certain conductive zones around the manifestation begin transforming into a higher resistivity zone, which is believed to be a transition zone between cap rock and reservoir. Medium resistivity values start to emerge around the surface features at a depth of 750 m and extend to a depth of 1000 m and are thought to correspond to the reservoir of the system (Rahadinata et al., 2017).

The cross-sections of the third and fourth tracks that intersected the area of surface features are shown in Figure 4. Both tracks show the existence of a conductive layer throughout the zone of surface features, extending

approximately 500 m from the surface and presumed to be the cap rock. A medium resistivity zone with 20-150 Ohm·m is assumed to be the reservoir. Meanwhile, the medium resistivity values outside the prospect area are believed to correspond to the pyroclastic Koya-Koya (Rahadinata et al., 2017).

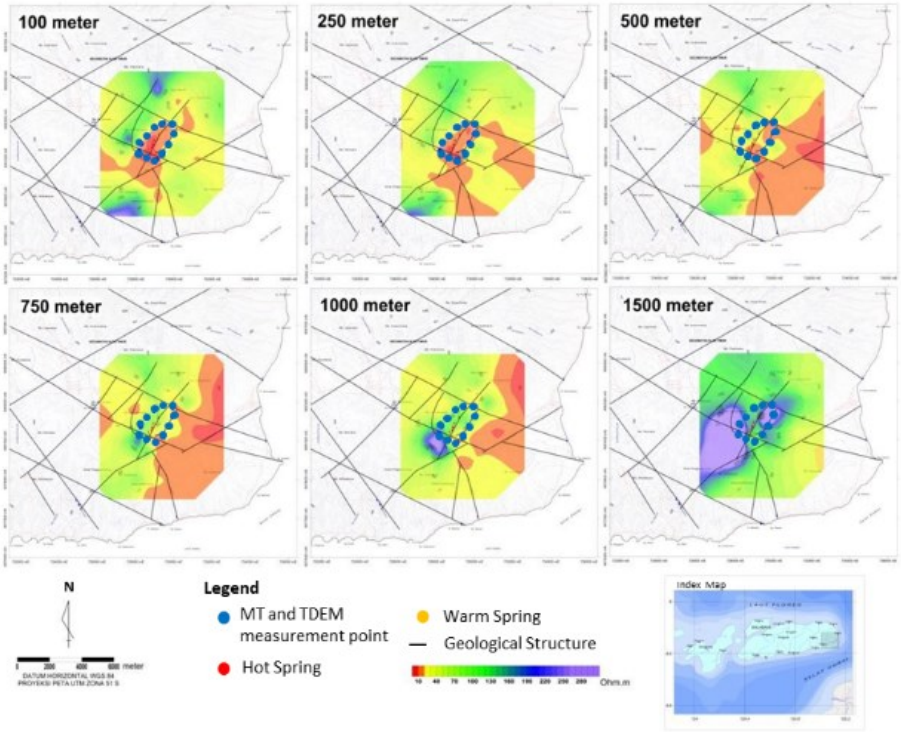

Figure 3: Resistivity maps for different depths 100 m, 250 m, 500 m, 750 m, 1000 m, 1500 m (Rahadinata et al., 2017).

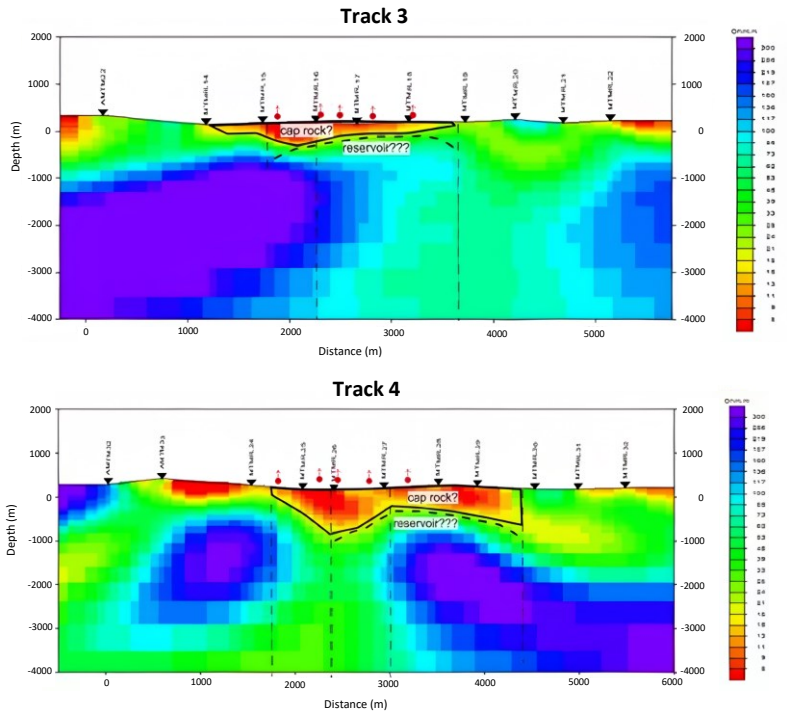

Figure 4: Cross-section display of MT measurements along track 3 and track 4 (Rahadinata et al., 2017).

2.3 Geochemical Studies

Nine water samples were analysed from hot springs and warm springs in the Maritaing geothermal system (Setiawan et al., 2015). The temperatures of the features range from 58° - 81ºC, and they are of chloride and chloride-bicarbonate type (Direktorat Panas Bumi, 2017). As shown by the ternary Cl-SO_4-HCO_3 plot in Figure 6, Kura hot springs, along with Alakalela and Mabata warm springs, are of chloride type. High silica content and the existence of silica sinter indicate that the hot fluid originates from the reservoir with little mixing with groundwater. The mixing of hot fluid and seawater is thought to happen at both Alakalela and Mabata warm springs, which appear on the beach. Additionally, intensive mixing of hot fluid with ground water, condensate water or carbonate rock is believed to be happening at other warm bicarbonate springs (Setiawan et al., 2015).

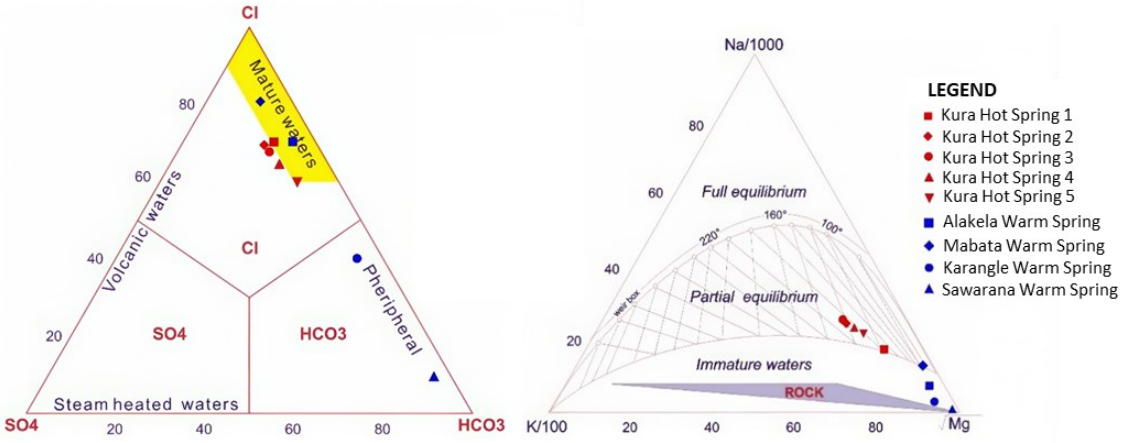

Figure 5: Ternary Cl-SO4-HCO3 diagram (left) and ternary Na-K-Mg diagram (right) (Setiawan et al., 2015).

2.4 Tentative Conceptual Model

Setiawan et al. (2015) developed a tentative conceptual model for Maritaing hydrothermal system, which was used to develop the 3D conceptual model for the current study. The tentative conceptual model is depicted in Figure 6.

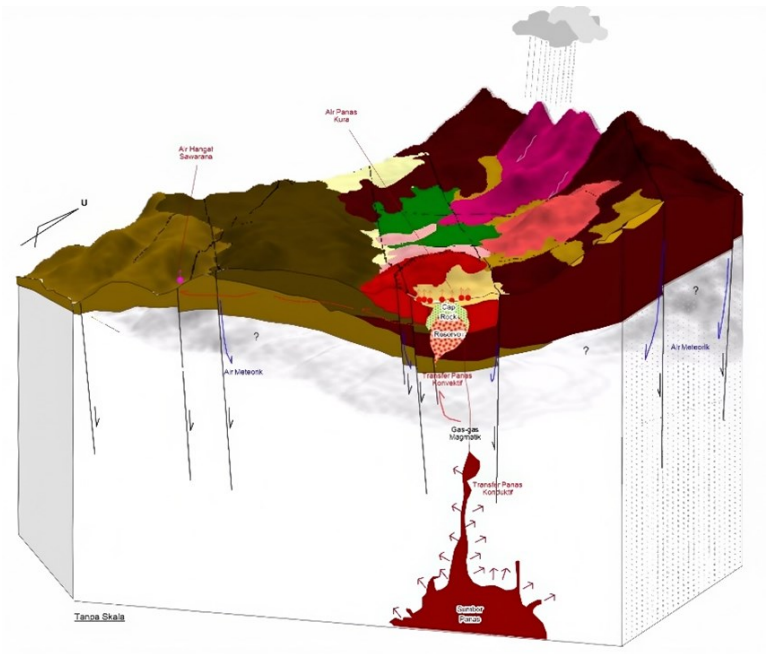

Figure 6: Tentative conceptual model (Setiawan et al., 2015).

The geothermal system in Maritaing is believed to be linked with young magmatic activity within the weak zone of the Maritaing Depression, characterized by volcanic rocks with an intensive fault system and supported by a substantial fluid supply from the north and south of the depression in a medium terrain setting. Meteoric water infiltrates the rainwater catchment areas in the north and south of the Maritaing Depression through permeable

zones. The residual heat from magmatic rocks around Mt. Karitemang has heated the meteoric water, forming the reservoir. The Maritaing reservoir is expected to be an intensively fractured system in volcanic rocks, consisting of tertiary lavas and breccias that have experienced repeated tectonic activities (Setiawan et al., 2015).

Alteration rock, which serves as the impermeable layer (cap rock), has been formed as a consequence of the interaction between hot fluid and the surrounding rocks. The cap rock layer of the system is assumed to be *montmorillonite* clay formed from an argillic-type alteration process of tertiary volcanic rocks (Setiawan et al., 2015).

The hot fluids, along with dissolved elements, accumulate in the reservoir around Karitemang Hill and move convectively to the surface through faults. These hot fluids emerge on the surface at the hot spring manifestations in the Kura area. Simultaneously, the warm springs formed further east and south are believed to have travelled laterally through faults from the Maritaing geothermal system before emerging (Setiawan et al., 2015).

3. 3-D CONCEPTUAL MODEL

3.1 Geological Model

Establishing geological model started by extracting X, Y, and Z coordinate points and imported to Leapfrog in order to set up the topography of the model. The area extends for 40 km around the surface features at Mt. Karitemang, which is believed to be the centre of the geothermal system. Large area gives ability of the reservoir to contain large-scale convective system and its surrounding meteoric charge. The rock stratigraphy and fault structure are set by digitising the boundary of each formation, horizontally and vertically according to the geology map. Table 1 gives the summary of stratigraphy units in the Maritaing geothermal area.

Table 1: Summary of the stratigraphy units in the Maritaing geothermal system.

Rock Units	Abbreviation	Geologic Age
Alluvium	Qa	Holocene
Limestone	Qg	Pleistocene
Conglomerate	Qk	Pleistocene
Karitemang Pyroclastics 2	Qppk2	Pleistocene
Karitemang Pyroclastics 1	Qppk1	Pleistocene
Lake Deposit	Tqd	Pleistocene
Karitemang Dacite Lavas	Tpdk	Pliocene
Bulamaka Andesite Lavas	Tpab	Pliocene
Kunatena Pyroclastic	Tppk	Pliocene
Meriaka Andesite Lavas	Tmam	Late Miocene
Pakmana Andesite Lavas	Tmap	Late Miocene
Inukamang Andesite Lavas	Tmai	Late Miocene
Koya-Koya Pyroclastics	Tmpk	Late Miocene
Koya-Koya Andesite Lavas	Tmak	Late Miocene
Worakena Andesite Lavas	Tmaw	Late Miocene
Katuwusi Pyroclastics	Tmpa	Late Miocene
Katuwusi Andesite Lavas	Tmaa	Late Miocene

As indicated in Table 1, the geological periods are categorised into three epochs, namely: Late Miocene, Pliocene, Pleistocene, and Holocene. The late Miocene includes the following formations (bottom to top): Katuwusi Andesite Lavas (Tmaa) alongside with Koya-Koya Andesite Lavas (Tmak), Inukamang Andesite Lavas, and Pakmana Andesite Lavas which are pyroxene andesite type lavas from Late Miocene. In addition, for the rock units in Late Miocene, Meriaka Andesite Lavas is of hornblende andesite type. The pyroclastics rock unit in the Late Miocene consists of Katuwusi Pyroclastics, which are composed of lapilli tuff and tuff breccia, and Koya-Koya Pyroclastics in the form of a breccia (Setiawan et al., 2015).

During the Pliocene epoch, volcanic rocks continued to form in the Maritaing depression zone. The rock units are Kunatena Pyroclastics (Tppk), Bulamaka Andesite Lavas (Tpab), and Karitemang Dacite Lavas (Tpdk). Kunatena pyroclastic deposits (Tppk) consist of tuff breccia with andesite and dacite fragments. Bulamaka andesite lava

(Tpab) is pyroxene andesite with fine fractures filled with quartz. Karitemang dacite lava (Tpdk) forms the crater structure of Karitemang Ridge, where the Kura hot springs are situated (Setiawan et al., 2015).

In the Pleistocene epoch, Lake Deposits (Tqd) in the form of conglomerate and sandstone from volcanic rock fragments were formed throughout the depression zone of Maritaing. Simultaneously, Volcanic activity from Mt. Karitemang led to the formation of Karitemang Pyroclastic 1 (Qppk1) in the eastern part of the crater. Following this, the Karitemang Pyroclastics 2 (Qppk2) formed within the crater and extended southwards. Both pyroclastic rock units are made up of tuff breccia with andesite and dacite fragments (Setiawan et al., 2015). A conglomerate rock unit in the form of sandstone and conglomerate was formed in the eastern part of the field, simultaneously with a Limestone rock unit in the southeast. Continuous deposition of an Alluvium rock unit (Qa) in the form of surface deposits has occurred along the mouth of the Irawuri River (Setiawan et al., 2015).

For the structural model, there are fifteen faults that are assumed to intersect each rock unit vertically 90º. In addition, certain faults are extended laterally. These assumptions were made since there are no data constraints and they help to optimise the fluid pathways and help with calibration of the numerical model. To facilitate calibration, the rock types for faults with a NW-SE orientation are named A to H and faults with a NE-SW orientation are named T to Z.

The NE-SW fault around Mt. Karitemang is expected to control the Kura hot spring features. Meanwhile, the NW-SE fault that crosscuts Mt. Karitemang controls the surface features in the southern part of the area of interest. These are expected to be the main faults that control the geothermal system at Maritaing.

3.2 Alteration Model

To build the alteration model, resistivity measurement data from the Geology Agency of Indonesia were imported along with the resistivity map (Figure 3) and the MT cross sections (Figure 4). They play an essential role in setting the boundaries, laterally and vertically, of the clay cap. It is believed that the clay cap consists of low permeability clays formed by the alteration process. The polylines method was also utilised to define the form of the clay cap. It appears that an up-dome formation is present beneath the northern part of the clay cap, leading to a thicker zone in the southern area. Additionally, the clay cap is exposed to the surface in the west area. Although the alteration model has a high uncertainty due to the interpretation applied, the model is able to be tested on the numerical model through the calibration process. Combined model of the geological and alteration model in Leapfrog is shown in in Figure 7.

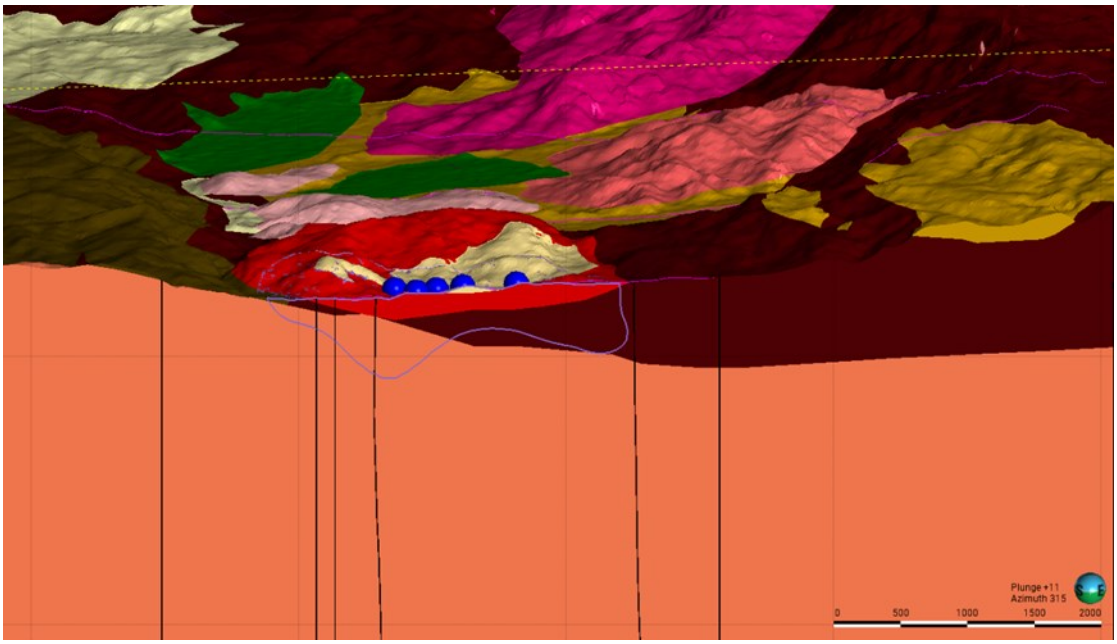

Figure 7: Combined digital conceptual model including geological, structural and alteration models. The black lines represent the faults while the purple line depicts the alteration zone.

4. NUMERICAL MODEL

4.1 Model Grid Setup

The initial model grid was created to be consistent with the Leapfrog model. The grid is oriented 26° from the azimuth to align with the main faults, facilitating model calibration. The model grid covers an area of 13 X 12 km

and the grid is comprised of 12,008 blocks. The largest blocks are 800 m X 800 m, with vertical thickness ranging from 500 m at the base to 100 m near the surface. In areas of interest, a smaller block size was set for better resolution.

The rock types of the blocks were automatically matched to the formations, structures and alterations in the Leapfrog model, allowing seamless integration using PyTOUGH scripts (Popineau et al., 2018). O'Sullivan et al. (2023) explain the rock-type naming convention related to the geology, structures and alteration zones. Figure 8 depicts the grid layout area imported into Leapfrog. The model tries to match the location and boundary of each formation, as shown by the colour of the blocks.

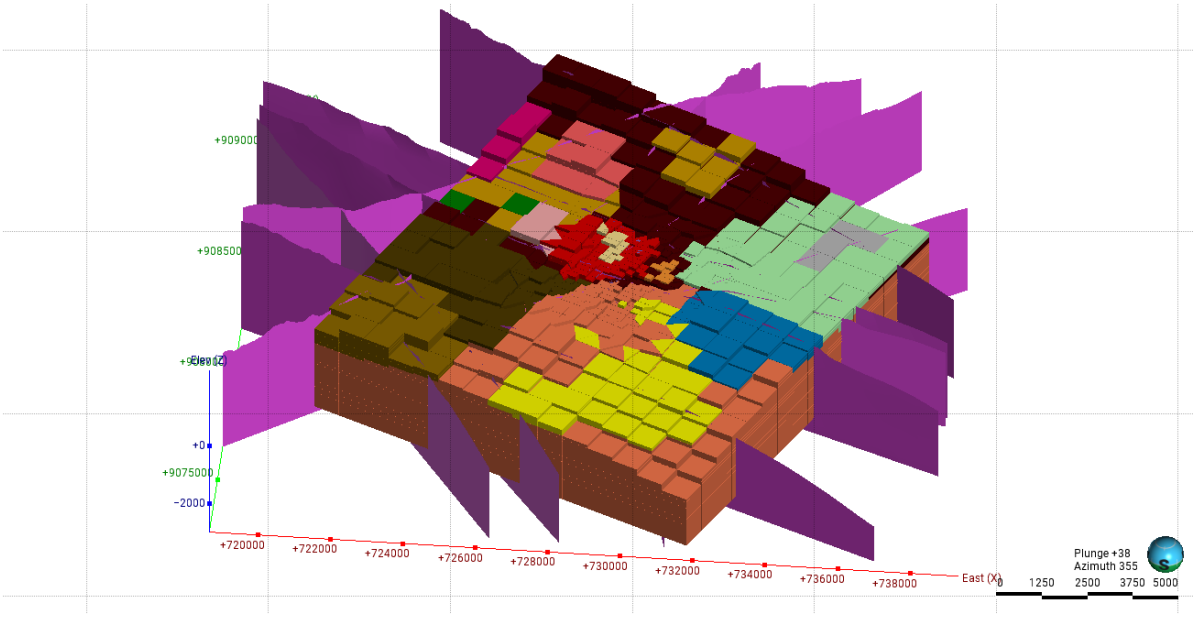

Figure 8: Grid Layout for Maritaing geothermal field in Leapfrog. The colour of the blocks represents the lithology, while the magenta-coloured planes are the faults.

4.2 Boundary Condition

Top boundary: The top boundary of the model is defined by the ground surface and dry atmospheric conditions are set, with a pressure of 1 bar and a temperature of 15ºC. The EOS3 equation of the state module in TOUGH2 provides the thermophysical properties of water and air for the mass and energy balance equations (Pruess et al., 1999). Moreover, the module allows the vadose zone to be included above the water table, at pressures close to the atmospheric pressure (O'Sullivan & O'Sullivan, 2016). A high permeability at the top layer was assigned to allow rainwater infiltration, which then flows from the higher elevation following the topography. An annual rainfall of 800 mm per annum with a 10% rate of infiltration was implemented.

Side boundary: The model has a no-flow side boundary condition implemented for the natural state because the model is sufficiently large to include the entire whole convective geothermal system without any side flows.

Base boundary: A uniform background heat flux of 64 mW/m² was applied to the base boundary. Furthermore, a total mass upflow of 33 kg/s with an enthalpy of 1200 kJ/kg of hot mass was injected into eight blocks, situated under the NE-SW fault around the Kura surface features.

5. NATURAL STATE SIMULATION

5.1 Model Calibration

Calibrating a model is a repetitive process required to ensure the reliability of the fit of the model to the data. A model that has been through calibration is expected to represent the real reservoir and field condition as precisely as possible. In calibration, changing one or several parameters affects several model results concurrently. Manual model calibration is generally a widely used method to improve a model (O'Sullivan et al., 2016) and was implemented in this study.

For calibrating this model, the parameters adjusted were the hot mass injected at the base of the model and the permeabilities of the rock types controlling the fluid flow. Permeabilities were adjusted, taking account of the

lithology and fault structures. High permeabilities were assigned to certain shallow structures, allowing some hot fluid to flow to the surface, matching the real surface features in certain areas.

In order to attain steady-state conditions, the model was run for 5 X 10^{13} seconds for each step of calibration. The 33 kg/s of hot mass was injected into the 5 blocks, concentrated under the NE-SW fault near Kura hot springs. It is expected that this fault mainly controls the upflow in the Maritaing geothermal field. On the other hand, the NW-SW fault which crosscuts Mt. Karitemang allows the fluid to flow to the northwest and southwest. Geological rules are consistently implemented on the different formations and faults. They allow an increased permeability along the strike and vertically up the dip of faults and a decreased permeability across the strike of the fault. Thus, anisotropic permeabilities are used for each rock type to represent the characteristics of the faults. Meanwhile, isotropic permeabilities are implemented for the base rock types as the baseline for adjusting the permeabilities of the faults.

Additionally, the altered clay cap is assumed to serve as a fluid barrier, restricting flow to the surface. Low permeabilities are assigned to certain blocks, representing the shape of the clay cap. Due to the irregular dome shape of the cap, the fluid flow from depth is forced to disperse underneath the cap.

Attaining a good match to data for downhole temperatures is a benchmark in the successful calibration of a natural state model. However, the well drilling stage has not been conducted since Maritaing field is categorized as a greenfield. Therefore, the calibration of the model was believed to be successful when several conditions were met, such as the temperature under the clay cap achieved the constraint temperature of around 200°C and, the model illustrates a significant amount of heat reaching the surface in zones where surface features occur, and the fluid flow in the model follows reasonable pathways.

5.2 Natural State Model

The natural state model was successfully calibrated by matching the estimated temperatures of the clay cap and the surface features data. Surface features used as reference for the model are in locations such as Kura River for the hot springs (KUA01, KUA02, KUA03, KUA04, KUA05) and for the warm springs in Alakalela (ALK01), Mabata (MBT01), Karangle (KRL01), and Sawarana (SWA01). Most of the surface features, especially surface features in Kura River area are chloride-type hot springs, indicating that the area is an upflow zone. The surface features outside Kura River are thought to result from the lateral flow of the fluid, indicating they are in an outflow zone.

The temperature under the clay cap was constrained to be 200°C as the result of geothermometer data and the expected temperature at which the rock is altered. The large size of the blocks is the reason why the temperature does not exactly match 200°C underneath the clay cap. Figure 18 and Figure 19 show temperatures on NE-SW and E-W oriented slices, respectively.

Upflow zones are identified, matching the temperature isotherm of 200ºC below the clay cap and the existence of hot springs of chloride type near the Kura River (KUA01, KUA02, KUA03, KUA04 and KUA05). The outflow zone is indicated by the locations of warm springs of bicarbonate type, such as KRL01 and ALK01. Additionally, the higher elevation zone in Figure 21 acts as the recharge zone for meteoric water.

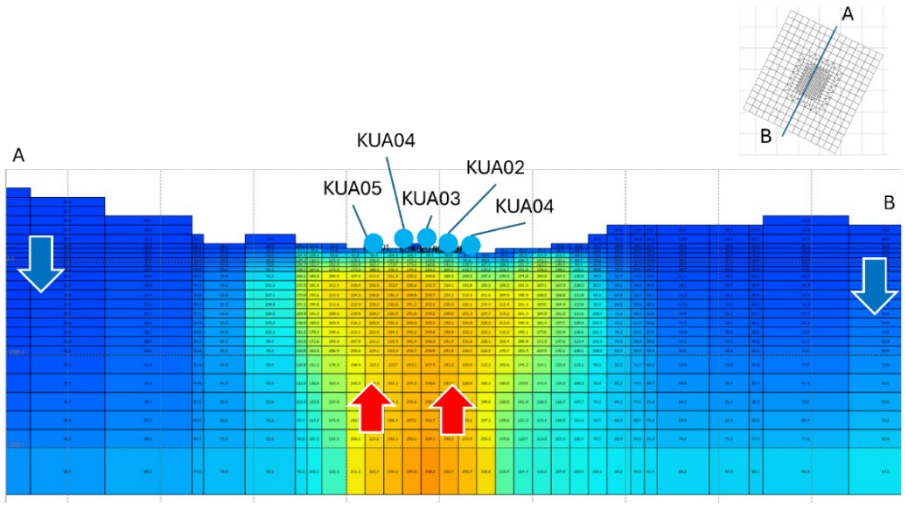

Figure 9: NE-SW oriented slice of temperature plotted with TIM. Red arrows depict the upflow, while blue arrows illustrate the recharge.

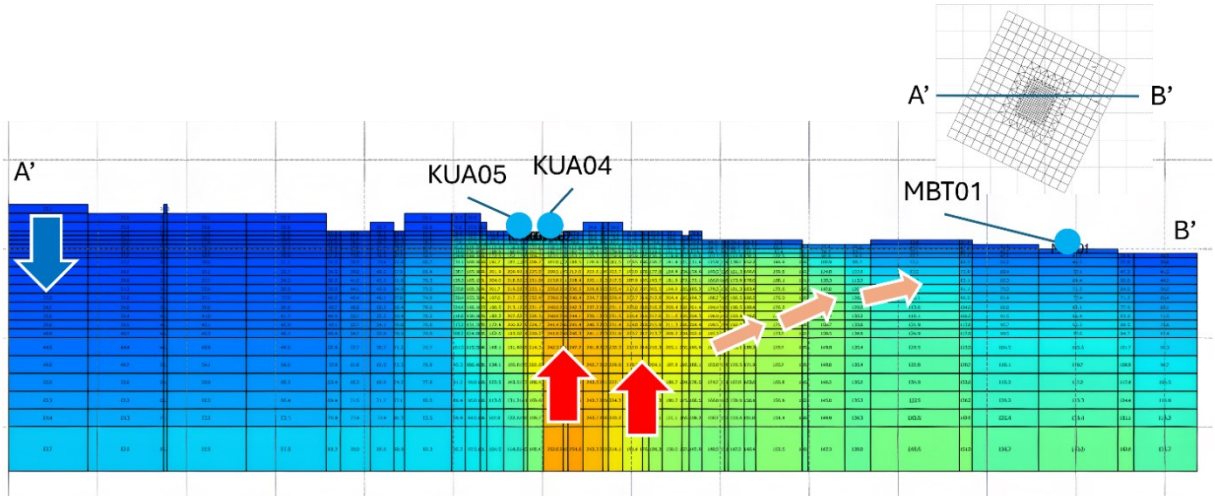

Figure 10: E-W oriented slice of temperature plotted with TIM. Red arrows depict the upflow, orange arrows depict the outflow while the blue arrow depicts the recharge.

6. UPDATED CONCEPTUAL MODEL

Based on the calibration result, an updated conceptual model of the Maritaing geothermal field is proposed. The plan view of the conceptual model with the fault are shown in Figure 11.

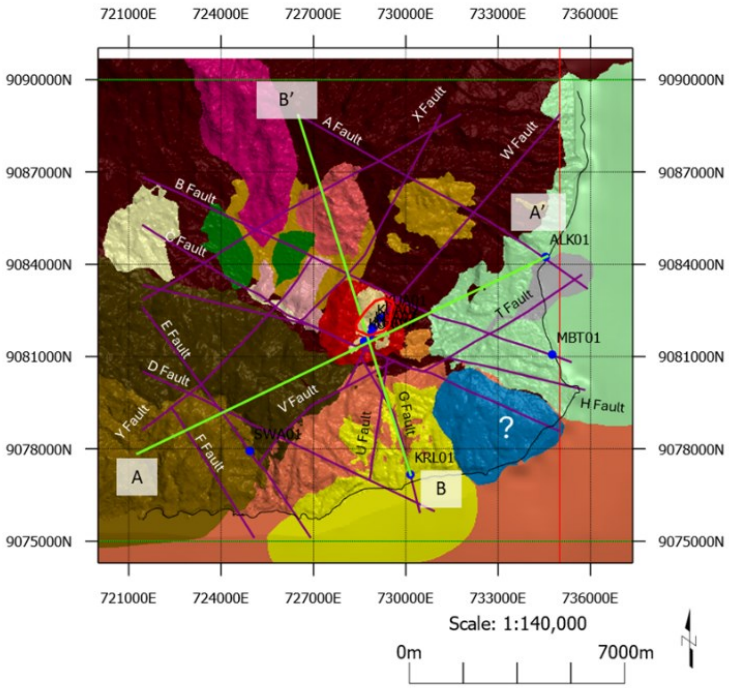

Figure 11: Plan view of the updated conceptual model, showing the fault lines (purple), surface features (blue dot), section lines of cross section images A-A' (Figure 23) and B-B' (Figure 24) (green lines)

Based on the interpretation of Magnetotelluric data, the altered zone is situated around the Kura hot springs. The possible heat is expected to rise directly under the Kura hot spring through the W fault (red line). B Fault is expected to act as the barrier of the fluid, restraining further flow to the NE, but cause the mass flow to the SE direction, resulting in Mabata warm spring (MBT01). Additional pathways of the fluid are expected to flow along the C fault, following the topography elevation. A low permeability area is estimated to lie on the western part of the Tmaw formation since the calibration results show less mass flow infiltration of the reservoir through the formation. Meanwhile, the north area of the field, where most of the Tmak formation lies, serves as the recharge area for the reservoir.

The slices of the updated conceptual model are shown in Figure 12.

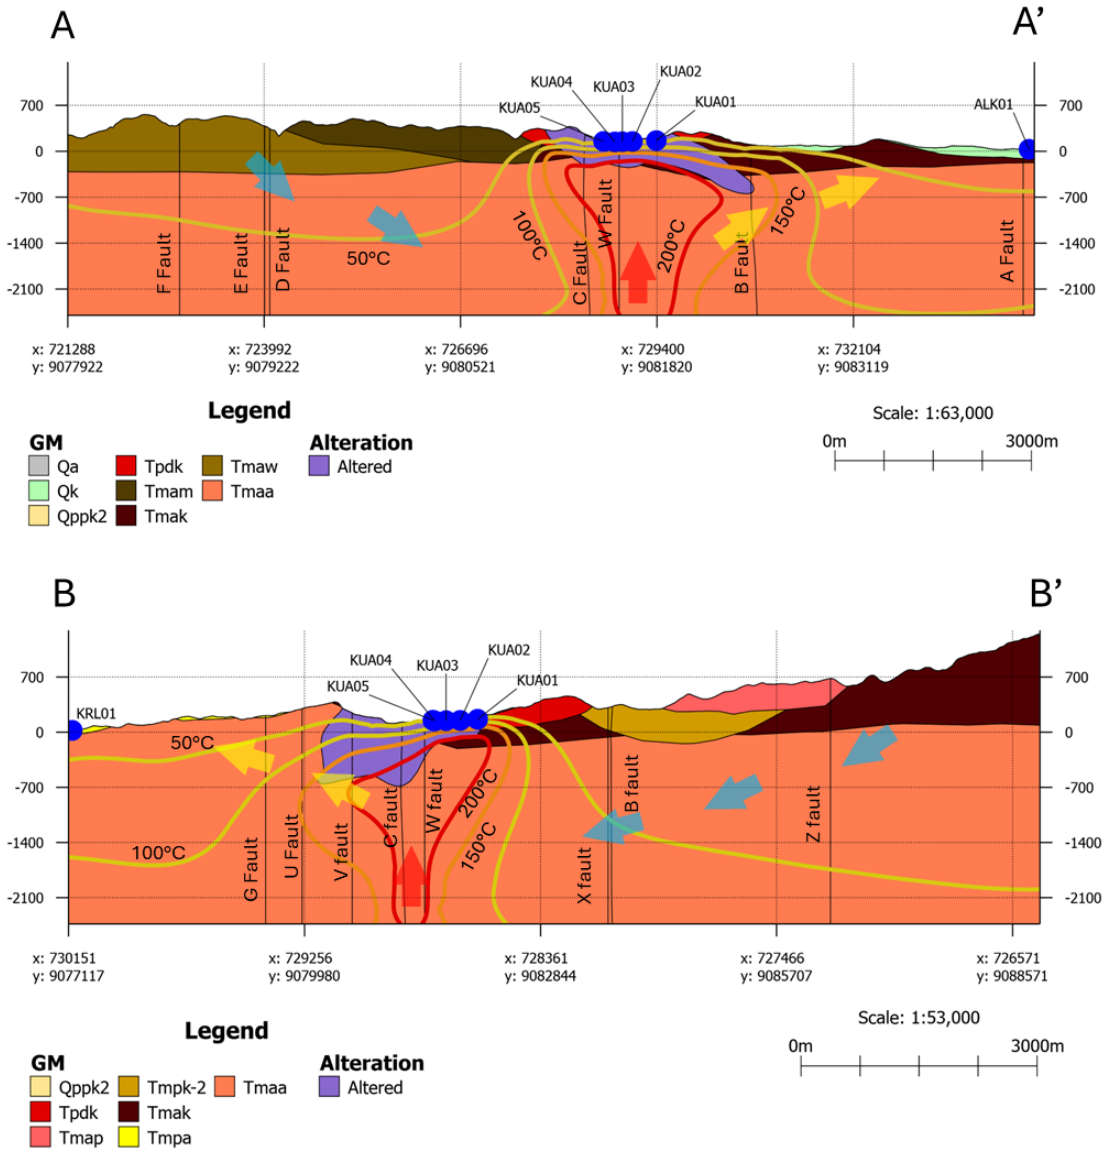

Figure 12: Proposed conceptual model of Maritaing geothermal field based on numerical modelling. The top part shows the A-A' and the bottom part shows the slice B-B', from the figure 22. The red arrow parti is upflow, the yellow arrow is the outflow while the blue arrow is the recharge

From slice A-A', the upflow comes beneath the Kura hot springs through the W Fault. The mass outflow goes to the NE part of the field, resulting in the existence of the Alakalela surface feature (ALK01). The recharge water comes from the SW part of the Maritaing, the infiltration water is relatively small based on the calibrated model. Similarly, the slice B-B' shows the upflow that goes through the W fault. The outflow travels laterally in the NE direction of the Maritaing, leading to the existence of the Karangle surface feature (KRL01). The main recharge zone is identified from the northern part of the Maritaing through the Tmak formation.

It can be shown the 200°C isotherm describes the estimated reservoir area. It is apparent that the Tmaa formation serves as the host rock for the reservoir. The altered rock was exposed to the surface for the western part of the alteration zone, resulting in a dome shape at the north-east part of the clay cap. The thickness of the clay cap ranges from 400 to 700 m. It appears that the W fault along with the C fault located around the Kura hot springs controls the Maritaing system.

7. CONCLUSION

This study has been successfully developed conceptual model based on 3D digital conceptual model and numerical model of Maritaing field. The calibration process yielded a good match based on the geothermometer data

temperature constraint of the geothermometer result and surface features data. The 3D digital conceptual model and natural state in numerical model are able to update the tentative conceptual model of the field, where the heat sources are estimated to be located below the Kura hot springs. Establishing the digital conceptual model in Leapfrog geothermal made the numerical model consistent with the available data and able to ease the modelling process.

ACKNOWLEDGEMENTS

The authors would like to acknowledge EBTKE and Geology Agency of Indonesia in providing the necessary data, and also to Seequent in providing the access to build the 3D digital conceptual model. Authors would like to give thanks to LPDP or Indonesia Endowment Fund to support the research project.

Keywords: Namora-I-Langit, Microearthquake, Reservoir Monitoring

ABSTRACT

Sarulla Operation Ltd. has been operating the Namora-I-Langit geothermal field since 2017. The field that is located in North Sumatra is part of the liquid-dominated reservoir within the Great Sumatran Fault segment. Since 2020, 18 seismic equipment has been deployed to support the reservoir monitoring from the microearthquake events in Namora-I-Langit and the neighbours' field in Silangkitang. The purpose in this study is to describe the current 2023 monitoring result in Namora-I-Langit field in relation to the reservoir process including the injection movement, drilling result, and the overall reservoir changes. Simultaneously, the possible faults/ fractures distribution can be observed and used for the future development plan. Currently, 2558 seismic events have been recorded over the 2023 timeframe, with an average of 4-7 occurrence each day as a baseline. However, some increasing seismic rates are recorded and may correlate with the operations, like the injection process, well drilling, well surveillance, and other activities. In addition, large earthquakes with epicentres in Tarutung region were recorded during monitoring in August 2023. To improve the seismic location, hypocentre relocation and waveform cross-corelation were utilized to minimize the residual travel time and pinpoint more exact position.

The results so far are quite consistent with the interpretation of injection channel which runs from eastern part from NIL3N injection wells to the south and west from production wells. Another conclusion from the recent WJR1-2 well drilling shows that the northern NIL area has an aseismic zone that been identified as permeable locations. Meanwhile the concentrated seismic event around Great Sumatran Fault may show the barrier zone that separates the NIL field from the tight zone on the eastern side of the Hutajulu Fault. Tomography and focal mechanism model were conducted to support the monitoring evaluation. Resulting in some consistent interpretation of reservoir geometry and fault direction. However, the model has considerable uncertainty due to the data distribution and limitation. Finally, the monitoring survey plans to continue in 2024 with certain improvements, such as the station relocation, velocity model, and the resolution boundary for tomography model. Some ideas for running the time lapse (4D) tomography or Ambient Noise Tomography are also considered as part of the future improvement.

1. INTRODUCTION

Sarulla Operation Ltd (SOL) has been given the right to operate power generation from Geothermal field in Sarulla contract block, North Sumatran Province. Currently, the total installed capacity 330 MW generates from Namora-I-Langit (NIL) and Silangkitang (SIL) geothermal fields under a single Contract as part of a Joint Operating Contract (JOC) with Pertamina. However, this study will be focused on monitoring the reservoir performance at Namora-I-Langit field from a geophysical perspective.

The geological background from Namora-I-Langit is a volcanic complex at the northwest end of the Sarulla contract block. The complex consists of two volcanic products from andesitic to rhyolitic lavas and tuffs. Namora-I-Langit also situated around the Great Sumatra Fault (Tor Sibohi and Hutajulu Faults) that makes the permeability is dependent on the fracture development around the area (Figure 1 (left)). Whilst the presence of geothermal activity manifested from thermal features such as fumaroles, acid sulfate springs, neutral Cl-sulfate-bicarbonate hot springs, gas seeps, and numerous warm bicarbonate springs covering an area of about 30 km2 (Gunderson et al., 2000). The field is currently operated with the high temperature system and produced from a two-phase fluid from the wells.

Starting from 2020. MEQ Monitoring has been initiated in Both NIL and SIL to understand the dynamic reservoir process in response to exploitation activity (injection movement, reservoir geometry). The total area for both NIL and SIL is ±224 km^2 covered by total of 18 seismometer-geophones (Yudha et al., 2021). The other advantage from MEQ Monitoring study is the characterisation of fractures/fault distribution along the field. The result is

useful for reservoir characterization and reservoir management plan (development strategy and well targeting). Another purpose beside the resource monitoring is as input for shareholder on potential hazard (large earthquake) and environmental issue related to geothermal activities (safe operation).

2. METHODOLOGY

Sarulla Operation Ltd has operated maximum 18 seismometers dedicated to monitor the reservoir development. The tools are using the shallow burial geophone from Geotech and equipped with SMART24R recorder and GPS to get the optimum tools performance. For the operation, the battery is equipped for the tools and needs to be replaced every 1-2 weeks for the charging.

Calibration and tool setting up were done before installed by synchronizing all the equipment to ensure the tools will run together. Then all the instruments were installed at each microseismic station location. The network arrays for the stations are shown in Figure 1 (right). The distribution is not ideal due to the accessibility to reach the high side location of Great Sumatran Fault and the security purposes. During monitoring from 2020 – 2023. Several 1D velocity model has been improved from previous model by using only events with high accuracy, azimuthal Gap < 180, and Immediate vicinity of Sumatran Fault & excluding mountains area. Velocity model has been stable and constant after June 2021. For data QC, wadati diagram was used to present the linear correlation and predict the uncertainty of waveform phase arrival time and the ratio of Vp/Vs. In average shows normal Vp/Vs trend of the rock ~ 1.713 + 0.011 with Total P-S pairs= 32.10. Therefore, using this diagram, the best practice for determining good correlation or good picking of P-wave and S-wave should be within the gradient value.

The normal Hypocenter determination is using the Nonlinear calculation, but to minimize the residual of "pair events" instead of "single events", the relative relocation (HypoDD) and waveform cross-correlation (WCC) were performed as it common applied for local scale, e.g. geothermal, underground mining. While, to obtain the Magnitude was determined using duration magnitude and Length/duration using the coda wave with the average Magnitude around 0.5-1. Later, the Hypocenter relocation & waveform cross-correlation has improved the travel time residual (RMS) and narrow the uncertainty to become ~ 100 m (x, y, z) correspond to 0.02 s RMS misfit.

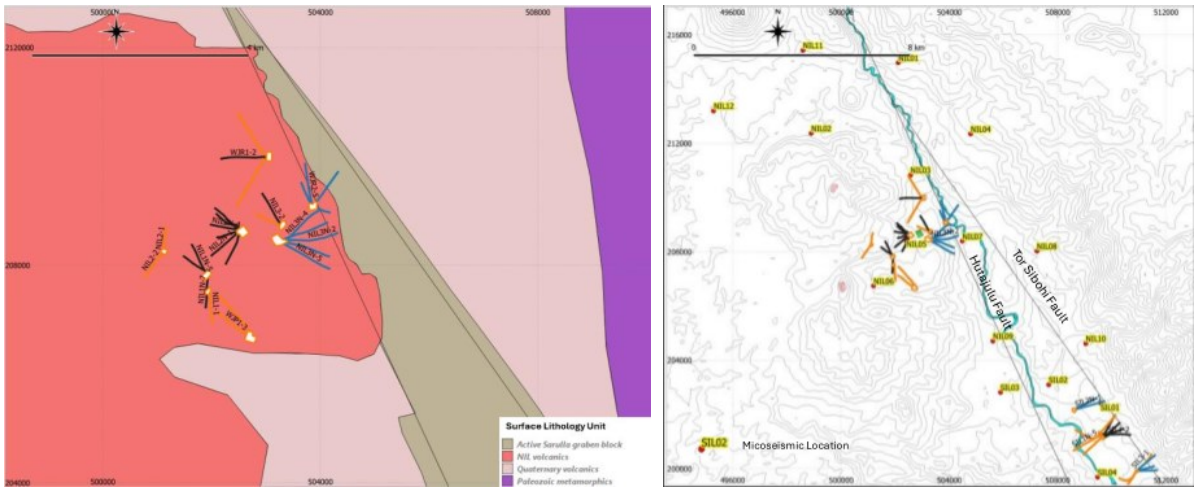

Figure 1: (left) Surface Stratigraphy and Regional fault Map and (right) Seismometer distribution including in Neighborhood field (SIL) with background topography and regional fault.

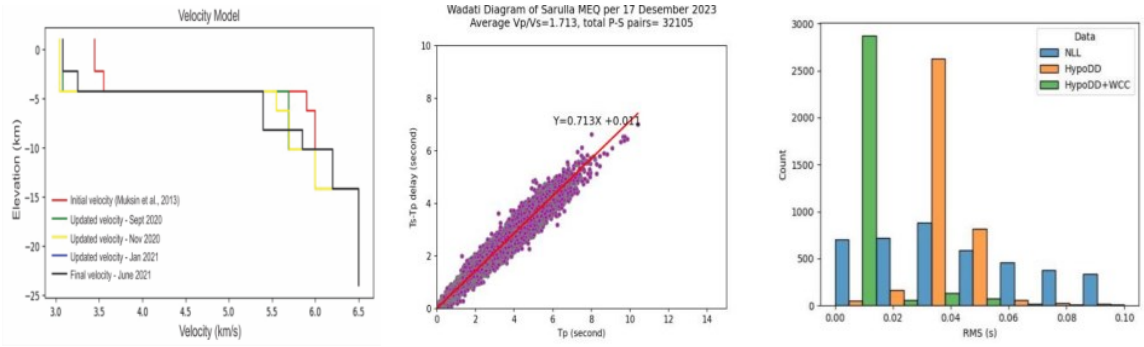

Figure 2: (a) Current 1D velocity model compared with previous model and (b) Wadati Diagram (c) RMS calculations from NLL, HypoDD, and HypoDD + WCC.

3. MEQ MONITORING RESULT

In 2023 Monitoring, 2558 seismic events were picked, covering around ±224 km^2 of NIL and SIL area. During the measurement, there were an average 4-7 event/day occurred as a background for both areas. Some increasing seismic trends are associated with outage/curtailment, well drilling, surveillance, and acidizing (workover). Some of the activities will be further explained in this chapter. While the high event rates also occurred in 2023 and interpreted from major earthquake with epicenters in Tarutung represent on red dashed lines. However, for the confidence level, only 418 seismic events will be presented on the general map from HypoDD+WCC relocation events.

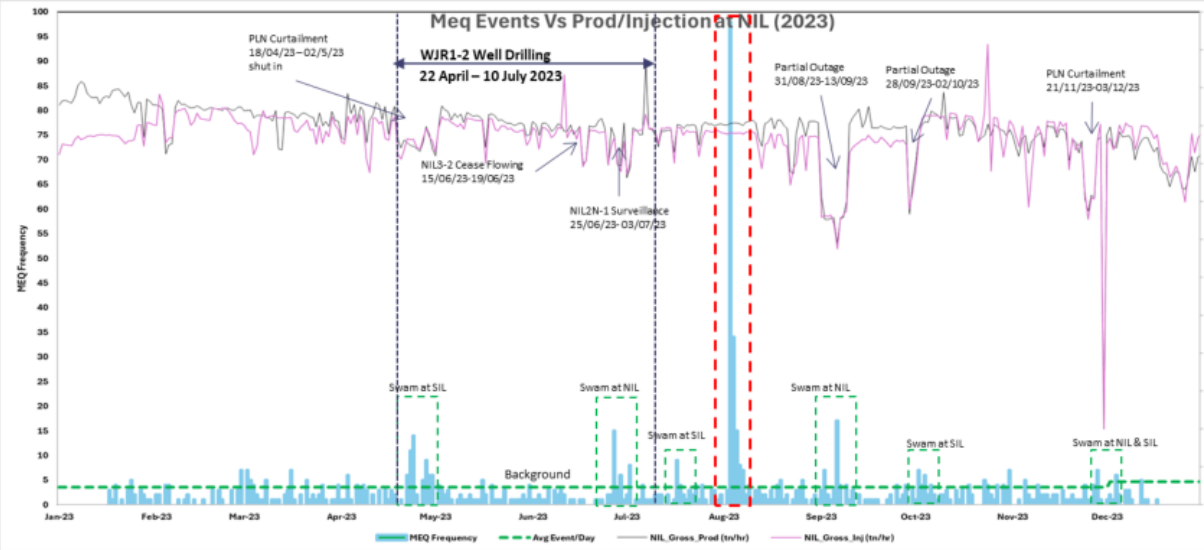

Figure 3: Production and Injection volume (tn/hr) at NIL compared with the MEQ frequency.

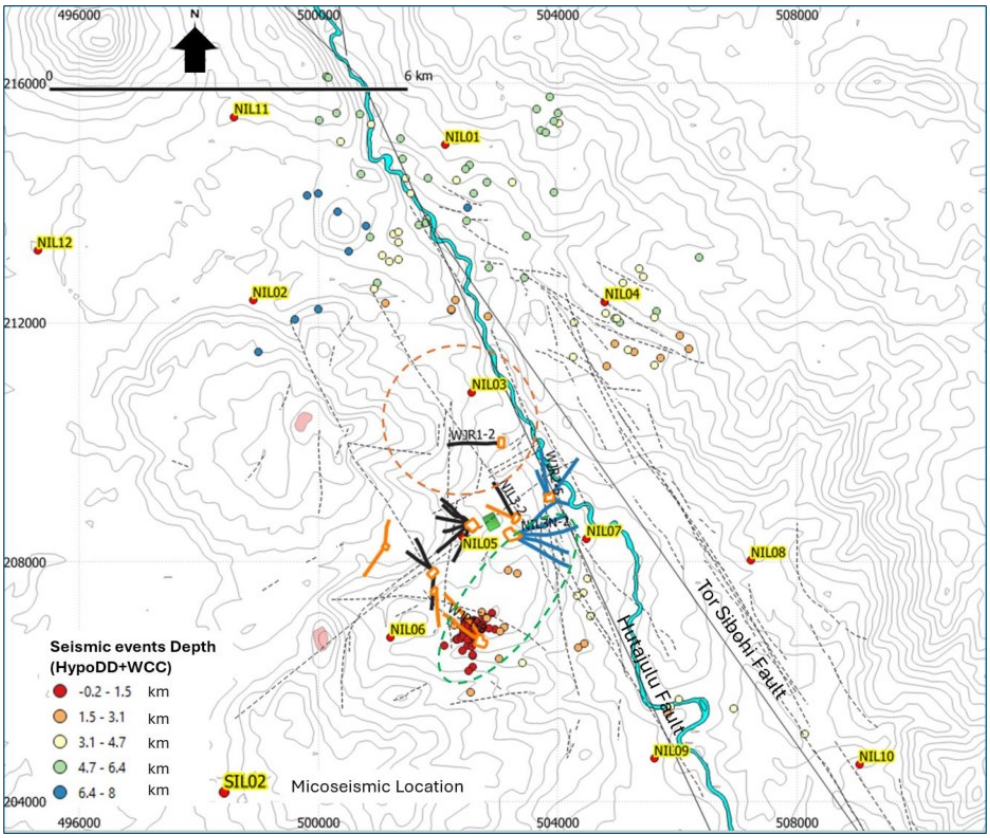

Figure 4: MeQ event distributions (HypoDD + WCC) with background topography contour in grey lines, MEQ station on red dotted symbol, and more detail faults in black dashed lines. The orange dashed circle represents the WJR1-2 well area and green dashed ellipsoid represents NIL injection movement.

3.1 WJR1-2 Well Drilling and NIL Injection Movement.

Sarulla Operation Ltd. has initiated the drilling campaign program to restore the steam recovery in Namora-I-Langit Field. The campaign will be in staged, with one well drilled in 2023 and two wells planned for 2025, all in northern region (Figure 4). WJR1-2 is the first well drilled between 22 April 2023 and 10 July 2023, and it has intersected the reservoir section and penetrating total loss condition (TLC) on 20 June 2023 (Figure 3).

During the drilling in reservoir/ TLC, no significant swarm events around WJR1-2 wells (Figure 4). However, the events are increased in the northern part and along Great Sumatran Fault after TLC condition. This might be because the pressure injection necessary to induce seismic event is still smaller than fracture gradient surrounding the wellbore. Or the area though to be permeable enough resulted in no event being recorded (aseismic area), yet the fluid still be indicated to flow direct to north area through the Great Sumatran Fault (Hutajulu Fault). This assumption provide weight to the idea that the northern part of Namora-I-Langit is still potentially exploitable.

Meanwhile, certain seismic occurrences may be attributed to operational changes, in particular to the injection location and the rate. The major changes for the injection rate had occurred in 2022. There was an injection maneuver from seven wells in two different pads into two wells in same pad and the injection scheme will continuing through 2023 (Figure 4).

Based on observation, some seismic pathway seen from NIL3N well to WJP (green dashed line). This NE-SW trend may relate to the fracture/injection path. However, compared with previous year before the maneuver, the event frequency seems slightly decreased. Some anomalies were seen on WJP pad area (red dots on south corner). These seismic events occurred rapidly in shallow level. This is interpreted whether the events derived from injection wells (blue line) or there is a natural downflow from shallow level.

3.2 2023 Tarutung Earthquake

The MEQ monitoring shows an increase in seismic occurrence, not only in shallow level from geothermal process, but also in deeper sections that related to natural earthquake. Figure 3 depicts the relationship between the rapid increase of MEQ frequency with more than 100 events in August 2023 and the natural earthquake occurrence. Based on the comparison with BMKG data, 33 seismic events recorded on 3rd of August 2023 on BMKG stations with magnitude 1.9-2.8 Richter Scale with penetration depth around 2- 3 km from surface.

Meanwhile, in the same time SOL has recorded a total of 106 seismic occurrences between 3 and 6 August 2023, with depths ranging from 5-7 km and magnitude less than 1 order. The seismic events which are centered on the east side of Great Sumatran Fault (Figure 5) reflect an extension of the larger seismic event from 2022 earthquake and are thought to be an ancient fault reactivation from the Great Sumatran Fault movement. This evidence is supporting the SOL data for earthquake mitigation plan for the future development.

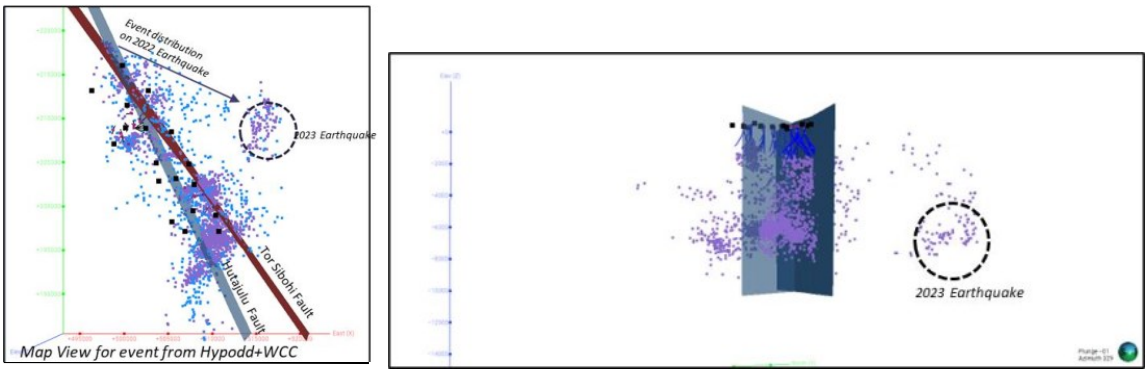

Figure 5: (left) Map view and (right) Cross Section for seismic event distribution from HypoDD+WCC analysis from 2020 – 2023 with focus on black dashed line for 2023 Earthquake in August.

3.3 Tomography and Focal Mechanism

Advanced processing such as tomography inversion and focal mechanism has been performed on the 2023 data. The color scale in Figure 6 shows for Vp and Vs represents a relative perturbation value compared to the initial 1D model, while Vp/Vs color scale shows an absolute number. P-wave velocity is commonly used to determine properties like the type of rock, porosity, and the presence of fluids. S-waves only travel through solids and are sensitive to shear modulus, so they are used to determine the rigidity of the material they travel through. The ratio of the Vp/Vs can provide insights into the present of fluid. A higher Vp/Vs ratio may indicate the presence of fluids in the rock, as fluids can significantly slow down S-waves more than P-waves. Based on the tomography modeling, NW-SE and NE-SW alignment of high velocity anomaly (Vp) were seen and may be associated with Sumatran Fault (Tor Sibohi Fault) as boundary and compartment location (south of WJP wells may have tight

permeability). While several low velocity (Vp and Vs) zones around the WJR1 area indicate highly fractured zone and the fluid/ steam zone also correlated in the southern part with the high Vp/Vs value around those area. In line with the figure, the focal mechanism around 0 – 2200 masl was exhibited, together with tomography. The result shows the possible orientation of the fault plane and slip on fault plane. Based on the beach ball trend, NIL area has act as normal fault - indicate tension zone with trend dominant parallel with major fault.

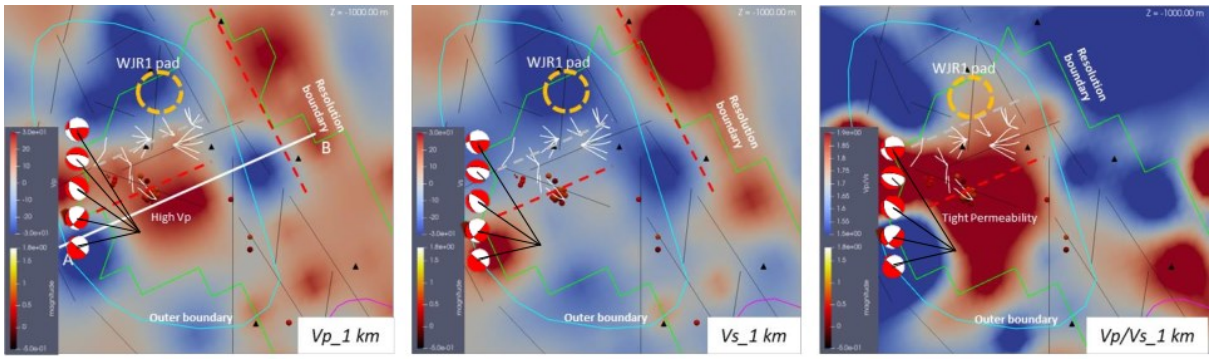

Figure 6: Map from tomography model from VP, VS, and ratio of VP/VS at 1 km depth. The heat color represents the values from low to high and the beach ball represents the location and trend of focal mechanism.

4. CONCLUSION AND RECOMMENDATION

Microearthquake events in Namora-I-Langit occurred from tectonic movement along Great Sumatran Fault or from local reservoir process/operation. Based on the comparison with the MEQ frequency, some increasing seismic trends proved to be coincided with those activity such as, outage/curtailment, well drilling, surveillance, acidizing (workover), and the rapid increase is related to natural earthquake.

Some examples of MEQ monitoring results in 2023 include the injection channel from in NIL location, which seems to be dominant to south-west within the compartment. This is consistent with surface structure and well data findings. However, no notable swarm events were observed during WJR1-2 drilling. Possibly the area is highly permeable or in aseismic zone. Finally, in addition to the shallow process, a natural earthquake around reported near Tarutung area, which was connected with BMKG data and interpreted as the re-activation of the ancient fault based on the movement of Great Sumatran Fault. These examples demonstrate how MEQ monitoring may help to support the reservoir monitoring, particularly beyond the well area.

Some advance processing was also studied and can support the general look for area with low permeability and general NW-SE trend from Great Sumatran Fault. However, the current model has some limitations and create some uncertainty. Based on the considerations, relocation some station to the West area, update velocity model, and improve resolution boundary will be improved in 2024 in order to raise data confidence and helps to identify the resource boundaries better. Some ideas for running the time lapse (4D) tomography or Ambient Noise Tomography (ANT) are also considered as part of the future improvement. In the meantime, the current result will be used as an input for reservoir characterization (conceptual model and resource boundary) & management (injection strategy, etc.), and assess the structure interpretation.

Keywords: Tracer test, thermal breakthrough, temperature decline

ABSTRACT

Production and injection wells are crucial to geothermal power plants, with their use varying due to reservoir differences. These variations are understood through tests, like tracer tests, which involve mixing injection water with a tracer at a specific temperature to study reservoir properties. In this context, Naphthalene disulfonate (NDS) tracers were used in four injection wells: Well I-1 with 2.6 NDS; I-2 with 1.5 NDS; I-3 with 2.7 NDS; and I-4 with 1.6 NDS. The highest NDS detection was 2.6 in Well A, followed by 1.6 in Well I-4. Starting January 21, 2020, 1150 tph of 150-152°C water mixed with NDS was injected. This resulted in a temperature drop of 10°C in Well A and 15°C in Well B, with initial temperatures at 195°C and 184°C, respectively. Predicted temperatures after 2500 days are 185°C for Well A and 164°C for Well B, significantly affected by the 600m (A to I-1) and 700m (B to I-4) distance between injection and production wells. By 2034, Well A is expected to breakthrough, and by 2028, Well B.

1. INTRODUCTION

Geothermal resources can be accessed at a depth of 4-5 kilometers, exhibiting temperatures that span a range of 200 degrees Celsius. The injection of water into an injection well via fractures in hot rocks results in the generation of steam or hot water, which can be harnessed to drive turbines for the purpose of electricity generation. Water may be located at specific depths or exist within the reservoir, thereby transforming it into a geothermal reservoir (Johnston et al., 2011). The energy derived from the surface surpasses the inherent thermal heat flux, thereby causing a decline in temperature of the reservoir over time. The gradual impact on production wells is anticipated as a result of thermal breakthrough, whereby even cold water can eventually be extracted (Nottebohm et al., 2012). The Ahuachapan Field in El Salvador experienced a thermal drawdown of 30 degrees Celsius over a period of four years. Furthermore, it has been observed that in the Palinpinon Field located in the Philippines, a thermal drawdown of 50 degrees Celsius has occurred over a period of four years subsequent to the implementation of injection. In year 5, a thermal breakthrough is induced, thereby emphasizing the significance of conducting a tracer test. One of the primary objectives of this test is to ascertain the correlation between injection wells and production wells (Axelsson, Björnsson, et al., 2005). (Axelsson et al., 2005; Kaya, Zarrouk, & O'Sullivan, 2011) suggest that in order to mitigate this phenomenon, a water reinjection process is implemented, along with measures to prevent the depletion of water in geothermal reservoirs, thereby facilitating repeated cycles. A viable approach to examine this phenomenon is through the utilization of a tracer test. The assessment of mass movement in geothermal reservoirs is a conventional technique that can serve as a valuable instrument for the regulation of production and injection activities. The conducted tests reveal a correlation between injection and production wells, thereby enabling the identification of the most favorable placement for these wells (Suzuki et al., 2014). The utilization of the tracer test has been established as a potent technique for the purpose of characterizing geothermal reservoirs throughout time. These devices are utilized for the purpose of monitoring fluid flow and approximating the duration of fluid retention within reservoirs (Nottebohm et al., 2012).

Thus, the present investigation aims to conduct a thermal drawdown analysis by means of a tracer test on production well A and production well B located in Field W. The present analysis aims to ascertain the thermal breakthrough. The present study's favorable outcome is anticipated to provide a foundation for comprehending fluid dynamics within the reservoir and devising strategies for ascertaining the placement of production or injection wells, along with future production schemes. Geothermal energy has a potential estimated at approximately 5000 EJ (exajoules) per annum, as determined through engineering calculations. Nevertheless, in order to harness such a quantity of energy, one must possess the necessary capability and technological advancements. Despite having a generating potential of 28.1 MW, geothermal power plants have not been extensively utilized in Indonesia. Therefore, it is imperative to undertake measures aimed at optimizing their utilization (Melysa & Fitrianti, 2015). In the context of geothermal exploitation, the ongoing production of energy may result in thermal breakthrough and consequent energy loss. To address this issue, the reinjection of water is implemented to establish a recurring cycle (Plummer et al., 2011). Kaya et al. (2011) have identified several

advantages associated with re-injection. An ecologically sustainable approach to the management of brine and condensate disposal and separation. This process facilitates the replenishment of the reservoir and mitigates the decline in reservoir pressure. The utilization of a reduced amount of gas in the steam enhances the efficiency of the generator. There is a need to enhance the output of hot water and energy generated. The comprehension of the mean velocity, dispersion, and fluid flow volume within the reservoir and tracer is essential (Bjarkason, 2014).

Injection wells are a necessary component for re-injection activities. However, in practical application, the re-production of injected water can be a time-consuming process, leading to significant uncertainty. As such, it is imperative to identify strategies to mitigate this challenge. The comprehensive nature of data collected from various fields such as exploration, geology, geophysics, geochemistry, and reservoir characteristics facilitates the examination of pertinent issues. This data can be incorporated into a simulation model to forecast the flow of the reservoir. Furthermore, the examination of concerns raised can be aided by conducting tests on geothermal wells, such as the tracer test (Maier et al., 2014). A tracer test is a type of well test that is conducted in conjunction with the reinjection of water that has been infused with a tracer substance. The purpose of this test is to ascertain the properties of a geothermal reservoir. As per Axelsson's (2013) findings, certain prerequisites must be met for a substance to qualify as a suitable tracer during a tracer test. The tracer can be detected in reservoirs even at lower concentrations upon injection. The tracer does not undergo any reaction or absorption by the reservoir rock. The tracer exhibits stable temperature under reservoir conditions, inexpensive, simple to evaluate and eco-friendly.

As per Lake's (2007) publication, the primary objective of the tracer test is to assess the correlation between injection and production wells. An additional aim is to assess the efficiency of the sweep and determine the overall volume of pores. At the outset, the process of conducting tracer tests necessitated a greater amount of time for larger quantities owing to the dissipation of tracer elements and loss of temperature. The employment of naturally occurring tracers such as chloride and ammonia has been supplanted by the utilization of an artificial tracer, namely tritium. Naphthalene-1-sulfonic acid (a) is a chemical compound characterized by the molecular formula $C_{10}H_7SO_3H$. The aforementioned compound is devoid of color, exhibits solubility in water, and finds extensive application in the dye manufacturing sector. Four distinct chemical compounds derived from naphthalene-1-sulfonic acid are utilized as tracer variants and are blended with the injection water. The aforementioned chemical entities include naphthalene-2,6-disulfonic acid (b), naphthalene-1,5-disulfonic acid (c), naphthalene-2,7-disulfonic acid (d), and naphthalene-1,6-disulfonic acid (e). Thermal breakthrough refers to a phenomenon whereby the production temperature of a well decreases to the point where it is no longer economically viable, resulting in the production of cold water. This phenomenon can be attributed to various parameters, as noted by Rijn (2018). The parameters of interest include distance, flow rate, reservoir thickness, reservoir rock density, specific heat of reservoir rock, depth, and injection temperature.

The proposed final project entails conducting a research study aimed at analyzing temperature drops and thermal breakthroughs through the utilization of a tracer test. The primary objective of this investigation is to establish the correlation between production wells and injection wells. The utilization of tracer tests has been employed for several years as a potent technique for the characterization of geothermal reservoirs. The material's stability under geothermal conditions and its non-reactivity with reservoir rocks are crucial factors for its practical application. The tracer utilized must possess the capability of being detected in low concentrations, while also being non-toxic to both the environment and human beings (Nottebohm et al., 2012).

2. MATERIAL AND METHOD

2.1 Data for Calculating Thermal Drawdown

In order to conduct thermal drawdown calculations aimed at assessing temperature fluctuations resulting from production activities, certain data is necessary. As per the study conducted by Reidus et al. (2019), the utilized data is presented Table 1.

Table 1: Data.

No	Data	Explanation
1	Temperature (T)	$T_{path,i}$; T_{inj}
2	Flow Rate (Q)	Q_{inj} & Q_{prod}
3	Fraction of tracer	ppm
4	Time (t)	Function of time
5	Additional data	

2.2 Calculation of Thermal Drawdown

The present study outlines the methodology employed for processing the thermal drawdown calculation data acquired from the geothermal well. The thermal drawdown formula proposed by Reimus et al. (2019) was utilized

for this purpose. Retrieve tabulated data from Excel pertaining to tracer test outcomes and associated supporting data. The computation of thermal drawdown can be achieved by utilizing the subsequent equation:

$$\Delta T = T_{Prod,f} - T_{Prod,i} = -f \frac{Q_{inj}}{Q_{prod}} (T_{path,i} - T_{inj}) \quad (1)$$

Symbol	Definition
ΔT	Change in production temperature.
Tprod,f	Final production temperature.
Tprod,i	Initial production temperature.
Qinj	Injection flow rate (mass or volume per unit time).
Qprod	Production flow rate (mass or volume per unit time).
Tpath,i	Initial temperature along the path between injection and production points.
Tinj	Injection temperature.

The equation is analytical, derived from first principles or assumptions about the system. It represents a relationship between temperature changes and fluid flow rates in the system. Key assumptions:

- The equation assumes steady-state conditions, meaning the system has reached a point where variables do not change with time.
- The flow rates Qinj and Qprod are constant over the period considered.
- The temperature difference Tpath, i−Tinj represents the driving force for heat exchange between the injected fluid and the surrounding environment.
- The fraction f is assumed to be constant and may encapsulate the efficiency of the heat transfer process, considering factors like reservoir characteristics or wellbore conditions.

3. RESULT AND DISCUSSION

The present study examines the phenomenon of temperature reduction in geothermal fluids, which can be attributed to production activities and may persist until a thermal breakthrough is achieved. The subject of investigation pertains to a geothermal field that comprises two phases and commenced drilling operations on October 15, 2016. The temperature of the fluid emanating from the wellhead exhibits a range of 155 ºC to 200 ºC. At present, there exist six operational production wells that cater to the energy demands of power plants. The tracer test was initiated on January 21, 2020 and data was collected and documented until July 7, 2020. Four distinct NDS tracers were employed and subsequently introduced into four separate reinjection wells, specifically identified as the I-1 Well employs the utilization of certain techniques or methods. 2.6 NDS, the I-2 Well employs certain techniques or methods. 1.5 NDS, the I-3 well is utilized for various purposes. 2.7 NDS, the I-4 well employs. 1.6 NDS.

Based on the production data, it can be inferred that production wells A and B exhibit favorable performance. The primary focus of this thesis will be on the two wells in question. Production well A is the well in closest proximity to reinjection well I-1, as depicted in Figure 1. The assertion is corroborated by the significant yield of 2.6 NDS in the operational well A, as illustrated in Figure 1. Furthermore, it is noteworthy that production well B exhibited a significant yield of 2.6 NDS, succeeded by a yield of 1.6 NDS. The reason for this is that production well B is in close proximity to the reinjection wells I-4. The results obtained from Tracer 2.6 NDS indicate a twofold increase in peak returns observed in production wells A and B. This observation provides valuable insights into the fluid dynamics and the time taken for the injection water to reach the production well. The aforementioned visual representation can be observed in Figure 1 and Figure 2.

This result is corroborated by Rijn's (2018) research, which posited that the spacing between wells is a critical factor impacting the likelihood of a breakthrough event. In instances where the spacing between wells measures 1500 meters, the temperature variation observed over a period of 50 years has registered a mere 0.1 ºC. The tracer distribution map appended to this document reveals that the spatial separation between production wells I-1 and production wells A is 600 meters, while the distance between reinjection wells I-4 and production wells B is 700 meters. Given that the inter-well spacing is below 1500 meters, it is probable that a breakthrough would transpire earlier than anticipated.

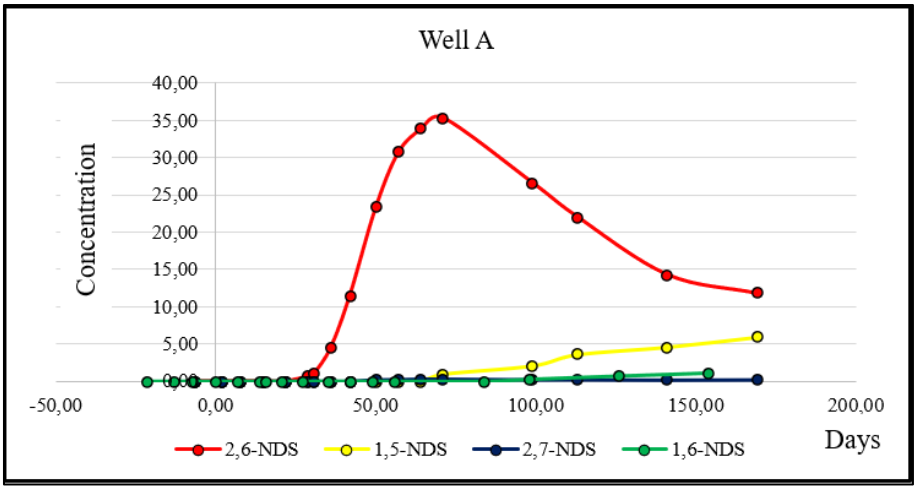

Figure 1: NDS Concentration from Tracer Test in Well A.

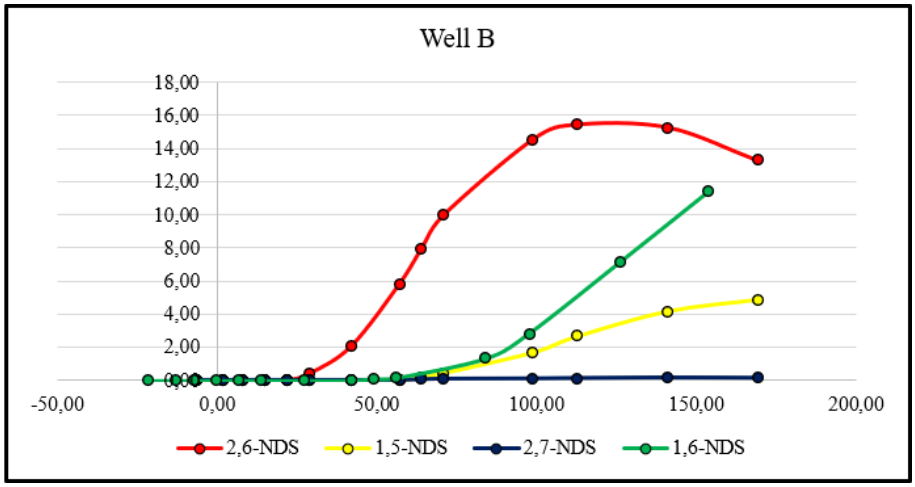

Figure 2: DS Concentration from Tracer Test in Well B.

As per the findings of Hidayat et al. (2019), it has been established that the principal source of geothermal fluid emanates from a specific production well, namely well C. The maximum temperature of the fluid recorded in this well has been determined to be 200 ºC. The temperature differential between production well A and well C is 5 ºC, whereas production well B exhibits a temperature differential of 15 ºC. The temperature decrease in well A can be computed by means of the subsequent equation, as inferred from the conducted tracer testing.

$$\Delta T = -f \frac{Q_{inj}}{Q_{prod}} (T_{path,i} - T_{inj}) \quad (2)$$

$$\Delta T = (-0.1) \frac{1150\ tph}{449\ tph} (191 - 150\ °C) \quad (3)$$

$$\Delta T = -10\ °C$$

This is further corroborated by the forecasted reduction in temperature observed in well A. According to Figure 3, a reduction of 10 ºC is anticipated to transpire in 2027, specifically 2500 days subsequent to the implementation of the tracer test. The calculation of the temperature drop in well B can be derived from the tracer testing results, utilizing the subsequent equation:

$$\Delta T = -f \frac{Q_{inj}}{Q_{prod}} (T_{path,i} - T_{inj}) \quad (4)$$

$$\Delta T = (-0.1) \frac{1150\ tph}{554\ tph} (184 - 150\ °C) \quad (5)$$

$$\Delta T = -7.06\ °C$$

This assertion is further corroborated by the forecasted reduction in temperature within borehole B. Nevertheless, the observed reduction in temperature was not 7.06 ºC, but rather 15 ºC over a span of 2500 days. The observed

disparity can be attributed to the proximity of the reinjection wells, which has resulted in a rapid decline of production well B.

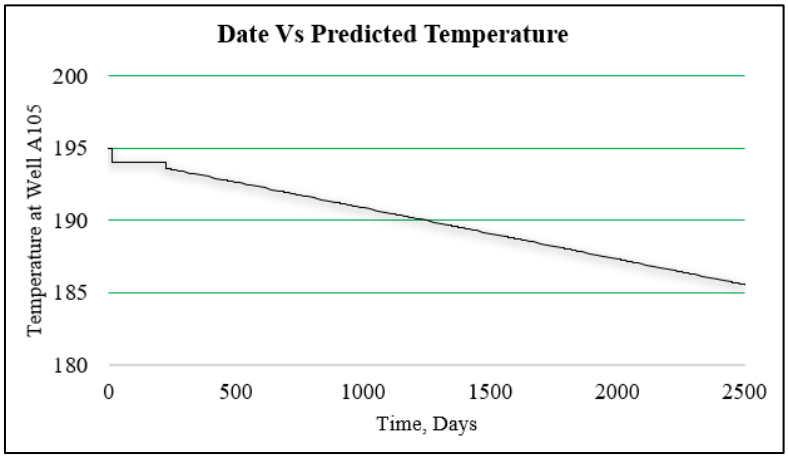

Figure 3: Prediction of Temperature in Well A.

Based on the given information regarding the decrease in temperature, it can be inferred that a reduction of 10 ºC will occur after a period of 6.8 years, equivalent to 2500 days. The thermal breakthrough in well A can be predicted by factoring in the condition that the temperature remains above 160 ºC. In January 2020, the temperature recorded in well A was 195 ºC. The temperature drop calculation indicates that it took approximately 35 ºC for the temperature to decrease, which is equivalent to 3.5 times the initial temperature. Thus, based on the available data, it can be inferred that the anticipated thermal breakthrough is likely to transpire in 2044, which is approximately 23.8 years from the present time.

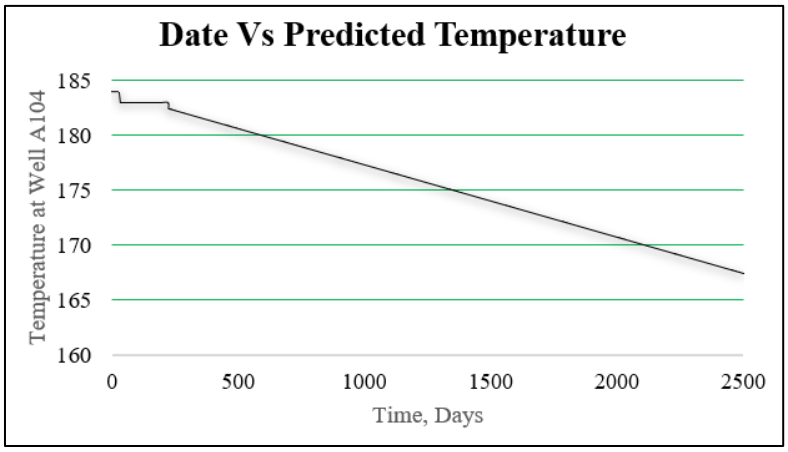

Figure 4: Prediction of Temperature in Well B.

The temperature of well B at the outset of January 2020 was recorded as 184 ºC. Subsequently, it was observed that the temperature experienced a decline of approximately 24 ºC. This value is equivalent to 1.5 times the result obtained from the computation of the temperature drop as described earlier. Thus, it is anticipated that a thermal breakthrough may transpire in 2028, which is eight years from now.

The aforementioned forecast is substantiated by the production scenario of the enterprise, which has remained unchanged subsequent to the execution of the tracer test. In the event of a modification in the given circumstances, it is plausible for a thermal breakthrough to either decelerate or accelerate. Various strategies can be employed to postpone the onset of thermal breakthrough, such as upholding the injection temperature, minimizing the frequency of injection rates, increasing the separation distance between injection and production wells, and implementing other relevant measures.

4. CONCLUSION

The proximity of production wells A to injection wells I-1 and production wells B to injection wells I-4 results in a more rapid decrease in temperature due to inadequate or insufficient time for the geothermal fluid to undergo maturation and subsequent production. The temperature of production well A decreased by 10 ºC, while that of production well B decreased by 15ºC. The proximity of the production and injection wells was found to have

influenced this temperature reduction. The projected occurrence of a thermal breakthrough in production well A is estimated to be in the year 2044, whereas in production well B, it is anticipated to occur in 2028. Given the limitations of the present study, it is anticipated that forthcoming investigations will employ a reservoir simulation model that closely approximates the W field to elucidate the dynamics of geothermal fluid flow. Additionally, it is recommended that tracer return data be recorded over extended periods for alternative injection wells to establish their interconnectivity with production wells. In order to expand its knowledge beyond the injection wells I-1 and I-4, it is imperative to undertake further research and analysis. In order to mitigate the swift thermal drawdown, it is necessary to either shut down existing injection wells or introduce new ones at a specific distance.

ABSTRACT

The Karaha Geothermal Field or Karaha Field is an active production field owned by PT Pertamina Geothermal Energy which has production problems, namely scaling of corrosion residue caused by the presence of acid content in this field's reservoir. This research aims to determine the production potential of the JTG-3 and GMB-2 wells in the Karaha Field which was obtained from the result of the PTS flowing survey and from geochemical samples. The research began by reviewing and analyse PTS flowing data and well configuration data which was obtained from the drilling process, those data are used to determine the condition of the wells and reservoir.

The result show that there has been a decrease in production figures at JTG-3 well from 102 t/hr mass rate with a dryness of 37% in 2018 to 43 t/hr mass rate with a dryness of 29% in 2022. Apart from that, GMB-2 well does not have the latest production data. However, in 2019 production reached 64 t/hr mass rate, which is much higher than the JTG-3 well considering that the GMB-2 well is a single phase well were the dryness will be assumed to be 100%. Later on, the result of electricity production potential also showed that were in line with the steam mass rate contained in each well, whre the GMB-2 well recorded the highest potential. Afterwards, from the result of the water sample analysis carried out, it can be seen that the wells studied experienced scaling problems, supported by the result of the fluid velocity curve which showed turbulent result. The scaling that occurred in the wells at the Karaha Field was Fe Scaling, which is a residue resulting from corrosion, and SiO2 which is mainly found in 2-phase wells with low dryness.

1. INTRODUCTION

Pressure, temperature, and spinner (PTS) surveys conducted under flowing conditions are essential procedures as the resultant data is invaluable for determining a well's fluid production capacity. Furthermore, these surveys assist in identifying the number of feed zones and assessing each feed zone's ability to channel fluid from the reservoir into the well. The collected data can also highlight potential issues within the well or the reservoir, exemplified by the challenges encountered in the JTG-3 and GMB-2 wells in the Karaha Geothermal Field.

This field faces a significant issue of declining production due to the acid content from the heat source intruding into the reservoir. Such acid intrusion can compromise the well's stability, causing damage to the well liners, leading to scaling, and subsequently reducing production over time. To address these challenges, this research involved collecting well water samples to analyse the fluid content. This analysis aims to identify the problematic constituents affecting well production and to establish benchmarks for mitigating these production issues. The research workflow is illustrated in Figure 1.

2. PTS FLOWING SURVEY

The pressure, temperature, and spinner measurements in this study were conducted on wells JTG-3 and GMB-2, with a total of three sets of data obtained from measurements taken in 2018 and 2022 for well JTG-3 and in 2019 for well GMB-2. Variations in cable speed were applied at two different speeds for each measurement to determine the slope used in calculating fluid velocity. Figure 2 illustrates the implementation of downhole logging.

The raw data obtained directly indicated the location of each feed zone, marked by a significant increase in spinner frequency as shown in figure 3. However, it is important to note that an increase in spinner frequency does not always indicate a feed zone position. The spinner's response to the fluid can also be influenced by the roughness of the surface it traverses and the casing ID. As a result, anomalies in the spinner response can be observed at different casing joints and areas with high roughness.

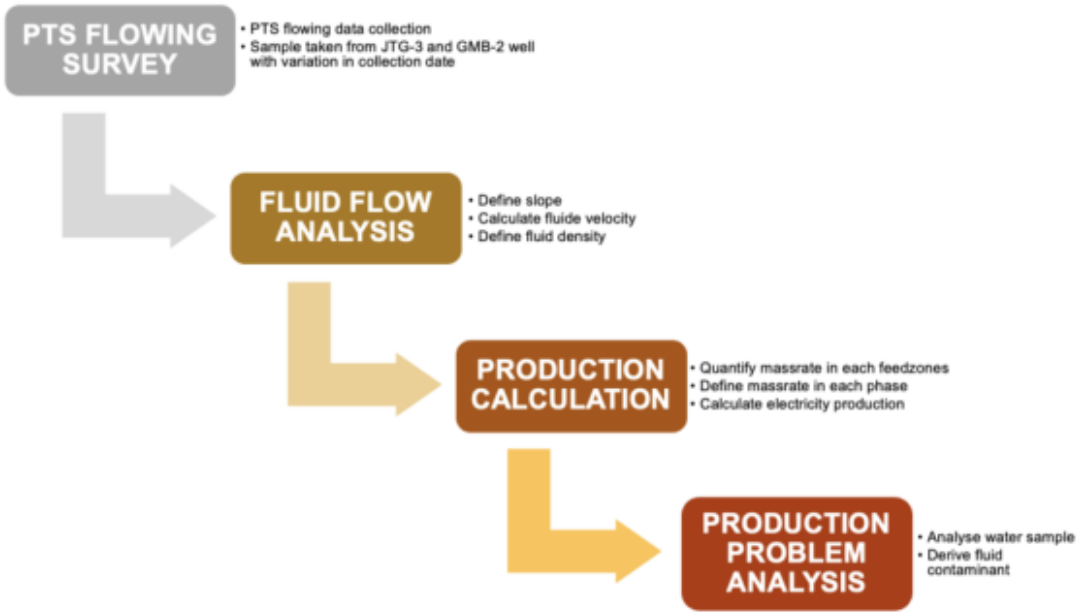

Figure 1: Detailed Workflow Implemented in the Research for Quantify Feedzone Fluid Production and Analyse Production Problem.

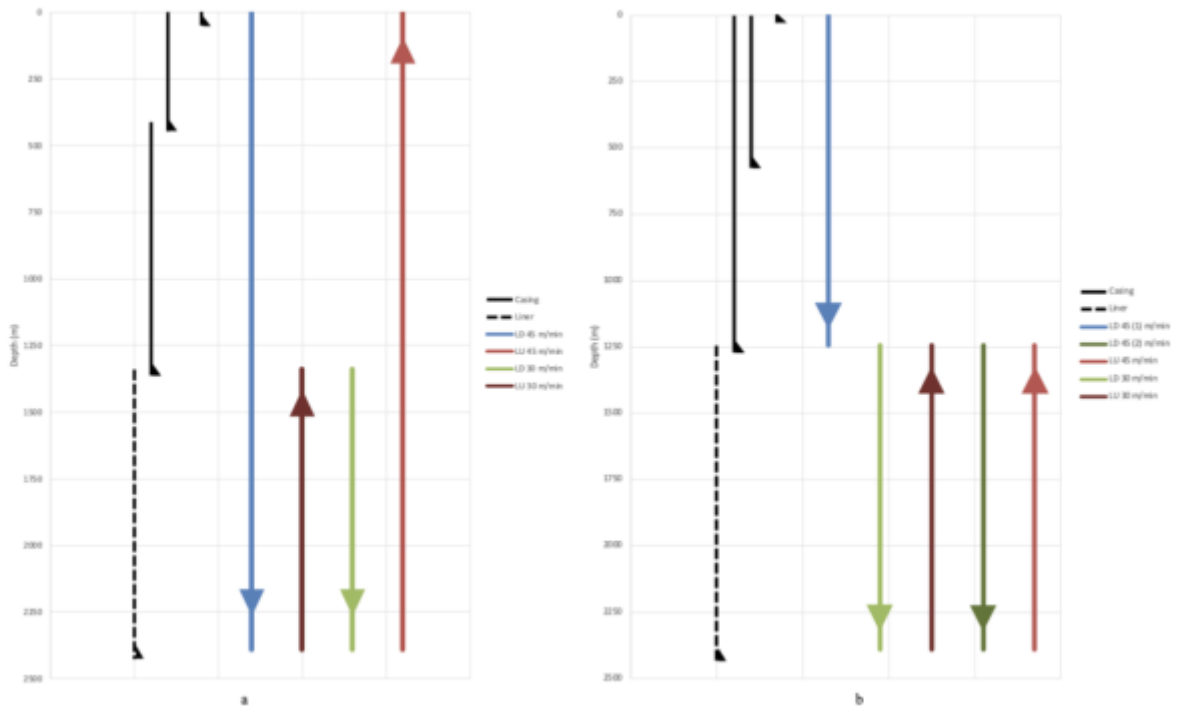

Figure 2: Illustration of the PTS flowing procedure, a) well JTG-3, b) well GMB-2.

3. FLUID FLOW ANALYSIS

Analysis of fluid flow patterns can be conducted by examining the fluid velocity curve. To determine fluid velocity, calculations based on spinner frequency and cable speed are necessary. Therefore, the slope is calculated using the following equation:

$$slope = \frac{V_t}{f} \quad (1)$$

Where Vt and f represent the cable speed and spinner frequency, respectively. The calculated slope results can be observed in Figure 4.

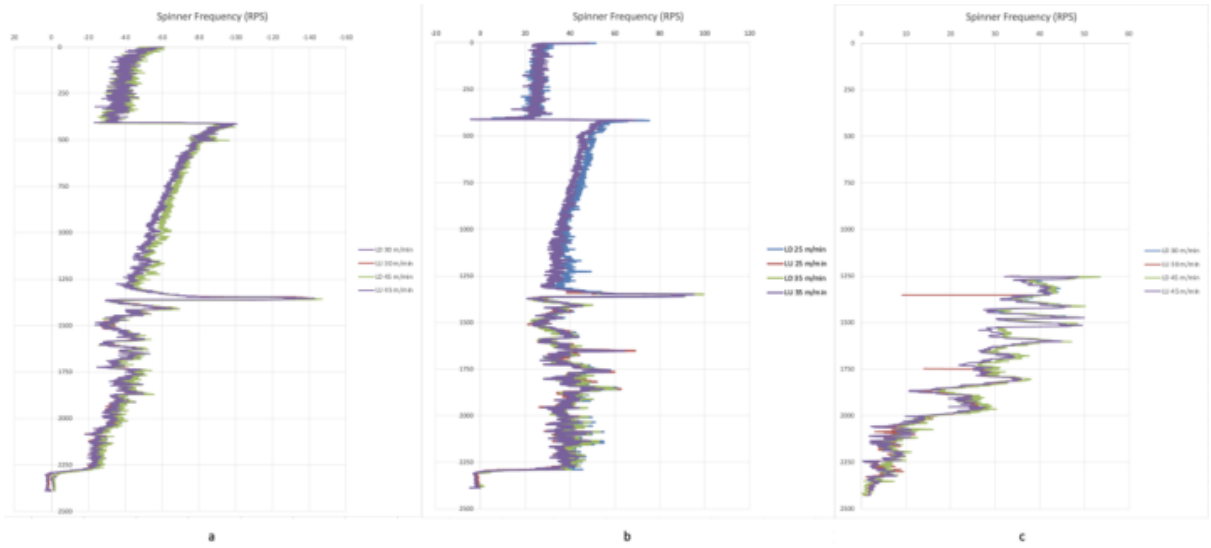

Figure 3: Spinner frequency curves, a) well JTG-3 (2018), b) well JTG-3 (2022), c) well GMB-2 (2019).

Figure 4: Slope observed, a) well JTG-3 (2018), b) well JTG-3 (2022), c) well GMB-2 (2019).

The slope is determined based on dominant data anomalies present in the curve. Subsequently, the determined slope value is used to compute fluid velocity based on the equation 2.

$$Vf = (f \times slope) - Vt \quad (2)$$

Here, Vf represents the fluid velocity. Grant & Bixley (2011) explain that anomalies in fluid flow patterns can be observed from the fluid velocity curve. More turbulent fluid flow is indicated by higher deviations in flow pattern anomalies, as demonstrated in the fluid velocity calculations for wells JTG-3 and GMB-2 shown in Figure 5.

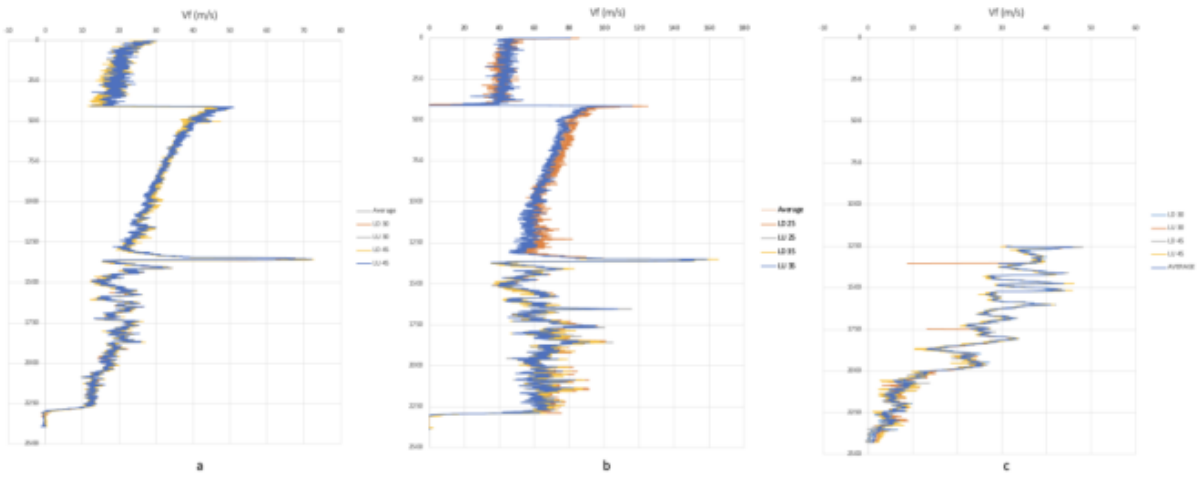

Figure 5: Fluid velocity curve, a) well JTG-3 (2018), b) well JTG-3 (2022), c) well GMB-2 (2019).

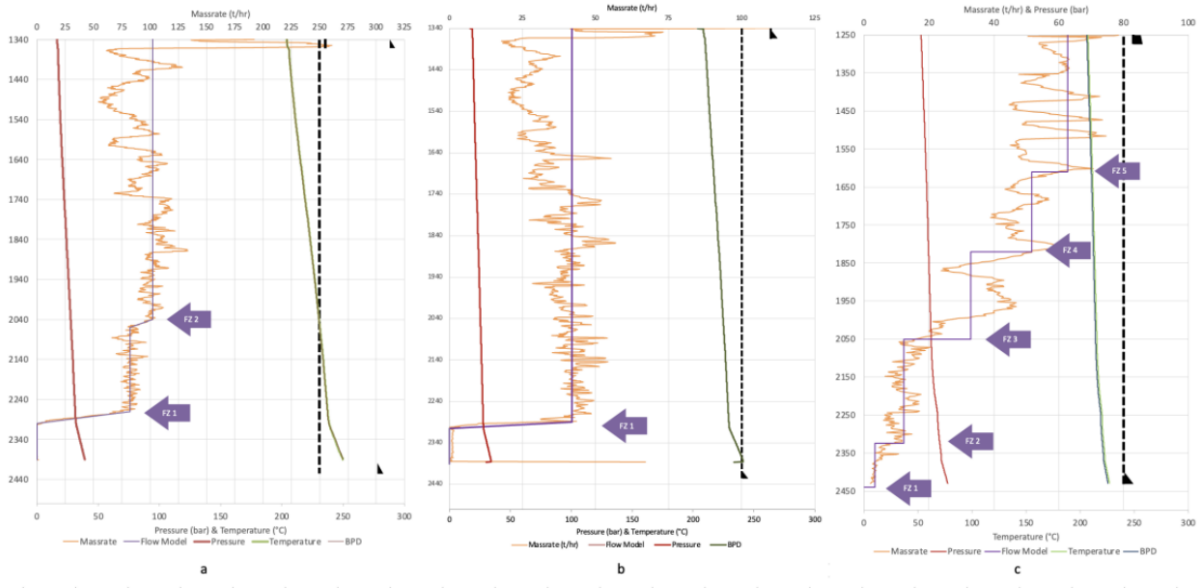

Figure 6: Mass rate curves with feedzone mark, a) well JTG-3 (2018), b) well JTG-3 (2022), c) well GMB-2 (2019).

The flow conditions in well JTG-3 tend to be more laminar, with significantly lower deviations compared to well GMB-2. However, in 2022, the flow conditions in well JTG-3 became increasingly turbulent, although not more turbulent than in well GMB-2.

4. PRODUCTION QUANTIFICATION

When calculating the production capacity of a geothermal well, the primary metric is the well's steam production. This is because the luid used to drive the turbine and generate electricity must be in the vapor phase. The key indicator of steam production is the mass flow rate of the fluid.

4.1 Mass Rate & Feedzone Contribution

Mass rate is the ultimate outcome of the PTS flowing survey, providing an indication of the well's production rate as elucidated by Buscato (2012). Unlike flow rate, which compares the fluid flow in volume per unit time, mass rate compares the fluid flow in mass per unit time, typically expressed in kg/s or t/hr. The distinction between mass rate and fluid velocity lies in the adjustments for casing diameter and fluid density, as defined equation 3.

$$\dot{m} = V_f \rho \left(\frac{\pi}{4} ID\ Casing^2\right) \quad (3)$$

Where $\dot{\mathbf{m}}$ and $\boldsymbol{\rho}$ is the mass rate and fluid density. The total mass rate measured for well JTG-3 in 2018 was 102 t/hr. In 2022, the total mass rate for the same well was 43 t/hr, while well GMB-2 had a total mass rate of 64 t/hr

in 2019. These results will be validated by examining TFT data corresponding to the PTS survey dates. Upon calculation and plotting the mass rate curve, the productive permeable zone, commonly referred to as the feed zone, should become apparent. This zone possesses high permeability, allowing geothermal fluid to flow from the formation into the well. The feed zone can be identified from the mass rate curve at the lower sections of the well (along the liner) by observing anomalies in mass rate changes. The location of the feed zones for each well data set can be seen in the figure 6.

Subsequently, the contribution of each feed zone will be quantified to ascertain the percentage contribution of each feed zone to the total well production using equation 4.

$$\%\ contribution = \frac{\dot{m}_1 - \dot{m}_0}{\dot{m}} \times 100\% \quad (4)$$

The contributions of each feed zone in each well are detailed in Table 1. The loss of the feed zone at a depth of 2060 m-MD in well JTG-3 has a significant impact on the fluid composition within both the well and the reservoir. Therefore, a further analysis of the fluid composition, reviewing the geochemical data of the well, is necessary.

Table 1: Each Feedzones Contribution.

Well	Measurement Date	Feedzone	Contribution (%)
JTG-3	2018	FZ-1	80.6
		FZ-2	19.4
	2022	FZ-1	100
GMB-2	2019	FZ-1	5.3
		FZ-2	11.6
		FZ-3	35.6
		FZ-4	29.8
		FZ-5	17.7

4.2 Production Potential

In the production process, after the fluid is extracted from the well, it enters a separator to divide it into vapor and liquid phases, since only the vapor phase is utilized to drive the turbine. The separated liquid phase then passes through a weir box to measure its mass rate, after which it is reinjected into the reservoir via a reinjection well. The mass rate of the brine passing through the weir box can

be determined, and by subtracting the known brine mass rate from the total mass rate, the steam mass rate can be ascertained. The mass rates of each phase can be calculated using equation 5 and 6.

$$\dot{m}_b = 2.362\left(C_d\ tan\frac{\theta}{2}\ h^{5/2}\right)\rho \quad (5)$$

$$\dot{m}\,s = \dot{m} - \dot{m}\,b \quad (6)$$

and the dryness can be calculated using the following equation:

$$dryness = \frac{\dot{m}_s}{\dot{m}} \times 100\% \quad (7)$$

where ṁ b, ṁ s, Cd, θ and h is brine mass rate, steam mass rate, dischange coefficient, v-notch angle and brine height in v-notch. With a v-notch angle of 90° and a discharge coefficient of 0.9, the calculated mass rates of each phase and their corresponding dryness are presented in Table 2.

Table 2: Result of the mass rate calculation for each phase.

Well	Measurement Date	h (m)	Massrate (t/hr)			Dryness
			Total	Brine	Steam	
JTG-3	2018	0.145	102	64	38	37%
	2022	0.15	43	30	13	29%
GMB-2	2019	-	64	-	64	100%

After all the steam is separated from the liquid phase, the steam enters the turbine to drive it. The turbine is connected to a generator that produces electricity. The electrical output from each well can be calculated based on the well's production mass rate and the specific steam consumption (SSC) of the turbine. In this study, the SSC of the turbine according to field specifications is 8 kg/MW-s. The calculated production capacity from each test is detailed in Table 3.

Table 3: Electricity production potential based on each test result.

Well	Measurement Date	$\dot{m}s$ (kg/s)	SSC (kg/MW-s)	Electricity Production (MW)
JTG-3	2018	10.5	8	1.31
	2022	3.6	8	0.45
GMB-2	2019	17.7	8	2.22

5. PROBLEM ANALYSIS

The issue of declining production at the Karaha Field is critical and warrants thorough investigation to identify the underlying causes. To this end, the productivity index (PI) of this field will be examined to elucidate the production decline in wells JTG-3 and GMB-2, as well as through the analysis of water samples from these wells.

5.1 Productivity Index

Wells can be classified into two categories: productive and non-productive. Musnal & Melisa (2016) assert that the capacity of a geothermal fluid accumulation in the reservoir to be extracted is contingent upon the reservoir's productivity. Consequently, a comparison is made between the well's production rate and the reservoir pressure, a value known as the productivity index (PI). According to Brown (1997), PI can be measured by comparing the bottomhole flowing pressure (Pwf) with the static well pressure (Ps) and the produced fluid, which expressed in equation 8.

$$PI = \frac{\dot{m}}{Ps - Pwf} \tag{8}$$

The PI calculation results for well JTG-3 and GMB-2 with its feedzones are presented in Table 4.

The PI data for well JTG-3, derived from measurements taken in 2018 and 2022, reveals a decline in PI in 2022, indicative of a reduction in well productivity. According to Wahyudityo et al. (2013), this necessitates the collection of well water samples to analyse the chemical content within the well, as well JTG-3 is a two-phase well with low dryness, rendering it susceptible to scaling, which can diminish well productivity. Furthermore, the PI data for well GMB-2 yielded a value of 0.86, which is considered quite satisfactory for a single-phase steam well, as it is assumed that all produced fluid will be utilised to drive the turbine. In contrast, well JTG-3, being a two-phase well with low dryness, undergoes a separation process, resulting in a smaller quantity of steam produced compared to a single-phase steam well.

Table 4: PI in each wells and its feedzones.

Well	Measurement date	Ps (bara)	Pwf (bara)	Feedzone	PI (kg/s.bar^{-1})	
					Feedzone	Well
JTG-3	1 Aug 2018	99.4	39.7	FZ-1	1.38	1.71
				FZ-2	0.33	
	9 Dec 2022	99.4	34.3	FZ-1	0.64	0.64
GMB-2	20 Mar 2019	50	50	FZ-1	0.05	0.86
				FZ-2	0.10	
				FZ-3	0.31	
				FZ-4	0.26	
				FZ-5	0.15	

5.2 Water Sample Analysis

The Karaha Field is indicated to have acidic content caused by the intrusion of magmatic fluids into the reservoir. This is evidenced by the closure of exploration wells in the Talaga Bodas Area. Although the issue of acidic content is common in geothermal fields, it is essential to collect fluid samples from the wells for chemical analysis. Additionally, several wells in this field are two-phase with low dryness, increasing the potential for scaling. The Cl-SO4-HCO3 diagram is shown in Figure 7.

A sample taken from a well must contain a high chloride (Cl) content, as Cl is the element that binds reservoir water, also known as mature waters. This water is the result of heating meteoric water by the heat source, but it does not necessarily contain the sulphate (SO4) element present in the heat source. The heat source and the reservoir must have a boundary separating them to prevent acidic sulphate from the heat source (volcanic waters) from contaminating the reservoir fluid. The indication of volcanic waters entering the reservoir is a shift in the well water sample point from the mature waters area near the Cl peak towards the volcanic waters area on the SO4 axis.

In essence, the currently active wells in the Karaha field are still considered free from volcanic water contamination. However, a closer examination reveals a shift in the GMB-2 well sample point towards SO4 compared to the JTG-3 well sample, which is precisely at the Cl peak. Although this shift is not significant and remains within the mature waters area, there is a trend of increasing SO4 concentration as samples are taken further north in this field. This supports the theory of magmatic fluid intrusion contaminating the northern reservoir, corroborated by the pH samples shown in Table 5.

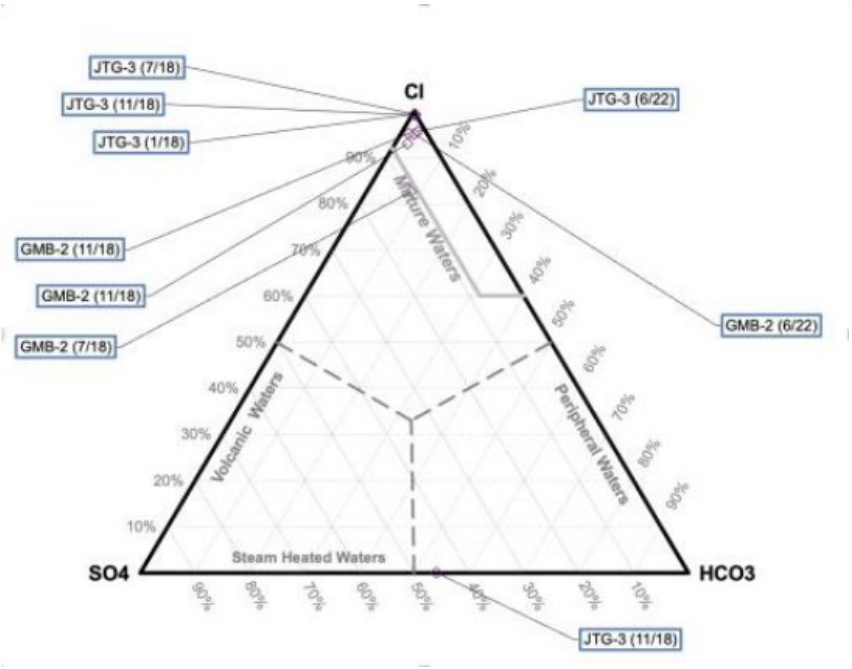

Figure 7: Cl-SO4-HCO3 diagram.

Table 5: pH data from well water samples JTG-3 and GMB-2.

Well	Sample Collection Date	pH
JTG-3	17 July 2018	7.5
	22 June 2022	7.2
GMB-2	7 November 2019	6.2
	23 June 2022	5.9

Table 6: Fe concentration in wells JTG-3 and GMB-2.

Well	Sample Collection Date	pH
JTG-3	17 July 2018	0.01
	22 June 2022	0.11
GMB-2	7 November 2019	0.02
	23 June 2022	0.35

With more acidic conditions observed in well GMB-2, which is located in the northern area of the field, compared to well JTG-3 in the southern area, a downward trend in pH is apparent. This aligns with the increase in acidic sulphate concentration, which will inevitably affect the production process of wells situated further north, such as well GMB-2. Higher acid content accelerates corrosion of the slotted liner used in the wells. The presence of Fe metal in the well water samples further evidences this corrosion, as shown in Table 6.

The highest concentration of Fe metal is found in well GMB-2, consistent with higher sulphate content and lower pH in this well. Unfortunately, there are no recent data for well GMB-2, so the corrosion rate in this well cannot be determined. Additionally, well JTG-3 also shows the presence of Fe metal, albeit at lower concentrations, but an increase in Fe metal concentration is observed from samples taken in 2018 compared to those in 2022. The residue from corrosion of the liner then moves with the fluid flow in the well.

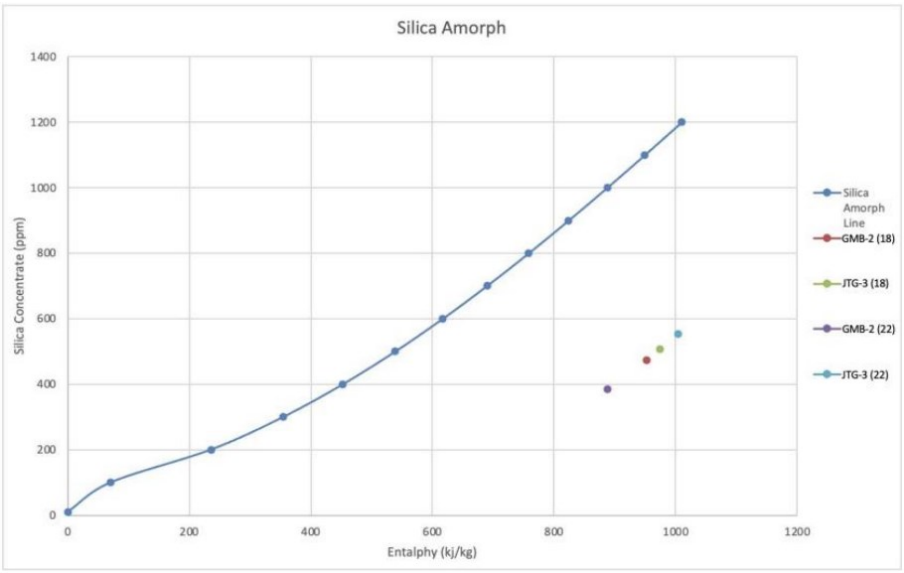

Figure 8: Silica amorph curve.

There is also SiO2 content in these wells, indicated through calculations with the silica amorph curve shown in Figure 8. The four sample points below the silica amorph line indicate that the silica content in these wells is still within acceptable limits. However, SiO2 will adhere to the casing and liner walls, causing scaling.

Well JTG-3 has a higher silica concentration than well GMB-2 because well JTG-3 is a two-phase well with low dryness, containing significantly more brine than well GMB-2. The higher the brine content, the greater the potential for SiO2 scaling. In the case of these two wells, the SiO2 present adheres to the well walls, serving as a medium for Fe metal corrosion residue to adhere as well, resulting in scaling composed of a mixture of SiO2 and Fe metal. Well JTG-3 has a lower Fe content due to lower sulphate concentration but higher SiO2 content due to more brine, which is the opposite of the condition in well GMB-2. Scaling in Karaha Field wells will undoubtedly cause production declines, as seen in Figure 6, and financial losses for the field.

6. CONCLUSION

Based on the result exercise, the following conclusion can be drawn:

1. Based on the fluid velocity curve, the results indicate turbulent flow patterns in both wells. However, the flow in well GMB-2 is deemed more turbulent compared to well JTG-3 due to the higher deviation observed in the curve for well GMB-2.
2. The electricity production derived from well JTG-3 based on the PTS flowing survey was 1.31 MW in 2018 and 0.45 MW in 2022, whereas the electricity production from well GMB-2 was 2.22 MW in 2019. This is based on the mass rate obtained from the PTS flowing survey, which was 102 t/hr in 2018 and 43 t/hr in 2022 for well JTG-3, and 64 t/hr for well GMB-2 in 2019.
3. According to the geochemical water sample review, well JTG-3 is assessed to contain less acid compared to well GMB-2, as evidenced by the lower pH and SO4 concentration. This results in a higher rate of corrosion and scaling from corrosion residues in well GMB-2. Conversely, well JTG-3 has a higher SiO2 concentration, affecting silica scale formation. Therefore, while well GMB-2 faces more severe issues related to acid-induced scaling, considering the actual production phase and silica solubility, well JTG-3 is likely to experience a greater production decline compared to well GMB-2.

In subsequent research, it is recommended to review PTS injection data to enhance the reliability of the findings. Additionally, it is advised to examine the latest PTS flowing data from well GMB-2 to enable a comparison of fluid velocity curves. Given that the PTS flowing test is conducted to ascertain the properties of the feedzone, data processing should focus exclusively on the data indicated along the liner, as it is assumed that no further feedzone exists once the casing is reached. Furthermore, a detailed study on the issues of acidity and scaling in this field is necessary to optimise production at the Karaha Field.

ACKNOWLEDGEMENT

The authors would like to express their appreciation to PT Pertamina Geothermal Energy for access to field data and continuous support.

Positive Impact of Reinjection Infill on Geothermal Field Pressure Support

ABSTRACT

Observations of downhole pressure and temperature in Sorik Marapi geothermal production wells has shown indications of reinjection impacts on continuously flowing wells. The cooling impact was observed from the temperature reversal observed in the flowing wellbore profile, which was not previously seen during testing. Injection infill began in 2021 to provide more pressure support in productive reservoir. The shift in injection strategy partially away from infill zone conducted in 2022 shows that the productive reservoir still impacted with pressure support while reducing negative cooling impact. From the second quarter of 2023, brine rate output of production well AA showed a declining trend. By mid-2024, the rate of decline in brine mass flow production had eased with further improvement potential. The continuation of injection strategy away from within production zone showed improvement in nearby production well's flowing performance. These downhole surveys and production data analysis provides sufficient indication and insights for field-wide resource optimization.

1. INTRODUCTION

Sorik Marapi reservoir, developed by PT Sorik Marapi Geothermal Power as a project under KS Orka Renewables Pte. Ltd (KSO - a Singapore based company), is one of the liquid-dominated geothermal fields situated in Sumatran Fault damage zone, specifically in Mandailing Natal Regency. Until mid-2024, Sorik Marapi has been exploited and developed aggressively in four phases since 2019, producing up to 1100 kg/s of total mass flow rate consisting of steam and brine for the dual-flash system and combined-cycle modular power generation technology by Kaishan. One of the major challenges faced in liquid-dominated geothermal field such as Sorik Marapi pertains to effectively managing the fluid reinjection strategy. To address this concern, multiple work related to reservoir tracer testing, routine surface wellhead data monitoring, routine geochemistry sampling and monitoring, tracer flow tests samplings, and downhole surveys are conducted among other possible testing and surveys to characterize well and reservoir. Observations discussed in this study had resulted in a proactive intervention in the existing reinjection strategy not only to protect the main production zone from negative cooling impact but also to drive a properly provided active reservoir pressure support.

This study is aimed to investigate the effect of specific reinjection strategy implemented within Sorik Marapi main production zone using interpretations of short-term downhole pressure and temperature surveys. Sorik Marapi main reservoir has observed a trend of two-phase expansion, related to Sorik Marapi fluid saturation and enthalpy measured at surface. Sample data of production wells-fluid enthalpy at the subsurface had been identified at an estimated averaged value ~1070 kJ/kg with an increasing enthalpy trend over the recorded history. The observed increase in production enthalpy as a result of two-phase fluid expansion was anticipated, because Sorik Marapi had continued to increase field-wide mass extraction rate with each completion of phase development.

Abundant knowledge and understanding were gained throughout the period of reinjection and production monitoring. Discrete interpretations from downhole survey data were obtained by Sorik Marapi Geothermal Power's in-house logging team using in-house logging truck and facilities are incorporated into the specific evaluation of infill reinjection strategy. Observations of downhole pressure and temperature in flowing surveys had shown indications of reinjection impacts, in which negative cooling impact confirms the observed decline in brine mass flow production.

2. REINJECTION STRATEGY AND RESERVOIR RESPONSE

2.1 Reinjection in Sorik Marapi Geothermal Field

Liquid-dominated Sorik Marapi reservoir has been continuously accepting continuous stream of mixed brine and condensate since production began in 2019. The reinjection strategy has evolved with Sorik Marapi's four phase developments up to mid-2024, in terms of reinjection temperature, total mass injected, and reinjection location. The source of reinjection into Sorik Marapi reservoir since 2019 has been situationally mixed with fresh water from drilling fluid waste from the concurrent drilling activities, which is estimated to have contributed as much as <1% of the total water volume injected up to mid-2024. As the drilling waste contribution had been relatively

little and intermittent compared with the overall brine and condensate injectate, the injectate chemistry changes due to drilling activity has been disregarded in this study which could be for potential future study.

Reinjection temperature in Sorik Marapi is equal to the mixed rejected temperature outlet from binary cycle modules and condensate outlet from the hybrid evaporative-cooled condenser. Throughout Sorik Marapi's four phase development, rejected temperature from power generator outlet averaged from 80°C to 90°C, depending on the amount of brine being utilized into the system. In general, excess brine supply allows for higher brine mass flow rate as heat source into the heat exchangers and therefore exits the brine Organic Rankine Cycle (ORC) system with an elevated rejection temperature.

Additionally, excess brine supply that do not enter the heat exchanger system will be bypassed to join the brine outlet from system to the reinjection line, which therefore increases the overall injectate temperature that is being accepted by Sorik Marapi reservoir. Increased reinjection temperature causes a downward shift of overall injectors injection capacity curve, and therefore requiring an adjustment in the reinjection strategy. Excess brine supply in Sorik Marapi occurs intermittently as newly drilled wells were being flow tested or brine utilization awaits for the upcoming phase development. By mid-2024, the injectate temperature within Sorik Marapi overall reinjection line and wellheads remain stable at the measured average of 80°to 86°C.

For the purpose of this study, the reinjection activity which targeted location within proximity of Sorik Marapi main production zone is mainly called infill reinjection. Historically, reinjection infill in Sorik Marapi had been actively conducted on several injectors located in different well pads, where major production wells also exist in the same corresponding well pads.

2.1.1 Reinjection Infill at Well ZZ

In particular, an infill reinjection well so called well ZZ, is of great interest for Sorik Marapi's reservoir characterization due to its uniqueness in presenting immediate reinjection impact to production wells within its proximity. Well ZZ is a single infill injector located in well pad ABZ which had been injecting mixed brine and condensate since mid-2021, with main objective of supporting Sorik Marapi's second phase development reinjection demand.

Injection well ZZ demonstrated an outstanding injection acceptance capacity while flow testing the well had confirmed that it remained a low performing producer, even for Sorik Marapi's standard. The opportunity of utilizing high injection capacity in well ZZ posed risk and challenges on managing Sorik Marapi's reservoir.

In response to this challenge, a well-executed monitoring routine program at surface and downhole was initiated to safely enable well ZZ as an infill injector. It is important to note that infill injector ZZ is located in the same well pad, well pad ABZ, as major production wells, including production well AA and well BB.

2.1.2 Reinjection Infill Strategy Remains Successful in Several Injectors

In the course of high-rate reinjection infill at well ZZ, production well AA within the proximity exhibits rapid performance decline observed from declining flowing wellhead pressure, declined total mass output, and confirmed by decreased non-condensable gas (NCG) content. As well ZZ eventually reduced injection rate and eventually stop injecting in 2024, well ZZ availability is maintained as an injector for the long term strategy planning or future field management strategy.

Nevertheless, the indicative success by far of reinjection infill can be attributed to the infill injectors other than well ZZ in Sorik Marapi. These infill injectors had been actively accepting mixed brine and condensate as injectate since mid-2021 and remained so up to early 2024. Further monitoring and evaluation is imposed into these other infill injectors with similar attentiveness as to the previously discussed well ZZ to ensure that the reinjection strategy is proper according to Sorik Marapi development phase. It is possible that future reinjection strategy would imposes shifting in infill injection strategy away to peripheral, according to Sorik Marapi's reservoir response to the planned fifth phase development.

2.2 Downhole Pressure and Temperature Observations

Downhole pressure and temperature profiles were measured during flowing condition to Sorik Marapi power plant system. At least two production wells in Sorik Marapi had demonstrated pressure support within the productive area due to infill reinjection. The effectiveness of reinjection infill not also indicated by lack of pressure drawdown observed, but also lack of thermal breakthrough to the nearby producers.

The analysis of the two production wells presented in this study, so called well AA and well BB, have consistently demonstrated the absence of reservoir pressure drawdown, offering strong assurance that reinjection infill in Sorik Marapi is functioning intended. Nevertheless, the strategic approach still require careful implementation as a concerning development of cooling impact was observed in specific well AA. This observation serves as a

reminder of the importance vigilant downhole reservoir surveillance and swift active response measures in maintaining the productivity of geothermal field.

Well AA stands as a vital active production well, contributing both steam and brine for the Sorik Marapi screw expanders, steam ORCs, and brine ORCs, which has a capacity of ~4.9 MW. Since its commissioning in 2019, well AA had been actively feeding supply into Sorik Marapi's power generation system.

For well AA, diagnosing its declined performance has highlighted the exhibition of cooling impact due to reinjection returns in Sorik Marapi. Production well AA had been continuously producing > 24 kg/s total mass flow rate for 5 years, discharged at wellhead pressure >11 bara. Comparison of well AA flowing temperature profiles well AA is shown in Figure 1 below, with surveys conducted in 2021 and 2024. Flowing profile in 2024 observes a window of temperature reversal measured from depth 1300 – 1700 mMD. The temperature deflection in flowing survey well AA in 2024 is observed from ~8 to 30°C, while previous 2021 survey observed fully-saturated temperature profile from top to bottomhole.

Remarkably, no cooling impact was observed in the downhole flowing survey of production well BB, within the proximity of the infill reinjection well ZZ. Production well BB had been continuously producing > 98 kg/s total mass flow rate for 5 years, discharged at wellhead pressure >11 bara. Comparison of flowing temperature profiles well BB is shown in Figure 2 below, with surveys conducted in 2021 and 2024. Flowing pressure profile in 2024 observes a higher wellbore flowing pressure at the bottomhole. There are differences observed in the temperature profile of well BB, in which the temperature profile follows fully saturation profile as a function of fluid pressure throughout bottom up of the hole.

Based on internal report analysis, the productivity performance as a function of permeability had not experience any significant changes in both wells AA and BB. Trianandra (2024). The well integrity and treatment remains similar for both production wells throughout 2021 until 2024, without any wellbore obstruction nor intervention applied.

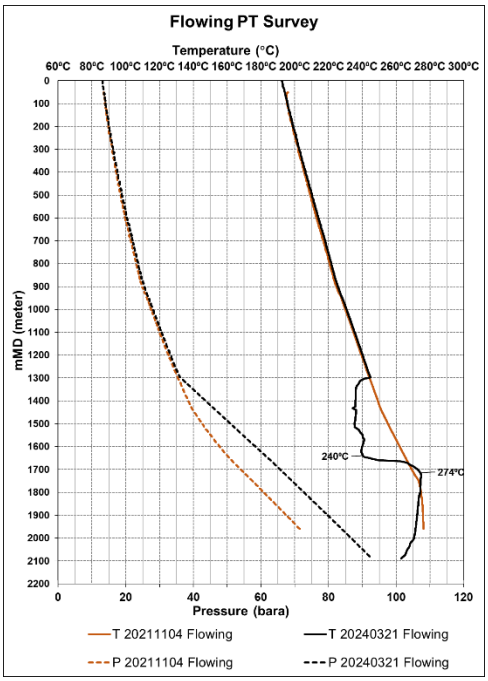

Figure 1: Comparison of Pressure Temperature surveys of flowing well AA in 2021 and 2024.

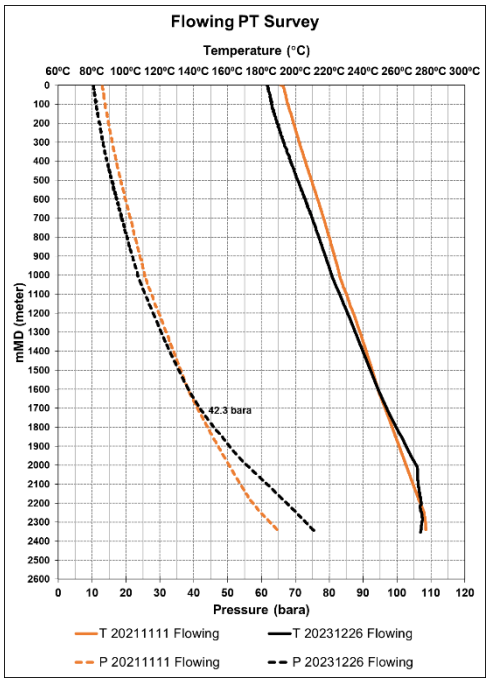

Figure 2: Comparison of Pressure Temperature surveys of flowing well BB in 2021 and 2024.

2.3 Impact of Reinjection

The shift in reinjection strategy to partially divert main production zone reinjection to across production zone boundary was conducted in 2022. Initiating the reinjection diversion was triggered by the rapid decline of wellhead pressure and production supply observed on well AA. This specific action is termed partial as it consists of targeted diversion of reinjection from a specific injector ZZ, while other wells injecting within main production zone remained unchanged.

As newly drilled wells were commissioned with excess hot brine into the Sorik Marapi reinjection system, well ZZ was initially designated to accept mixed brine and condensate at noticeably higher flow rate beginning in

early-2022. Well ZZ high injection capacity availability leads it to be the main objective of accommodating higher capacity reinjection required for the hot reinjection overall demand.

Rapid performance decline which was observed in well AA was analyzed and eventually understood as a direct cooling impact from the high-rate infill injection imposed on the nearby injector well ZZ. After the observation of rapid decline at well AA, a stop injection was imposed to the injection at well ZZ once plausible. The window of beginning injection at well ZZ until executing the reinjection shift away was imposed within several months which may likely to have avoided detrimental impact on Sorik Marapi reservoir long term utilization.

3. CONCLUSION

Even though analysis and interpretation of data collected during Sorik Marapi reinjection infill is still on going at the time of writing of this study, available results are highly positive. On the one hand, negative cooling impact or rapid production decline is not expected in production wells during long term injection in the current partially infill injection strategy. On the other hand, steam and brine production from Sorik Marapi field may be supported by the partially infill reinjection strategy, by maintaining stable pressure drawdown.

Similarities in well AA and BB were observed in the positive impact of reinjection infill as flowing pressure support to improve nearby production well's flowing performance. The shift in injection strategy partially away from infill well ZZ conducted in 2022 shows that it is likely that Sorik Marapi productive reservoir is still impacted with pressure support while reducing negative cooling impact.

The Sorik Marapi continued development will significantly affect reservoir fluid pressure and temperature balance, as well as its geochemistry. The optimized strategy in the upcoming term may differ significantly from the current discussion. Therefore, it may be concluded that reservoir surveillance by downhole surveys is important for Sorik Marapi field management, with additional allowance of flexibility to optimize the extraction and reinjection strategy.

Keywords: Intervention, wellbore simulation, cost-benefit analysis, risk assessment, decision matrix tool

ABSTRACT

Continuous exploitation of two-phase geothermal reservoirs often encounters challenges such as mineral scaling, pressure drawdown and thermal breakthrough. These challenges can abruptly affect production, reduce a well's effective lifetime or increase the overall project expenses required to achieve sustainability of a geothermal resource. Several well and reservoir interventions like scaling inhibition, broaching, acid treatment, mechanical workovers using coiled tubing and reinjection optimisation have proven to be successful in mitigating the negative effects of these challenges. However, the probability of success is not guaranteed and therefore, the economic benefits are unique for each solution. This variability, along with changing priorities and preferences such as lesser budget allocation for geothermal subsurface maintenance compared to other asset maintenance activities, makes it challenging for geothermal production managers to make informed decisions regarding well and reservoir intervention activities.

In this paper, a decision matrix tool is established to prioritise the approach for each well and reservoir intervention based on technical, financial and risk factors. Wellbore simulation is used as a tool in predicting outcomes such as productivity enhancement and capacity gain, while a cost-benefit analysis is also done to provide the initial ranking. To finalise the assessment, risks based on operational perspective are considered against the overall ratings. Lastly, the decision matrix tool is applied to case studies showing the sensitivity of factors in determining the likelihood of success for each well and reservoir intervention.

1. INTRODUCTION

Geothermal energy production particularly for electric power generation are unique for every location and operation. It is common that the maintenance of steam fields and power stations becomes challenging due to dynamic changes in reservoir processes, which include pressure drawdown and thermal breakthrough among others. The former usually occurs faster in high-enthalpy fields and can be mitigated by optimum reinjection. However, the latter could be more difficult to manage when the reinjected fluids result to invasive cooling and dwelling in the reservoir. These issues often lead to changes in pH, temperature and ion concentration due to flashing, and alteration of fluid composition resulting to mineral scaling either in the wellbore or reservoir formations. As a result, operating expenses attributed to intervention increase and accumulate over time.

Managing the expectations in addressing these challenges effectively start with meticulous planning based on the combination of technical evaluation and experience. Parameters such as production and injection rates frequently indicate the need for intervention to recover or optimise the well capacity, while selection of the desired solution considers the overall program and operational duration. It is critical to assess downhole conditions by determining the type and size of mineral scale, as well as any casing issues that may impede the progress of intervention operations (Erichatama, Adityatama, Al Asy'ari, & Purba, 2024). Though various well and reservoir interventions like scale inhibition, broaching, acid treatment and mechanical workovers have proven to be effective, the probability of success remains variable and makes economic benefits highly dependent on the skills and experience of people involved. As a result, the decision-making process becomes complicated with the equally important consideration of other necessary asset maintenance activities that also affects the cost in operating the geothermal field.

With the aid of an *Intervention Decision Matrix Tool*, geothermal production managers will be able to visualise the relative benefits and risks of each well and reservoir intervention for successful navigation towards mitigating geothermal challenges. This would also allow quick delineation of best options supporting timely decision-making that could save time and efforts from designing multiple solutions.

2. METHODOLOGY

The success of well and reservoir interventions is difficult to predict. It could be based on priorities or preferences of asset owners depending on historical experience and available budget. Technical prognosis, financial projection

and risk rating are the key considerations in reducing bias for selecting the most suitable intervention after downhole information and condition have been reviewed. The decision matrix tool that can be used to prioritise the well and reservoir interventions applicable for a particular scenario has a straightforward process (Figure 1). It starts with wellbore simulation to predict possible capacity recovery from implementing the interventions, followed by a cost-benefit analysis that covers the revenue from electricity sales and costs attributed to the intervention and opportunity losses. The next step is to evaluate the uncertainties based on perceived risks of each intervention relative to one another in the context of addressing a particular scenario. Risk ratings would differ between the wellbore and reservoir scaling scenarios. The probability of success for each intervention is estimated and a Monte Carlo simulation is applied to determine the confidence level of having the likelihood that an intervention will succeed. Once the success factors are scored, the ranking may be used to suggest a course of action in selecting the most viable intervention.

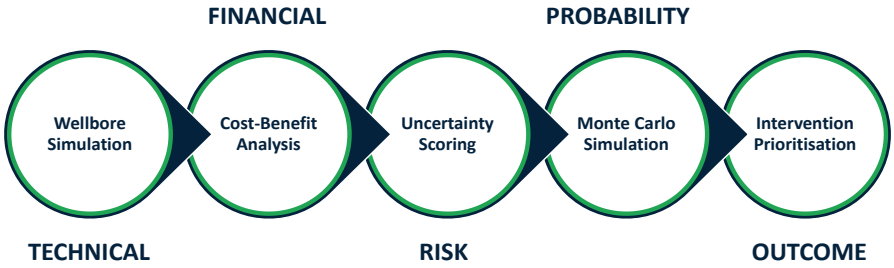

Figure 1: Decision matrix tool framework for well and reservoir interventions.

2.1 Success Rating

A four-point scale with scores from 0 to 3 is used to evaluate each factor: (a) technical, (b) financial, and (c) risk. The technical factor considers well deviation, casing condition, age of well and scale location. If the anticipated mineral scaling is inside the wellbore, it is important to consider the hardness, interval, diameter and deviation at point of the scales. The financial factor is based on the present value ratio of costs and benefits from implementing the intervention for 5 years. Costs include the expenses to conduct the intervention and opportunity losses while the production capacity is declining, and the missed revenue if the baseline capacity is not achieved by the potential maximum output recovery. Lastly, the risk factors are relative to the interventions and scaling problem. The operational risks of interventions being considered are safety, schedule, supply chain, structure of the team and stakeholder obligations. Hence, an intervention may have a different score for the issue on scaling inside the wellbore compared to scaling in the reservoir formations. Also, weights are imposed on each factor for sensitivity analysis. With the weighted factors in place, the success rate is then calculated using the Equation below:

$$S = \frac{Tx+Fy-Rz}{Tx+Fy} \quad (1)$$

where *S, T, F, R* are the success rate, factor scores for technical, financial and risk with corresponding weights *x, y, z,* respectively.

2.2 Monte Carlo Simulation

The success rate may become insufficient at times when decision makers have different priorities. In the case of an operating geothermal field, maintenance activities for assets other than the subsurface are usually given higher priority due to being the recurring cost drivers. This often results in reduced budget for well and reservoir interventions leading to more future expense such as drilling a new well. To supplement the calculated success rate, a probabilistic approach using Monte Carlo simulation is incorporated to consider random variability in the results. Since the success of interventions are highly dependent on the activity program and schedule, the PERT probability distribution is used in simulating the confidence level. The Program Evaluation and Review Technique (PERT) analysis is ideally used for activities with defined duration with variables regarded as independent of each other (Hajdu & Bokor, 2014). In the case studies, success rates of each intervention are treated independently to predict their individual confidence levels.

3. CASE STUDY

A hypothetical production well is created using *Gudrun* from the Volsung software package. The model is a deviated well consisting of standard 9-5/8" production casing and 7" liner with 3 feed zones. Table 1 summarises the baseline well and reservoir parameters used while Figure 2 shows the wellbore schematic from the Gudrun graphical user interface.

Table 1: Summary of basic well parameters used in the wellbore model.

Well Parameters	Value
Total Depth	3,000 mMD
Deviation	11°
Production Casing	9-5/8" (40 lbs/ft; 0.05mm rugosity)
Production Liner	7" (23 lbs/ft; no rugosity)
Feed Zones	1,500 mMD / 1,800 mMD / 3,000 mMD
Maximum Bottomhole Pressure	120 bar
Maximum Bottomhole Temperature	325°C at 3,000 mMD

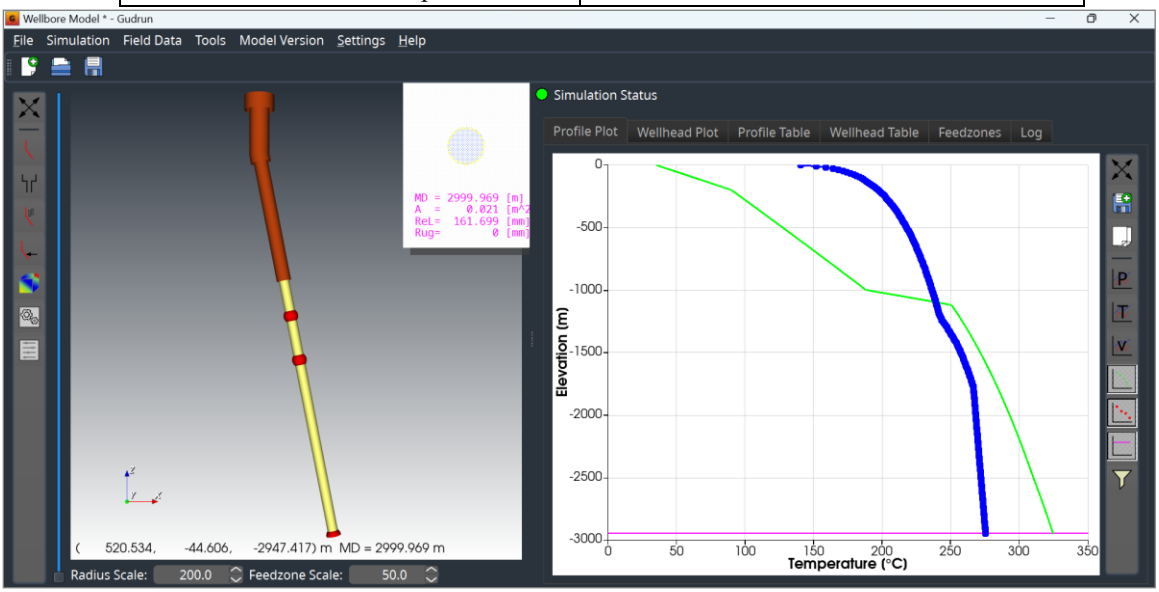

Figure 2: Graphical user interface of Gudrun showing a representation of the wellbore model created.

Table 2: Assumptions for wellbore scaling scenario.

Indicators	Baseline	Assumption
Downhole Condition	No issues	5" opening remains at 1,500m; 2" opening remains at 1,800m; no known casing defects
Scale Information	None	1-meter interval at the 11° deviated liner just above the 1,500 mMD and 1,800 mMD feed zones; aged calcite
Total Mass Flow	42 kg/s	24 kg/s
Enthalpy	1953 kJ/kg	1935 kJ/kg
Power Potential	12.8 MWe	7.2 MWe

3.1 Wellbore Scaling

Geothermal well output declines naturally due to reservoir pressure drawdown but an abrupt loss indicates that there is a worse cause usually attributed to mineral scaling or casing damage. The former can be easily resolved with well interventions such as broaching and work overs using coiled tubing or drilling rig. Options to increase the chance of success also include acid treatment by bullheading and pumping through a drill string or coil tubing. The most common mineral scaling issue is due to calcite, which occurs mainly at the flash point in the wellbore. If not addressed, it will continuously aggravate as the flash point moves when the wellbore internal diameter decreases over time (Wilson, Aranas, Bixley, Anderson, & Patterson, 2015; Wilson, Gilliland & Austin, 2015). Table 2 shows the changes between baseline and wellbore scaling conditions assumed for the case study. The wellbore model was evaluated based on the remaining diameter of the production liner where the flash point occurred, and thus scaling. The obstruction in this model is more severe at the middle feed zone (1,800 mMD) as compared to the shallower feed zone (1,500 mMD), which resulted to about 5-MW decrease in electric power potential of the well.

3.2 Reservoir Scaling

Compared to scaling inside the wellbore, the production output decrease could be slower when scales deposit in the reservoir formation. In the case of calcite, it may also deposit in the reservoir when carbon dioxide (CO_2) separates from the fluid solution along with other triggers like high pH and over-saturation of calcium ions as well as carbonate minerals (Akin, et al., 2015). Intervention options become limited to acid treatment by bullheading and pumping through a drill string or coil tubing unlike in wellbore scaling scenario wherein you can opt for the cheaper mechanical cleanout. Table 3 shows the changes between baseline and reservoir scaling conditions assumed for the case study. The wellbore model was evaluated based on the reduction of productivity index at the middle feed zone (1,800 mMD). The focus of the model is the effect of reduced permeability due to scaling in the formation, thus skin factor is not considered. In this scenario, the permeability of the feed zone at 1,800 mMD was significantly affected by reservoir scaling and resulted to a decrease in productivity index from 2.0 to 0.1 kg/s-bar. Although the reduction in electric power potential is almost the same as the wellbore scaling scenario, the perceptible change is on the enthalpy having a relatively lower value. In a real scenario, one possible interpretation could be that the reservoir scaling may have been caused by reinjection returns with fluids that have been over-saturated with calcium.

Table 3: Assumptions for reservoir scaling scenario.

Indicators	Baseline	Assumption
Downhole Condition	No issues	Productivity index of the feed zone at 1,800 mMD decreased from 2.0 to 0.1 kg/s-bar
Scale Information	None	Scaling in the reservoir formation affecting the permeability of the feed zone at 1,800 mMD
Total Mass Flow	42 kg/s	24 kg/s
Enthalpy	1953 kJ/kg	1918 kJ/kg
Power Potential	12.8 MWe	7.0 MWe

Table 4: Wellbore scaling scenario – predicted best outcomes from simulation and other considerations.

Intervention	Maximum Recovery, MWe	Post-intervention Power, MWe	Assumption
Broaching	4.8	11.9	Wellbore simulation – 100% cleared 1,500 mMD; 50% cleared 1,800 mMD
Mechanical Cleanout (Coiled Tubing)	5.2	12.4	More cleared scales than broaching due to more sophisticated downhole tools
Mechanical Cleanout (Drilling Rig)	5.4	12.6	More cleared scales than coiled tubing due to more rotation and weight on bit
Acid Treatment (Bullhead)	4.8	11.9	Assumed the same outcome as broaching; acid pumping instead of mechanical cleanout
Acid Treatment (Coiled Tubing)	5.4	12.6	Better outcome than bullheading due to reaching the target zone for acid treatment
Acid Treatment (Drilling Rig)	5.7	12.8	Better outcome than using a coiled tubing due to more weight on bit in case of need for mechanical cleanout
Acid Treatment (Drilling Rig) and Scaling Inhibition	5.7	12.8	Same as acid treatment using drilling rig

4. DISCUSSION AND RESULTS

The success rates of each intervention option are evaluated independently between the wellbore scaling and reservoir scaling scenarios due to the difference in scale locations. Mechanical cleanout is not applicable for reservoir scaling but acid treatment can be suitable to either case. Additionally, scaling inhibition is considered in

the wellbore scaling scenario to test its viability if selected from other well intervention options. Table 4 and Table 5 summarise the best possible outcomes of each intervention in terms of maximum increase in power potential. For the wellbore scaling scenario, acid treatment using a drilling rig has the highest recovered output mainly due to its combined capability to pump acid at the specific target zone and drill-out scales with more weight and capability to rotate than of the coiled tubing.

Table 5: Reservoir scaling scenario – predicted best outcomes from wellbore simulation and other considerations.

Intervention	Potential Recovery, MWe	Recovered Power, MWe	Assumption
Acid Treatment (Bullhead)	4.1	11.2	Wellbore simulation – 50% recovery of productivity index at 1,800 mMD feed zone (from 0.1 to 1.0 kg/s-bar)
Acid Treatment (Coiled Tubing)	5.3	12.4	Better outcome than bullheading due to reaching the target zone for acid treatment
Acid Treatment (Drilling Rig)	5.3	12.4	Better outcome than using a coiled tubing due to more weight on bit in case of need for mechanical cleanout

Table 6: Initial ranking of interventions for wellbore scaling scenario.

Intervention	Technical	Financial	Subtotal	Ranking
Broaching	2.20	2.63	2.42	7th
Mechanical Cleanout (Coiled Tubing)	2.20	2.74	2.47	5th
Mechanical Cleanout (Drilling Rig)	2.20	2.71	2.46	6th
Acid Treatment (Bullhead)	2.70	2.46	2.58	4th
Acid Treatment (Coiled Tubing)	2.95	2.59	2.77	3rd
Acid Treatment (Drilling Rig)	3.00	2.61	2.80	2nd
Acid Treatment (Drilling Rig) and Scaling Inhibition	2.70	3.00	2.85	1st

Table 7: Initial ranking of interventions for reservoir scaling scenario.

Intervention	Technical	Financial	Subtotal	Ranking
Acid Treatment (Bullhead)	2.70	2.48	2.59	3rd
Acid Treatment (Coiled Tubing)	2.95	2.40	2.67	1st
Acid Treatment (Drilling Rig)	3.00	2.32	2.66	2nd

4.1 Preliminary Ranking

Based only on technical and financial factors that are treated equally important, an initial ranking is obtained to show a preliminary comparison for each well and reservoir intervention. Table 6 shows that the most attractive intervention for wellbore scaling would be acid treatment using a drilling rig with scaling inhibition afterwards. This is mainly because the well output is maintained at maximum potential annually despite the required initial expense for an acid treatment to ensure that the wellbore is clear prior to installation of a scaling inhibition system. In the case of reservoir scaling, the most attractive intervention is acid treatment using coiled tubing (Table 7). The reason for coiled tubing to lead the scores in acid treatment for reservoir scaling is because of the cheaper cost compared to using a drilling rig for the same capability of being able to pump acid at the specific target zone that bullheading may not achieve.

4.2 Sensitivity Analysis

Calculating the success rating of the interventions provides further justification for possible plans of action. If the decision maker is a person who is technically inclined, the selection process would be biased to factors (i.e., downhole condition and scale information) that will drive the success during operations. Meanwhile, decision makers who safeguard the financial aspects would highly consider the cost-benefit analysis outcome. An organisation's current circumstance usually dictates the preference during selection and makes it difficult for production managers to amplify their decisions. There are cases when the urgency to execute an intervention takes over the financial aspects, while there are also occasions when budget is a constraint.

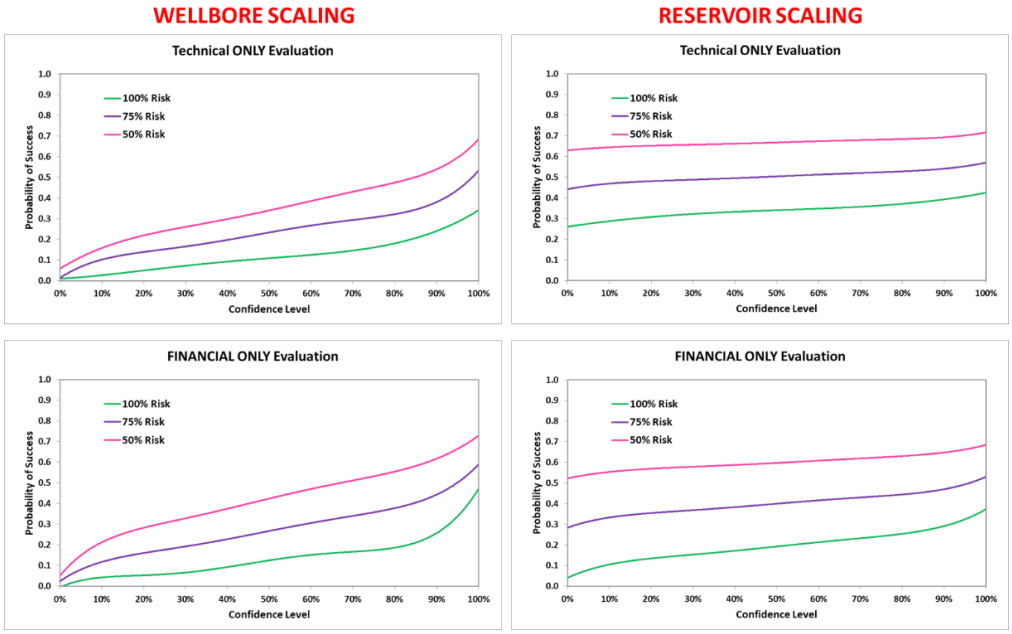

Figure 3: Probability of success and confidence level at various risk magnitude for scaling interventions based on technical and financial scoring only.

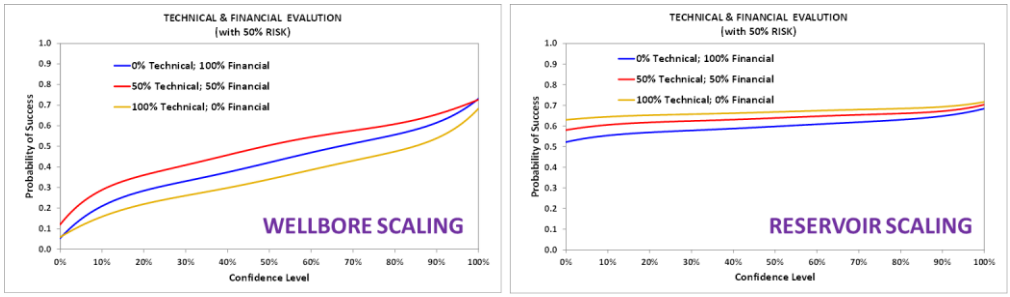

Figure 4: Probability of success and confidence level at various technical and financial magnitudes with 50% risk for scaling interventions.

Applying the Monte Carlo simulation helps define the confidence level based on historical trends or events, which can be correlated with the success rate. Figure 3 shows that the probability of success increases as the risk factors are reduced whether the assessment is biased to the technical or financial aspects. Moreover, the probability of success is more sensitive to the increase in confidence level of a decision maker in the wellbore scaling scenario possibly because there are more intervention options available than in the reservoir scaling scenario. If the risk factors are presumed mitigated by 50%, the wellbore scaling scenario suggests that having a balanced view between technical and financial factors is most desirable followed by giving more weight to financial factors while the reservoir scaling scenario indicates that the best outcome is more dependent on the technical factors (Figure 4).

4.3 Success and Confidence

Integrating the success rates and confidence levels with the preliminary ranking changes the impression on well and reservoir interventions. However, the values should not be treated as absolute figures to conclude which intervention is better since the calculations and assumptions were based on the best outcome considering potential maximum electric power output recovered and absence of issues during execution despite the risk factors. Table

8 summarises the estimated success rates and confidence levels at 50% weight each of the technical, financial and risk factors specific to the parameters in the case studies. Mechanical cleanout using a drilling rig has a negligible success rate due to the risk factors scoring higher than the technical and financial factors, but the confidence level of having this value is only 25%. This means that there is still a 75% opportunity that the success rate could be higher by significantly mitigating the risk factors.

Table 8: Success rates and confidence levels at 50% weight on each of the factors specific to the case studies.

Intervention	Success Rate	Confidence Level
Broaching	0.74	100%
Mechanical Cleanout (Coiled Tubing)	0.55	61%
Mechanical Cleanout (Drilling Rig)	Nil	25%
Acid Treatment (Bullhead)	0.56 – 0.71	66% – 96%
Acid Treatment (Coiled Tubing)	0.55 – 0.63	32% – 62%
Acid Treatment (Drilling Rig)	0.51 – 0.58	1% – 52%
Acid Treatment (Drilling Rig) and Scaling Inhibition	0.52	54%

5. CONCLUSION AND FUTURE WORK

The *Intervention Decision Matrix Tool* is a chain of steps that builds the framework for the selection of fit-for-purpose well and reservoir interventions. It is a quantitative approach to providing justification for decision makers and is an ongoing development envisaged to be an "input-output" spreadsheet deck and eventually may further become an application or software for the geothermal energy industry.

Keywords: Ulubelu, steam sustainability, two-phase reservoir, hot water geothermal system, updoming structure, clay cap

ABSTRACT

The Ulubelu geothermal field, operated by PT. Pertamina Geothermal Energy Tbk. (PGE), is located in Lampung Province at the southern tip of Sumatera Island. Geologically, the field is situated within a Quaternary volcano-tectonic depression characterized by a strong caldera environment that predates post-caldera tectonic activity (Prasetyo, 2023). It lies approximately 15-20 km from the Sumatera Fault System (SFS) and exhibits a slightly different trend (NNW-SSE) than the SFS. Currently, the Ulubelu field generates up to 220 MW of electricity from four 55 MW steam plants. To ensure sustainable steam supply and counteract reservoir performance decline, Ulubelu Field has planned regular drilling campaigns for make-up wells.

Since 2014, two years after the initial production of Units 1 and 2, make-up wells have been drilled to supply steam to the Ulubelu Geothermal Power Plants (GPP). Due to the limited current well targeting area and significant well interference, PGE opted to drill delineation wells to the north of the central production area. This designated area, within the inferred upflow zone of Mt. Rendingan crater, was identified as a promising site for field expansion based on geoscientific and reservoir data. The area features a classic volcano-hosted geothermal system with an updoming clay cap structure near the volcanic edifice.

Between 2018 and 2024, six wells were drilled from two wellpads (UBL-J & UBL-M) in the northern area. The first three wells were drilled sequentially from Pad UBL-J to confirm the hypothesized upflow and the existence of a two-phase reservoir beneath Mt. Rendingan crater. The results were promising, revealing a two-phase reservoir with temperatures around 260-280°C and enthalpies of 2400-2800 kJ/kg, yielding substantial output. Subsequently, three more wells were successfully drilled from Pad UBL-M to exploit the northern production area east of Pad UBL-J, showing similar characteristics.

Targeting the northern area with the MT-Resistivity updoming structure beneath Mt. Rendingan crater has proven valuable for sustaining steam availability in the Ulubelu field. The productivity in this two-phase steam-dominated reservoir is generally high. However, as steam-dominated reservoirs tend to experience rapid decline in production, rigorous reservoir monitoring is essential to manage fluid production effectively.

1. INTRODUCTION

The Ulubelu geothermal field, located in Tanggamus Regency, Lampung Province, at the southernmost part of Sumatra Island, generates up to 220 MW of electricity through four 55 MW condensing steam plants. The geothermal power plant installation began in 2012 with the commercial generation of units 1 and 2, while units 3 and 4 went online in 2016 and 2017, respectively. Since then, a total of 62 wells, including production, injection, and make-up wells, have been drilled in the Ulubelu field.

The decline in reservoir performance during geothermal field exploitation is common and can be attributed to various factors, such as decreased reservoir pressure and wellbore issues (e.g., scaling and restrictions). To maintain a sustainable steam supply to the geothermal power plant (GPP) and counteract the decline in reservoir performance, well interventions and drilling of make-up wells are typically conducted. PGE has planned and executed a series of well interventions and a make-up well drilling campaign. Between 2018 and 2024, PGE drilled 12 wells from new wellpads, specifically UBL-J and UBL-M.

Generally, make-up well will optimize the existing area of production. However, due to limited availability of space both at surface and subsurface, new area of production need to be delineate. The strong candidate to target is the upper-north area where the previous wells drilled and integrated geoscience data show near-upflow zone area with high productivity potential.

2. ULUBELU GEOTHERMAL SYSTEM

Ulubelu Geothermal Field lies on the southern tip of the Sumatera Fault System with an NW-SE trend. It is physiographically located within Bukit Barisan Mountain Range (Figure 2.1). The Sumatera Fault System is believed to have a close relationship with the volcanism along Bukit Barisan Mountain Range. The segmented Sumatera Fault limits the southern part of Sumatera Island by the Semangko Segment. It corresponds to the dextral slip movement of oblique convergence plates beneath Sumatera Island that terminates at Teluk Semangko. It also exhibits several fault splays and prominent pull-apart basins (Suoh Sekincau). The field is located around 15-20 km from Semangko Fault and has a slightly different trend from Semangko Fault (NNW- SSE).

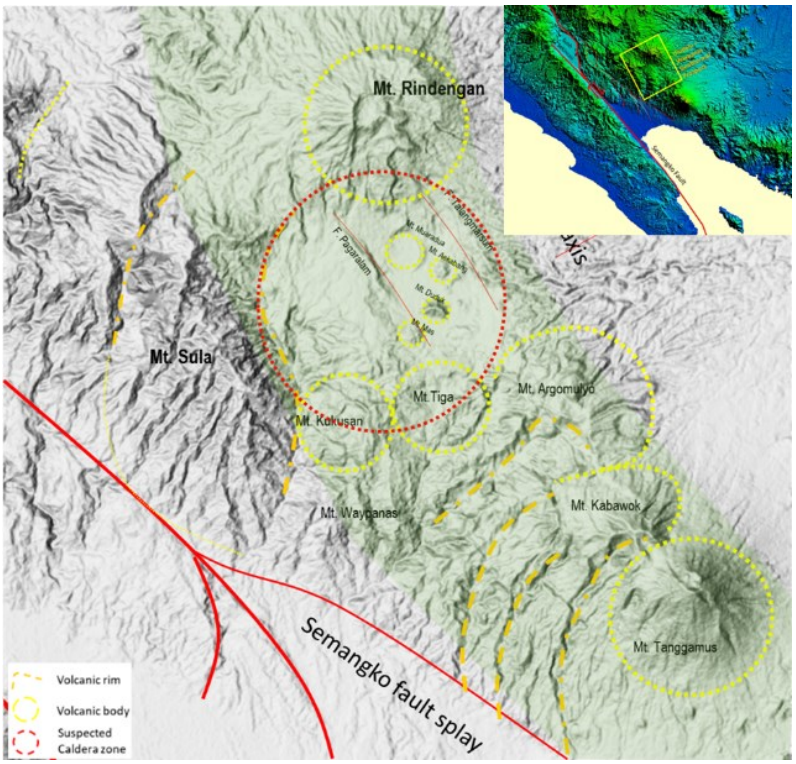

Figure 1: Location of the Ulubelu field at southern tip of Sumater near the Semangko segment.

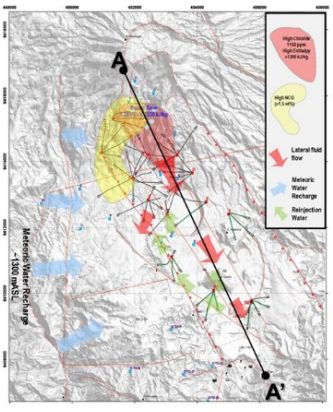
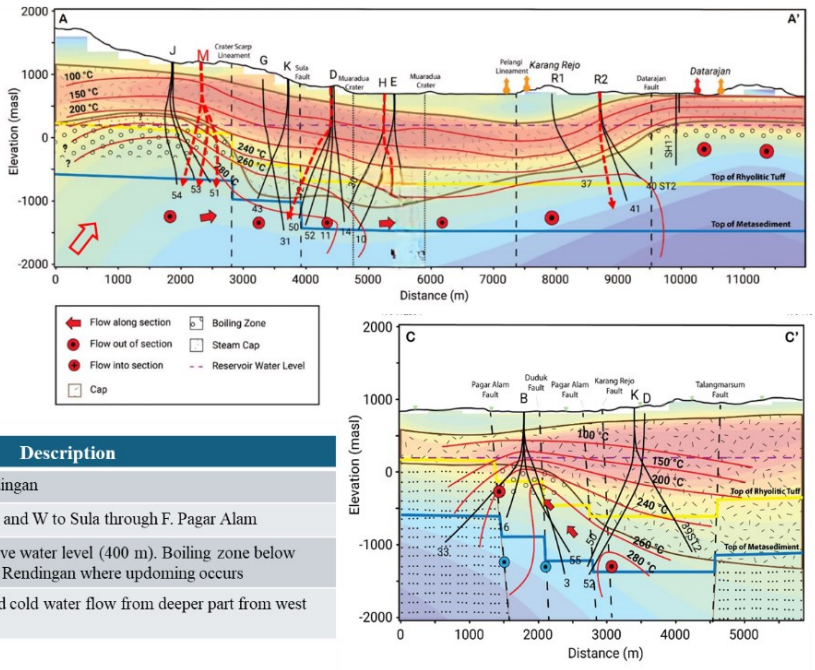


Hydrology model of Ulubelu System



Elements	Description
Upflow	Fluid rise beneath Mt. Rendingan
Outflow	Flows SE towards datarajan and W to Sula through F. Pagar Alam
Clay Cap	Firm clay cap generally above water level (400 m). Boiling zone below clay cap exhibits below Mt. Rendingan where updoming occurs
Cold water flow	Pagar Alam Fault introduced cold water flow from deeper part from west

Figure 2: Summary of Ulubelu field's hydrology.

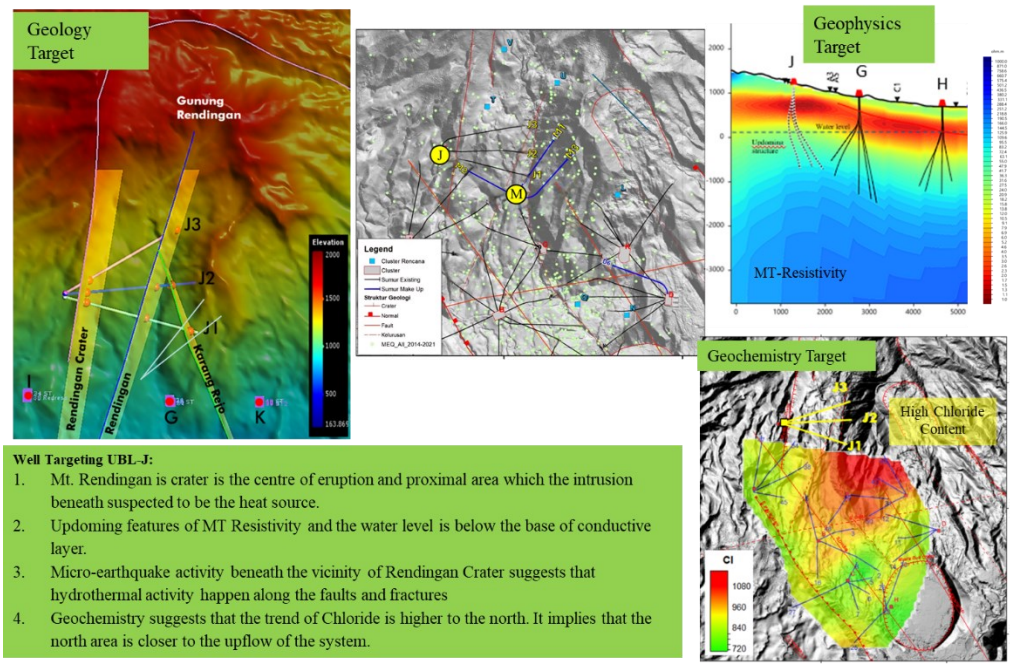


Figure 3: Rationales behind targeting the upper-north area (Mt. Rendingan's crater) of Ulubelu field.

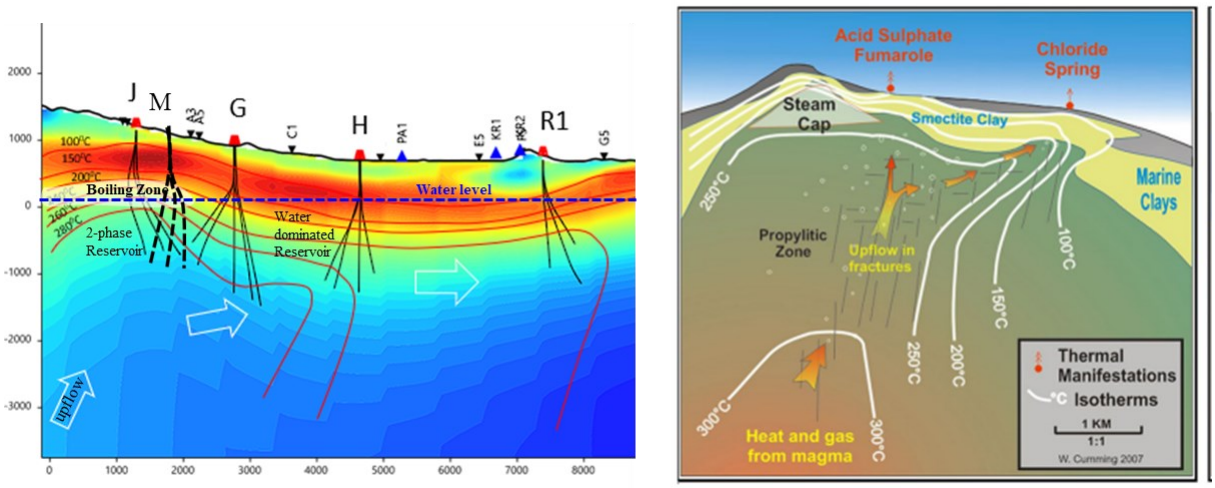

Figure 4: NW-SE MT-Resistivity structure of Ulubelu Field. Comparison of MT-Resistivity model of Ulubelu with the volcanic-hosted geothermal system as described by Cumming (2016). The updoming feature and water level below the base of conductive layer provide hint of two-phase reservoir existence.

The hydrology of Ulubelu field is postulated arise beneath G. Rindengan high and moves away laterally to the lower elevation through NW-SE geological structure (Pagar Alam, Duduk, Karangrejo Faults) and permeable Rhyolitic Tuff Unit. The geothermal fluid is benign and has chloride content of 1200-1300 mg/kg with temperature at the upflow up to 285°C. As it moves away from the upflow zone, it becomes more diluted and lower in temperature. The reversal temperature profile from wells in the west suggests that there are fluid outflows from deep reservoir to the shallower reservoir to the west. It also suggests that cooler deep fluid may also intruded from west to east from Pagar Alam to the graben. The outflow characterized by its high permeability, lower temperature, more dilute chemistry and temperature reversal profile. The temperature reversal profile shows particularly in wells that intersecting the Pagar Alam Fault.

Firm clay cap recorded by MT Resistivity model extent along NW-SE graben. It exhibits updoming structure in the north area beneath Mt. Rendingan and thicker to south east. The NE-SW MT-Resistivity structure exhibit thickening to the east. This implies that the reservoir is deeper in the east. The tilted geometry of the reservoir seems to be controlled by deposition of rhyolitic tuff units along the graben structure. This feature in the north-east acts as deep upflow that rise toward shallower aquifer toward SW.

3. TARGETTING TWO-PHASE RESERVOIR ZONE

In 2018, PT Pertamina Geothermal Energy (PGE) initiated a make-up wells drilling campaign to maintain steam supply to geothermal power plant (GPP). A major challenge of this campaign was the limited area available for drilling both surface and subsurface. To address this, a detailed analysis of integrated subsurface data was conducted, leading to the decision to delineate the upper-north area towards the Rendingan crater for additional well placements. Some of the rationales drilling to the upper-north area are :

1. Mt. Rendingan is crater is the centre of eruption and proximal area which the intrusion beneath suspected to be the heat source.
2. Updoming features of MT Resistivity and the water level is below the base of conductive layer.
3. Micro-earthquake activity beneath the vicinity of Rendingan Crater suggests that hydrothermal activity happen along the faults and fractures.
4. Geochemistry suggests that the trend of Chloride is higher to the north. It implies that the north area is closer to the upflow of the system.

Identifying a two-phase steam-dominated system within a predominantly water-dominated geothermal field may seem counter-intuitive. However, certain geological and geophysical indicators can provide critical insights.

1. Updoming of MT-Resistivity Structure: Magnetotelluric (MT) resistivity surveys, which measure the earth's natural electromagnetic fields, can reveal subsurface structures. An updoming resistivity structure indicates regions with concentrated heat and fluid flow, suggesting high permeability and significant heat transfer in volcanic geothermal systems.
2. Thinning of the Clay Cap: The thickness of the clay cap, a low-permeability layer, is crucial in geothermal systems. Thinning but highly conductive beneath a volcanic center due to thermal buoyancy facilitates the upward migration of hot water. When this heated water encounters the base of the clay cap, it can spread laterally, potentially forming steam-dominated zone if boiling conditions are met.
3. Water Table Position: A water table located below the base of the conductive layer (typically associated with the clay cap) strongly indicates a two-phase reservoir. This condition implies that pressure and temperature conditions support the coexistence of liquid and steam phases.

Ulubelu field's NW-SE MT-Resistivity cross-section provides insight of the subsurface structure. The model exhibits updoming structure beneath Mt. Rindengan and thickening of clay cap to the SE. Pressure measurement from previously drilled wells indicates water level throughout the field. The water level in Ulubelu generally has same elevation indicating that it is within the same hydrology and no compartmented reservoir. It is located beneath the clay cap on Mt. Rendingan suggesting that two-phase reservoir potentially exist during the initial stage of well-targeting.

4. RESULT FROM DRILLING

The delineation of the upper-north extension towards Mt. Rindingan began from pad UBL-J. PGE prepared three sequential wells in pad UBL-J, with one well drilled from the existing pad (UBL-D) between the first and second wells of UBL-J. This strategy allowed flexibility to evaluate the results from UBL-J1 before deciding to drill two more wells in UBL-J.

The UBL-J drilling campaign commenced in early 2018 with UBL-J1 and concluded with the third well (UBL-J3) in August 2018. All wells were directional, targeting the eastern region inside the Rindingan Crater, reaching total depths between 2100-2200 mMD or approximately -650 to -700 mRSL. The Top of Reservoir (ToR) is located between 100 mRSL and sea level, with major feed zones between -100 to -500 mRSL.

Well completion tests were conducted to understand the reservoir characteristics in the area. The gross permeability tests from the UBL-J wells indicated injectivity indices ranging from 280-900 lpm/ksc. By April, the wells had heated up to static temperatures, recording average maximum temperatures of 260-280°C. Interestingly, the Boiling Point Depth curve between sea level and -500 mRSL aligned with the convective profile of the UBL-J wells, suggesting the existence of a boiling zone near the UBL-J wells.

Well testing commenced with UBL-J1 in 2019 and continued sequentially with UBL-J2 and UBL-J3 in the same year. The results from UBL-J1 were promising, exhibiting dry steam with a dryness of averaging above 90% and enthalpy of 2400-2800 kJ/kg. This marked the discovery of the first two-phase steam-dominated reservoir in the PGE field in the Sumatra region.

In 2022, PGE initiated another drilling campaign to expand the upper-north Ulubelu area. Wellpad UBL-M was constructed east of UBL-J, targeting the eastern extension area from UBL-J where the two-phase steam-dominated reservoir was discovered. The campaign started in 2022 with the drilling of UBL-M1. Following the same strategy, the rig was moved to another well in an existing pad while UBL-M1 was being evaluated before proceeding with

the drilling of UBL-M2 and UBL-M3. The results from UBL-M1 were also encouraging, confirming the presence of a two-phase reservoir in the area east of the UBL-J wells.The summary of drilling result can be seen in Table1.

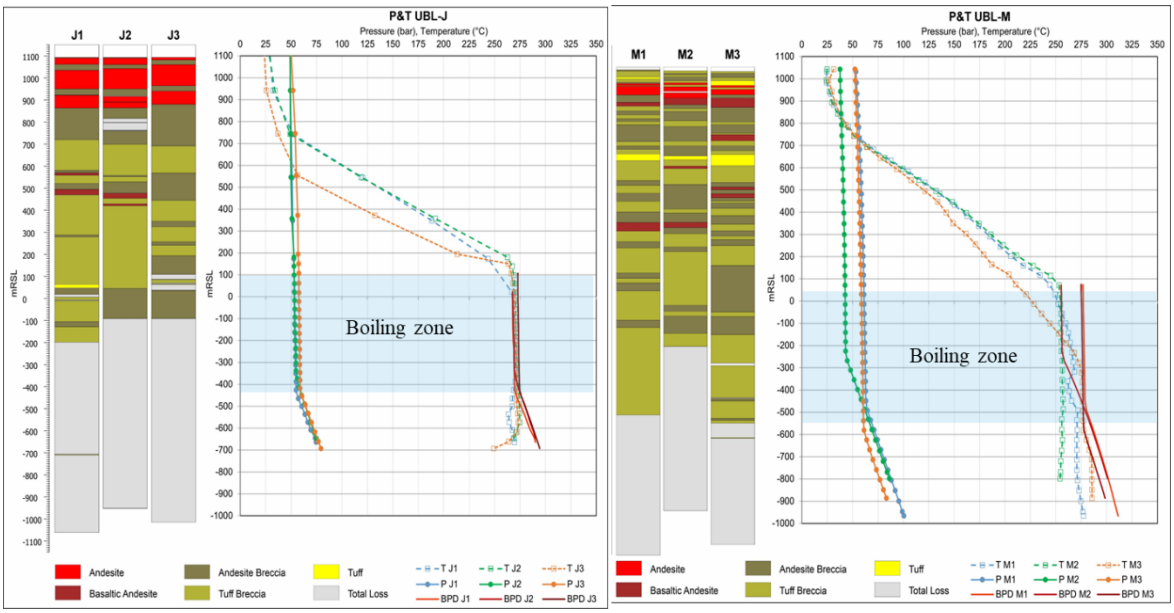

Figure 5: Composite log of static PT measurements and borehole geology of UBL-J and UBL-M wells.

Table 1: Summary of well testing from UBL-J and UBL-M production test. It exhibits overall high dryness and high productivity in upper-north area.

Well	WHP (barg)	Throttle Valve (%)	Dryness	Enthalpy (kJ/kg)	Steam flow rate (t/hr)
J1	23.5	40	1	2801	159.5
J2	25	40	1	2786	338.2
J3	20.6	47	0.89	2569.9	196
M1	25.0	25	0.82	2400.9	88.2

5. CONCLUSION AND RECOMMENDATION

Targeting the upper-north area with the MT-Resistivity updoming structure beneath the Mt. Rindingan crater has proven valuable for sustaining steam availability in the Ulubelu field. The depth of the water table provides insight into the field's thermodynamics and, together with the updoming MT-Resistivity profile, can indicate the presence of a steam cap. This method can also help predict whether the reservoir will be two-phase or water-dominated with low dryness, in addition to geochemical plots.

The overall productivity in this two-phase steam-dominated reservoir is generally high. However, as steam-dominated reservoirs exploitation tend to experience rapid declines in production, rigorous reservoir monitoring is essential. One pitfall in targeting this feature, as mentioned by Cumming (2016), is the need for caution when there are no strong indications of thermal manifestations such as fumaroles at the surface (hidden geothermal systems). This absence may reflect relict alteration with past high-temperature propylitic alteration recorded by MT-Resistivity. A thorough examination of the field's geology, identification of the rock's age, and the possibility of metamorphic rock exposure at the surface can strongly indicate a fossil geothermal system, which is significantly cooler in recent times.

Keywords: Geothermal Reservoir, Production, Injection Breakthrough, Injection Recovery

ABSTRACT

Reinjection of produced brine allows a sustainable geothermal field operation. It also helps to avoid environmental waste while minimizing reservoir pressure decline that can affect well productivity. However, in some fields injection of produced brine could cause catastrophic circumstances. In particular at the field that uses a binary system, where the rejection temperature can be as low as 65-100˚C. This condition can be worst in fractured controlled reservoirs in which fracture or fault becomes a toll-way of reinjection water. As a result, the injection breakthrough occurs prematurely causing a production decline.

Well-B is an infill producer well that was drilled to provide steam and brine for power plant generation. Despite having a good permeability as well as pressure region, this well performs very poorly with cycling wellhead pressure behavior as shown by the initial flow test activity. Meanwhile, Well-A is a good injector that accepts 95°C brine up to ~1000 tph.

Amalgamating several data such as daily monitoring data, pressure-temperature surveys, geochemistry observation, and geology yields a quite concluding outcome. The analysis shows there is indeed certain connectivity between those wells that cause thermal breakthroughs. Therefore, several actions were taken to overcome the situation such as managing the injection rate of the injection well while shutting in the production well to allow heating up. Moreover, during the well flows, the well production opening is kept as low as possible to avoid cooling. The practice yields a fruitful outcome, the performance rebound, evidenced by a sustained flow with higher discharge pressure (higher MDP) with the absence of cycling behavior.

1. INTRODUCTION

Sorik Marapi geothermal field is a project of PT. Sorik Marapi Geothermal Power (SMGP), a subsidiary of KS Orka Renewables Pte Ltd. that located in Mandailing Natal Regency, North Sumatra. From its 15 active production wells and 18 Injection wells, Sorik Marapi currently delivers 160 MW of electricity to supply the North Sumatra PLN grid.

Sorik Marapi implements the double-flashed binary ORC (Organic Rankine Cycle) system on its power plant to optimize the generation. However, utilizing this strategy can either be beneficial or drawback to the reservoir due to its rejection temperature can be as low as 65-100˚C.

Well-B is an infill producer well that was drilled to provide steam and brine for power plant generation. Despite having a good permeability as well as pressure region, this well performs very poorly with cycling wellhead pressure behavior as shown by the initial flow test activity. Meanwhile, Well-A is a good injector that accepts 95°C brine up to ~1000 tph. This paper discusses the impact of injection operation in the Sorik Marapi geothermal field and its influence on the nearby production well.

2. WELL-B CHARACTERISTIC AND INITIAL FLOW TEST

Well-B is an infill well that was drilled towards the southwest and reached a total depth of 1750 m-MD. Partial loss circulation (PLC) started to occur at a depth of ~950 m-MD in the 12-1/4” hole section, which was later followed by the total loss circulation (TLC) up to 240 tph at ~1250 m-MD (SMGP, 2021a).

A completion test was done soon after drilling was completed to identify well potential productivity. The Pressure Temperature Spinner (PTS) survey indicated that the majority of the injected fluid was leaving the wellbore from the shallow feed zone around 950-1050 m-MD (SMGP, 2021b). The occurrence of permeable zones in this well is also supported by the presence of fractures through the borehole image logging (SMGP, 2021c). Based on the completion test data, if the well is heated up to 270°C the maximum discharge pressure (MDP) of Well-B can reach up to 20 bara.

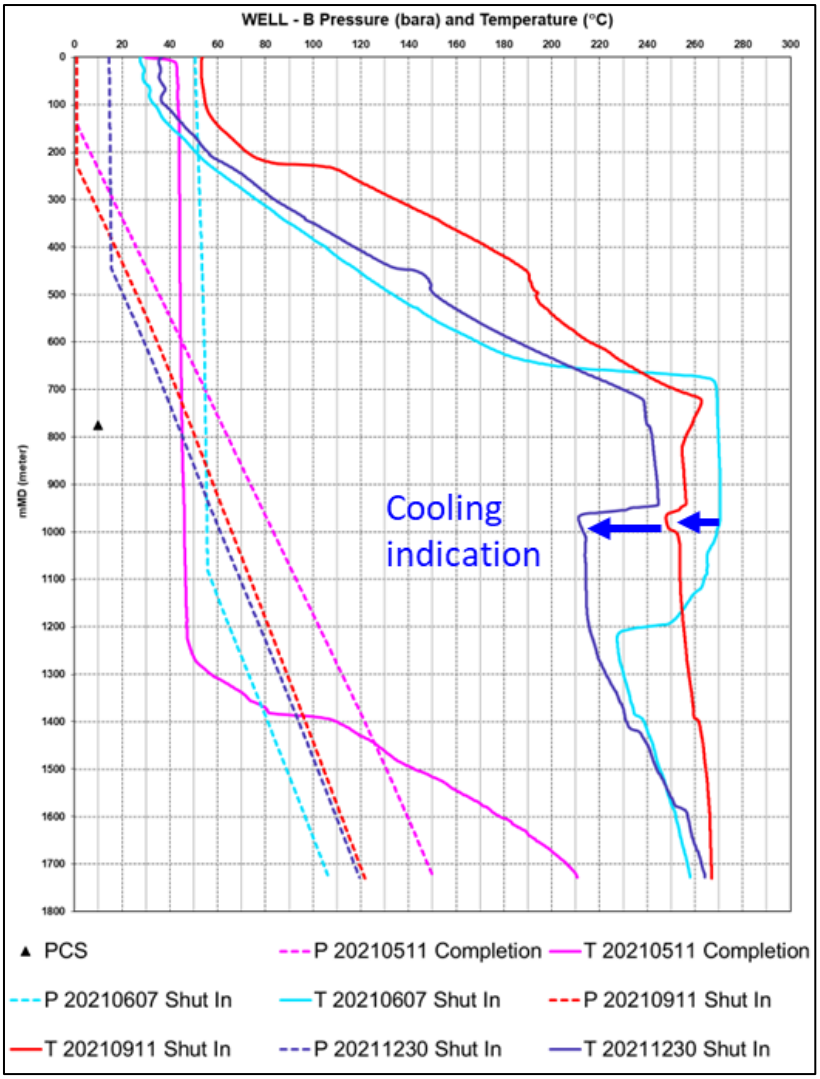

Figure 1: Well-B Heat Up Profiles showing cooling at shallow permeable zone.

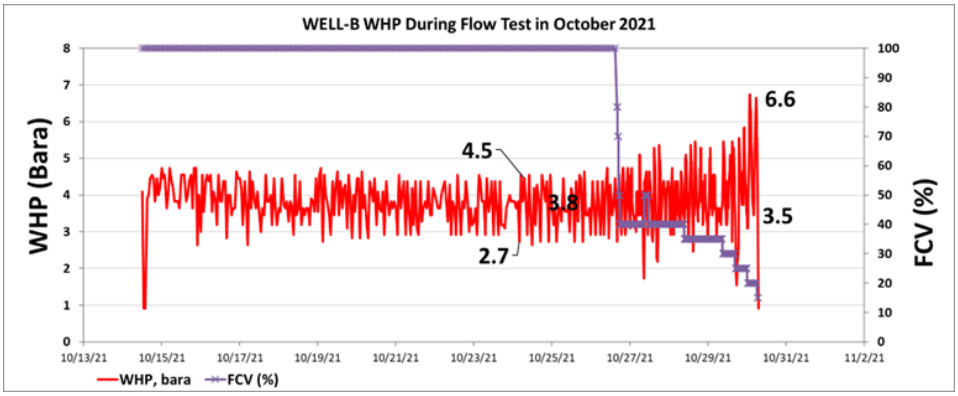

Figure 2: The Wellhead Pressure (WHP) of Well-B During October 2021 Flow Test.

Several shut-in surveys were performed after drilling to observe the heating-up process as shown in Figure 1. On the June 2021 heat-up survey (light-blue line in Figure 1), the temperature around the permeable zones was up to 270°C with an unheated section around the TLC depth. However, on the August 2021 survey (red line in Figure 1), whilst the deep unheated section was absent, well temperature decreased as a function of time, and slight temperature deflection was also noticed at a depth of ~950 m-MD.

The initial flow test was successfully conducted in October 2021 through air-capped stimulation. However, the well flowed with lower wellhead pressure (WHP) than expected and showed cycling behavior. Figure 2 shows

the oscillation of wellhead pressure clearly exhibited at various well opening with larger amplitude at lower Flow Control Valve (FCV) opening.

Cycling is normally caused by the presence of two significant feeds of different enthalpy and permeability (Grant & Bixley, 2011). Well-B stopped flowing at FCV of ~15% noted by the drop of WHP yielding MDP of ~6 bar. Afterward, Well-B was left shut in to heat up.

Post-flowing PT survey was conducted two months after the flow (December 2021), where temperature up to 50°C cooler than the June 2021 survey was observed (dark-blue line in Figure 2). The deflection temperature occurred at a depth below 950 m-MD where the major feedzone is located. A well discharge that purposely accelerated the heating-up process by discharging any left drilling fluid and materials, but insinuated cooling was happening on this well.

3. COOLING SOURCE INVESTIGATION

The causes of cooling phenomenon were investigated and nearby injection is one of the suspects. The upper feed zone of Well-B (the biggest fracture aperture from the image log) directly connects with the shallow entry of Well-A via the fault (Figure 3). Karmila et al (2021) stated that faults can be one of the contributors to the cooling risk of producer well, although there is a considerable distance between production and injection.

Prior to the Well-B flow test, the aforementioned Well-A was injected at a quite high rate up to ~1000 tph. Continuous high injection and pressure drawdown could cause adequate hydrostatic pressure to allow the injected fluid to be pushed toward the shallow wide aperture feed zone of Well-B.

A recommendation was made by reducing the injection rate to a minimum, even stopping the injection temporarily to effectively enhance energy recovery.

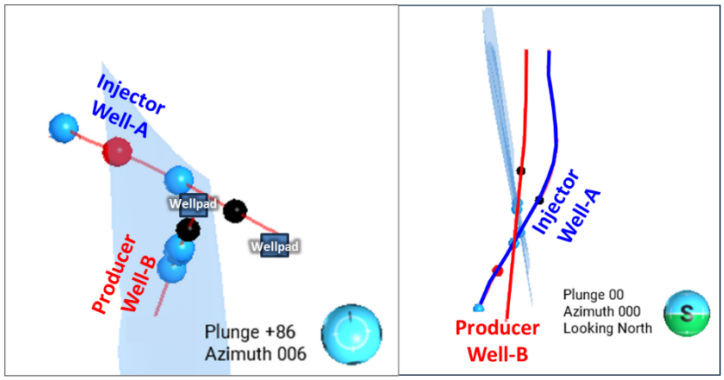

Figure 3: 3D section of fault (blue plane) that intersects the feed zones of Well-A and Well-B.

4. WELL-B PRODUCTION REBOUND

The heating-up process of Well-B took place over the period of 22 months with the latter 14 months of stop to low injection of Well-A. Comparing the PT shut-in in December 2021 with the latest PT shut-in in August 2023 (green line in Figure 4), Well-B shows a considerable heating-up process up to ~40°C. The previous cooling or temperature reversal at the shallow zone is absent. This indicates the applied injection strategy yields a positive response.

The second flow test was conducted in August 2023 to observe the heat-up process. Well-B was pre-compressed to 30 barg in preparation for air-cap discharge. During compress, sudden WHP built up to ~40 barg observed, and Well-B was directly released to the rock diffuser through the bleed line. At WHP of ~16 barg, the wellhead temperature (WHT) increased and the flow was diverted to the silencer through the production line.

Figure 5 depicts the wellhead pressure (WHP) during the flow test. Cycling WHP was observed at the beginning before it stabilized at ~3.7 barg with an MDP of ~5 barg at 19.9% FCV. After ~13 days flowing, remarkably WHP upsurge was observed from 5 barg to 17 barg, which later stabilized at ~14 barg yielding the highest MDP of Well-B. Afterward, flowing PTS was conducted to assess any potential improvement. Based on the analysis, the absence of previous cooling allows for the well rebound productivity. A significant enthalpy increase is observed at the shallow feed zone, resulting in a higher overall flowing enthalpy of the well.

Currently, the well has a sustainable flow and is connected to the power plant to boost the field generation at lower FCV opening to avoid any possibility of similar thermal breakthrough.

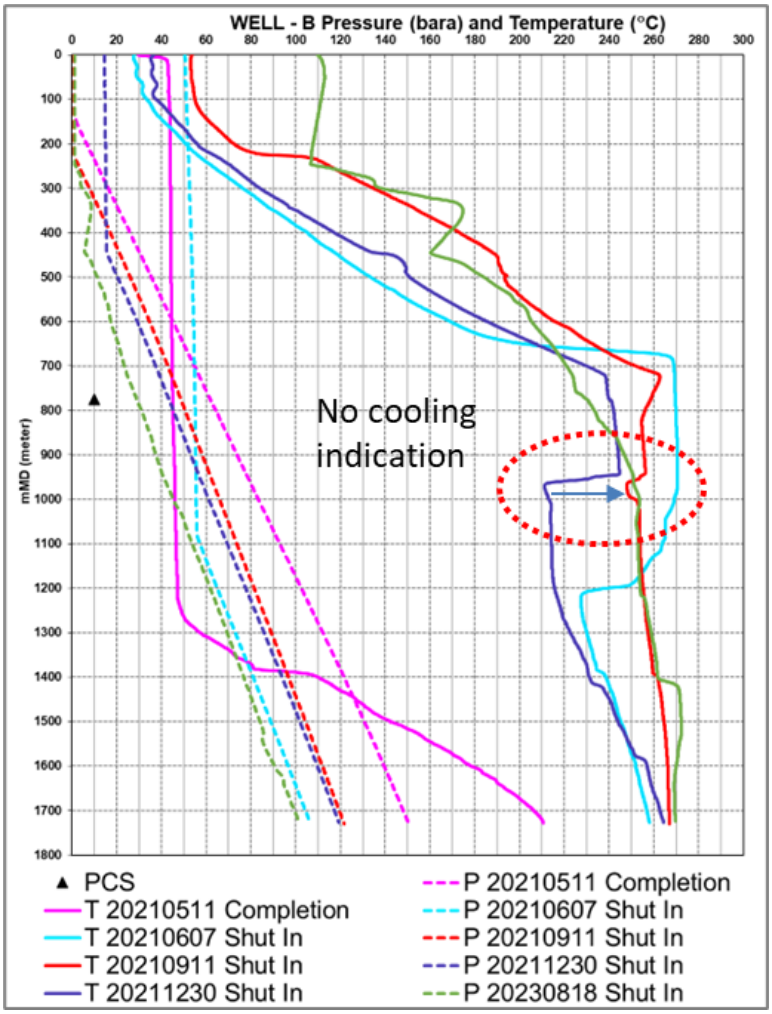

Figure 4: PT Profile after 22 months heating up process (green line).

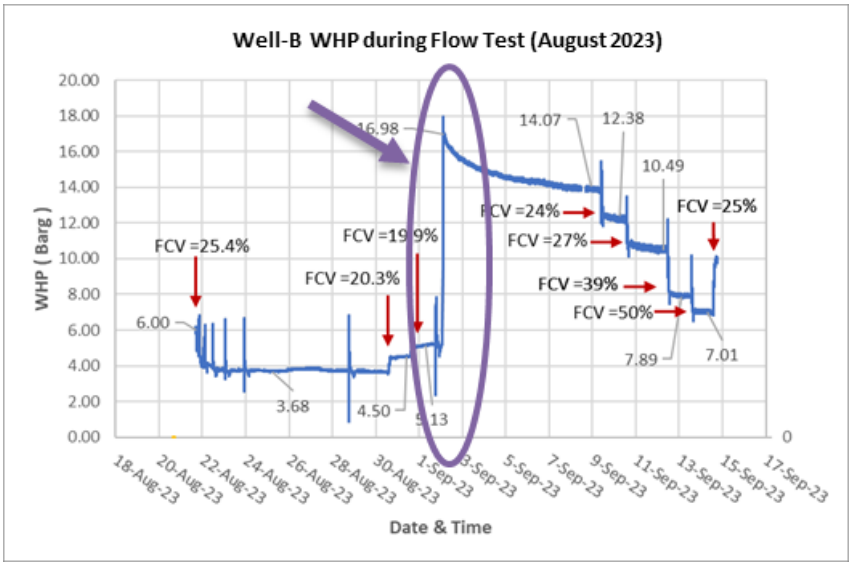

Figure 5: Wellhead Pressure (WHP) of Well-B during flow test in August 2023. Sudden WHP upsurged during flow at a similar FCV opening.

5. CONCLUSION

Good management of reinjection strategy has been proven to assist in sustainable geothermal field operation. Reinjection is required not only to comply with environmental regulations but also to allow better reservoir performance by providing pressure support and minimizing cooling from thermal breakthroughs.

Amalgamating several data such as daily monitoring data, pressure-temperature surveys, geochemistry observation, and geology may assist the reinjection strategy. The analysis shows there is indeed certain connectivity between Well-A and Well-B those that cause thermal breakthroughs resulting in poor performance of Well-B.

Therefore, several actions were taken to overcome the situation such as managing the injection rate of the injection well while shutting in the production well to minimize pressure difference between both wells thus helping accelerate the heating-up in the production well. Moreover, intervention during the well flows, such as keeping the well production opening as low as possible to reduce pressure sink in the production well area had successfully avoid further cooling. The practice yields a fruitful outcome, based on Well A result the performance rebound, evidenced by a sustained flow with higher discharge pressure (higher MDP) with the absence of cycling behavior.

Keywords: Sokoria, Production Well, Wellbore Perforation, Injectivity Index

ABSTRACT

Sokoria geothermal field has produced 8 MW of electricity from two units since July 2023. PT Sokoria Geothermal Indonesia, a subsidiary of KS Orka Renewables Pte Ltd, developed the field. So far 4 production wells and 3 injection wells have been drilled to maintain steam supply for generation. MTB A-03 is one of 4 wells that act as a production well to operate 8 MW generation in Sokoria Geothermal Power Plant. The well has a maximum temperature of 190-200 °C at stabilized conditions. The well is the only one that produces neutral fluid from the initial flow and does not need to use NaOH treatment like other wells.

The post-completion test in MTB A-03 well revealed the presence of a shallow feed zone behind the cemented 9 5/8" casing in the well at approximately ~800-900 m depth, where further analysis observed this feed zone as an additional production zone. That feed zone also had the highest temperature profile. To optimize the flow rate, such a zone had to be perforated. As a result, a production path was created from the production zone into the wellbore. Water loss tests were conducted along each step of the operation as a reference for future analyses.

The wellbore perforation resulted in an overall increase of 6 times of injectivity index for MTB A-03 well. Currently, the well is operating at WHP 2.8 Bar and WHT 138 °C. Along with MTB A-04 well, both are supplying steam to the Sokoria Power Plant unit-2 with a capacity of 3 MW.

1. INTRODUCTION

The Sokoria geothermal field is a project developed by PT Sokoria Geothermal Indonesia, a subsidiary of KS Orka Renewables Pte Ltd. This field is located at Flores Island, East Nusa Tenggara Province, Indonesia. Sokoria Geothermal Indonesia (SGI) has produced 8 MW of electricity from 4 production wells. The first commissioning was conducted in March 2022 and continued with the second commissioning in July 2023. PT Sokoria Geothermal Indonesia was the first developer who applied combined steam and brine binary technology. This is applicable in the island setting countries, especially in Indonesia where many but small geothermal resources or markets have been identified. This technology has several advantages, including:

- Utilize low-pressure wells (2 - 4 bar)
- Reduce heat and pressure loss in pipelines
- Closed loop system thus minimizing the potential for emissions
- Applying the appropriate technology for pH and scale treatment
- Smaller construction (footprint) area
- Relatively shorter construction duration

Sarmiento et al. (2019) explained that Sokoria geothermal field is a typical volcano-hosted geothermal system associated with a heat source from magma underneath Mount Kelimutu. An attempt to mitigate the risks associated with the presence of acidic and magmatic fluids at the three lakes at its summit has been made by drilling the first five wells several kilometers from the summit craters, where either a separate upflow or a lateral deep outflow of the summit system is found. The temperatures encountered by wells are consistent with those predicted by the gas geothermometer (220-260 °C) and a higher pH (4.2- 5.7) was encountered than those from the lakes. The base of the electrically conductive layer and the depth of the transition zone between the clay cap and the reservoir have been consistent with the drilling results, where the top of the reservoir (200-220 °C) is delineated at elevation 400 to 500 m mASL. The Sokoria geothermal field is a single-phase water-dominated reservoir that discharges fluids with medium enthalpy (850-950 kJ/kg) close to the feed zone temperatures measured in the wells. WHP ranges from 3 to 5.4 Bara based on the results of the brief discharge tests.

Well MTB A-03 is the third deep exploratory well completed in the Sokoria geothermal field. This standard well was spudded on cellar 3 of Pad A and was deviated to explore the postulated deep neutral geothermal reservoir at the Sokoria prospect area. The well was spudded on 13th February 2018 and achieved total depth (TD) on 21^{s}t

March 2018, the bore reached a TD of 2072 mMD. MTB A-03 completion was performed safely on 23-24 Jan 2024. Injection PT-Spinner, multi-rate II tests, pressure fall-off, and static PT have been successfully performed to identify the location of the permeable zone, injectivity index, and near wellbore characteristic of MTB A-03. Permeable zones of MTB A-03 are identified from the analysis consistent with the evidence of PLC and TLC during drilling.

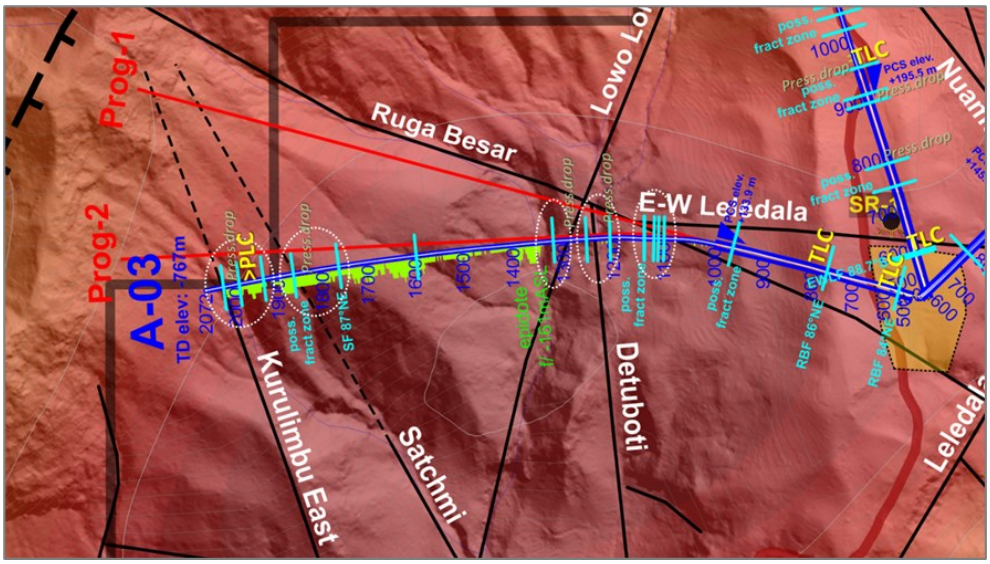

Figure 1: Faults target of MTB A-03 well.

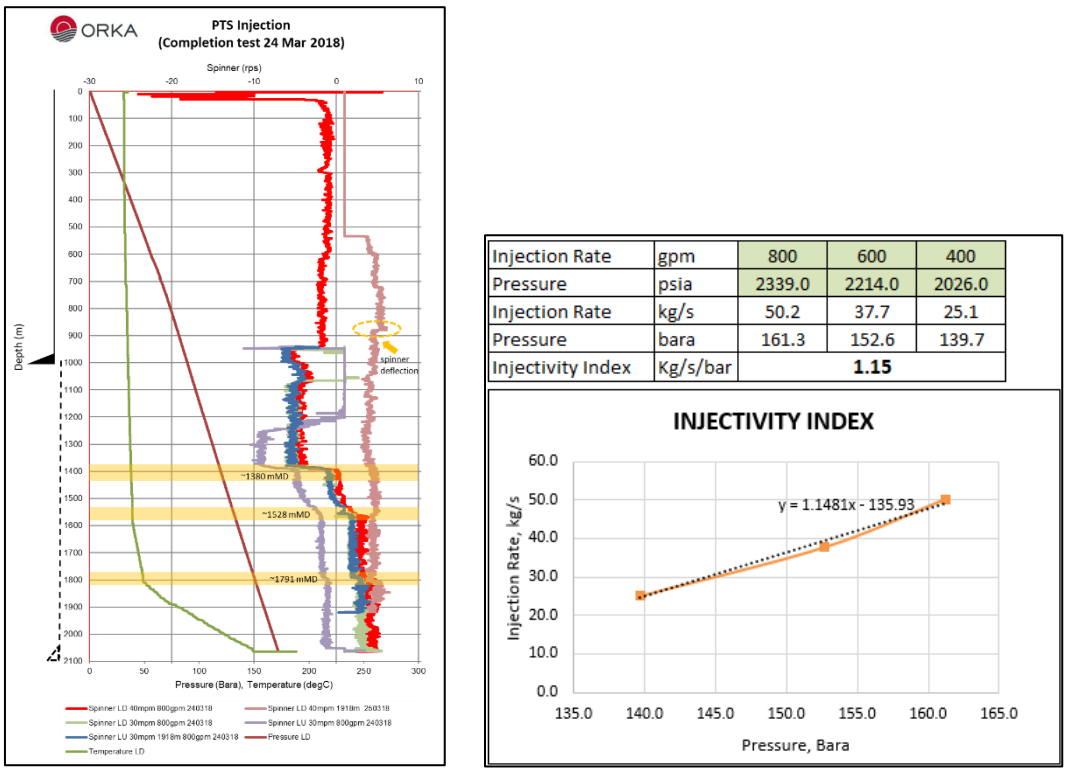

Figure 2: PTS Injection and Calculated Injectivity Index of MTB A-03 well.

2. WELL CHARACTERIZATIONS

2.1 Completion Test (2018)

Three feed zones were estimated according to this PTS survey, the feed zone at 1791 m correlated with Satchmi Fault 87° NE at 1761 mMD, and the appearance of epidote with a moderate abundant amount which indicates the presence of high-temperature minerals, then other feed zones indicated at 1460 m and 1570 m. Spinner deflection was also observed at a range of ~800 - 900 mMD inside the production casing.

The injectivity test was conducted during this completion test. The well was subjected to 3 different pump rates (800 GPM, 600 GPM, and 400 GPM) with the PTS tool set at 1918 m. The injectivity index was calculated by plotting the measured pressure taken at the end of each pump rate against the injection rate. Tabulated in the table above is the data used in calculating the well's injectivity index. The calculated injectivity index of the well is 1.15 kg/s/bar, indicating that MTB A-03 has low permeability (Internal Report, 2018).

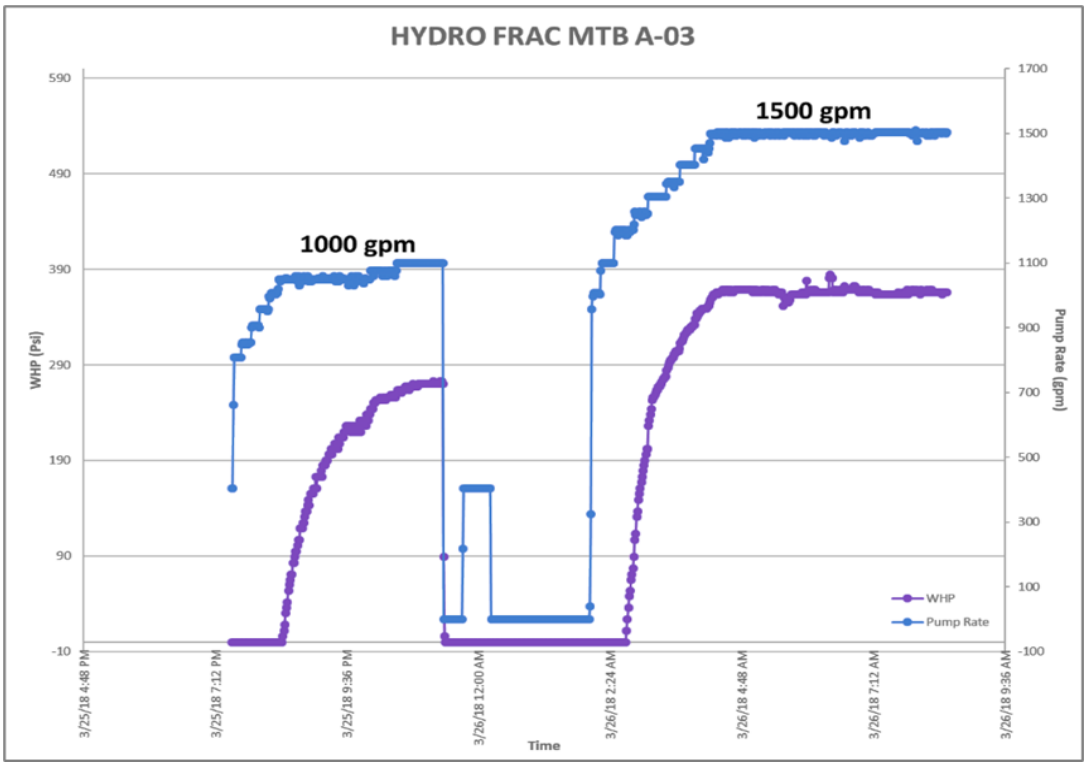

Figure 3: Hydro-fracture test on MTB A-03 well.

2.2 Hydro-Fracturing Test (2018)

Hydro-fracturing test was conducted to increase productivity or injectivity index, by pumping pressure to the reservoir by injecting water for at least 6 hours while pumping at the maximum rate that the well can take without building so much pressure at the wellhead, e.g. 500 psi. The objective is to give the well a chance again in case some fractures are plugged with cuttings and drilling fluids which could be opened at high pressures. This will be done after completing the PFO. Note that WHP remains zero at pumping rates of 800, 600, and 400 GPM.

The hydro-fracturing test was conducted at MTB A-03 by injecting water with a 1500 GPM pump rate for 13 hours. When injecting water with pump rates of 850 GPM and 950 psi, WHP was still at 0 psi. WHP slightly increased to 113 psi and stabilized at 226 psi after increasing the pump rate to 1000 GPM. The pump rate was later increased to 1500 GPM, and wellhead pressure also increased and stabilized at 366 psi for about 6 hours of pumping.

2.3 Heat-up Surveys (2019)

Several heat-up surveys were performed from day 1 after the completion test until 30 days after the well shut-in. Based on PT days 30, the highest temperature increase is observed at 750 mMD, reaching 223°C. This depth is located inside the production casing. Temperature deflection also was observed at a range of ~800-900 mMD. This depth confirms the spinner deflection which is identified from PTS injection data. Meanwhile, the permeable zones (1461, 1570, and 1761 mMD) also show a heating-up profile with temperatures of 202 °C, 173 °C, and 199 °C, respectively.

The pressure control point (PCP) or "pivot" pressure is a strong indication of the feed zone location in the well. This indicates a strong connection to the reservoir at this depth, which keeps the pressure constant at this depth, while it changes above and below due to changes in the density of the fluid column as the temperature increases in the well (Zarrouk, et al 2019). In wells that have multiple feed zones, like MTB A-03, the PCP will generally be located in between the feed zones. For these wells there will usually be associated internal wellbore flow between zones resulting from the pressure differences (Grant, 2011).

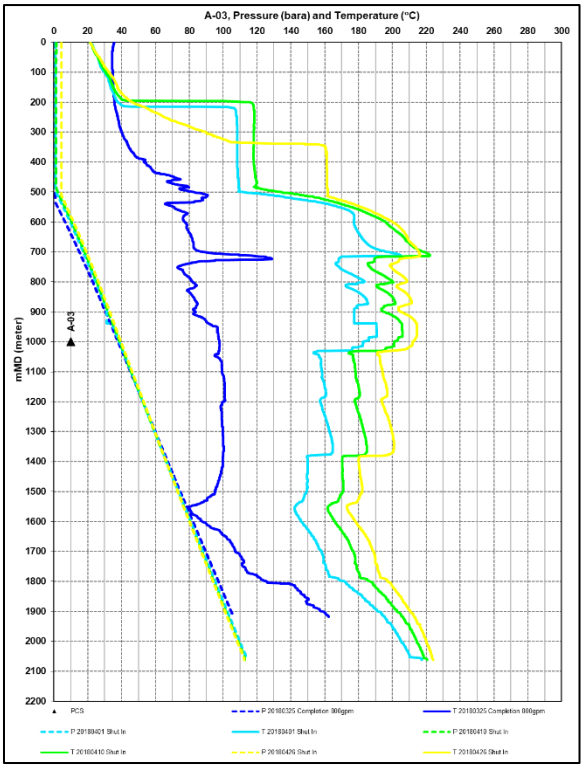

Figure 4: Pressure and Temperature profiles of MTB A-03 well during cold water injection and heat-up.

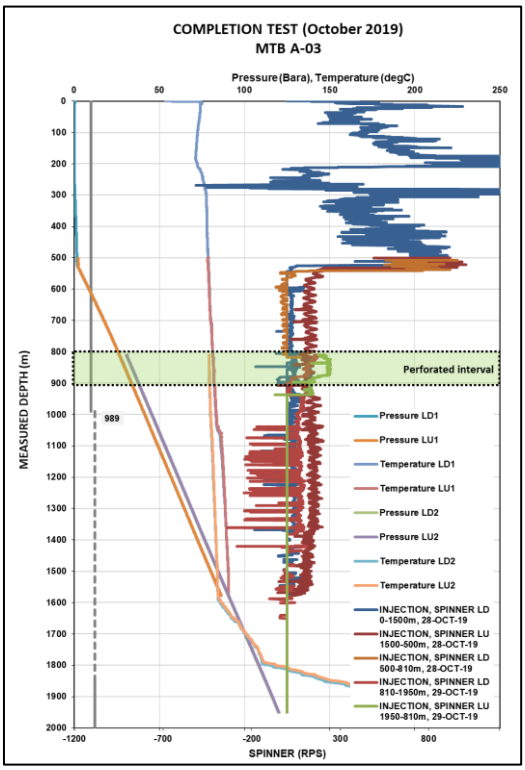

Pressure		Injection Rate	
bara	psia	gpm	kg/s
26.75	387.908	200.00	12.60
28.11	407.665	400.00	25.20
30.57	443.333	600.00	37.80

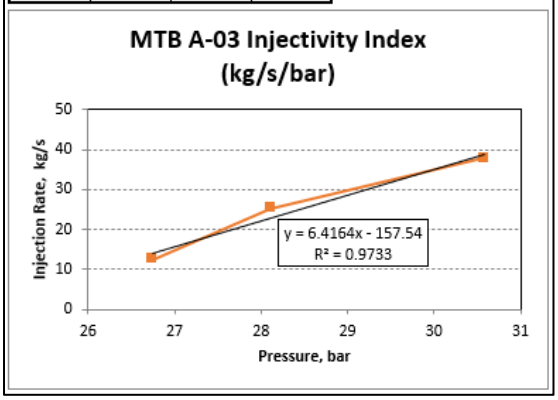

Figure 5: PTS Injection and Calculated Injectivity Index of MTB A-03 well after perforation job.

Figure 4 shows heating profiles in MTB A-03. The pressures from a pivot at 1150-1250 mMD between the two feed zones were identified by the injection profiles. There are permeable zones at ~800-900 mMD and 1461 and 1570 mMD. The upper zones inflow during the heating period, with a downflow to the lower zone. This internal

flow rapidly heats the well, and in 30 days the inflow at ~800-900 mMD has heated the well up to 223 °C. Part of the wellbore remains below the lower feed zones and is heating more slowly.

2.4 Completion Test Post Perforation Job (2019)

The previous analysis states that there was an indication of a shallow feed zone at a range of ~800-900 mMD. The location is inside the 9-5/8" production casing. To optimize the flow rate, such a zone had to be perforated. Perforation operation was completed with a total of 100 m perforated from the bottom of the production casing. The 2nd completion test was conducted to observe well characteristics qualitatively and quantitatively after the perforation job. The stages are the same as before, starting from dummy run, and PTS injection and ending with PT shut-in for 8 hours.

The result of the completion test in October 2019 showed an improvement of the Injectivity Index to 6.4 kg/s/bar or an increase 6 times larger than the previous injectivity index in March 2018. There is no change in MCD (maximum clear depth) during the completion test which indicates that no problems were found with wellbore integrity after perforation activity.

3. WELL PERFORMANCE

3.1 Output Test

MTB A-03 was discharged for the first time on 13th December 2019 through an air compression technique to stimulate the flow. This well was discharged for 126 days or almost 5 months before being switched to shut-in condition on 30 April 2020. The horizontal discharge method has been implemented in MTB A-03 to reduce the effects of direct exposure from geothermal fluid to the environment. Two-phase fluid has flowed to the atmospheric separator through the short-closed pipeline. In the separator, steam has been flashed to the atmosphere and brine has been flowed to the flash tank. The calculated enthalpy and total mass flow rate from the flow test are presented in Fig. 6. The well has an average WHP and total mass rate of 3.2 Bara and 16 kg/s respectively at 100% FCV opening.

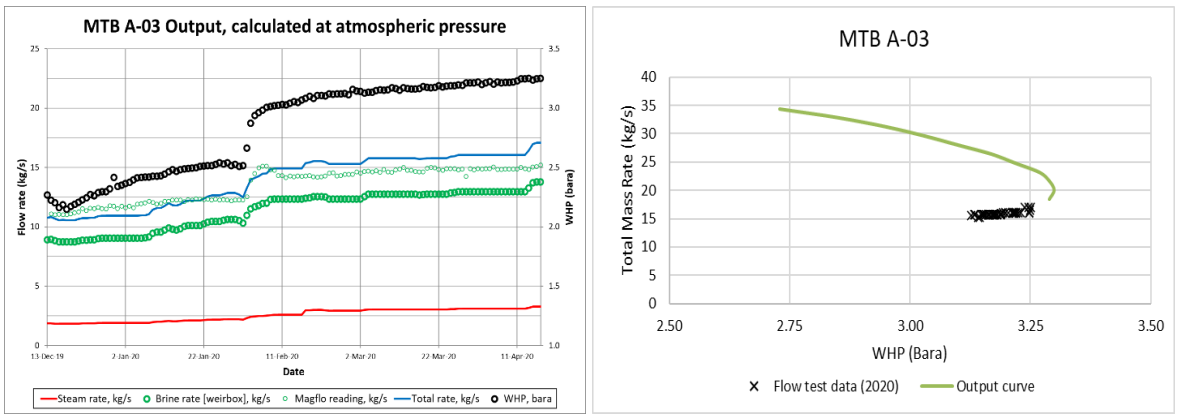

Figure 6: MTB A-03 flow test data (2019-2020) and estimated output curve.

The second test was performed on 7 December 2022 to assess well performance while nearby wells were online to the system. The test only lasted for 10 hours. The well appears to flow at a higher WHP (~4.8 Bara) and total mass rate (~21 kg/s), compared to the previous flow test (2019-2020). Discharge enthalpy is about 850 kJ/kg and pH after 10 hours flowing is 6.6 without caustic treatment. The flow test result concluded there was no observable impact from A-03 discharge to the flowing WHP of nearby wells. The flowing PTS also was conducted two times in December 2019 and February 2020. Figure 7 below compares the 2020 flowing survey with the previous log in December 2019. The temperature was observed to have increased by 9 °C in the perforated zone and ~15 °C in the production area (above 1400 mMD). Based on the analysis, flowing mass enthalpy is estimated at ~850 kJ/kg.

3.2 Online to Modular Power Plant

Currently, Sokoria Geothermal Indonesia operates 2 generation (modular power plant) units with a capacity of 8 MW, with a total development of 30 MW which is being planned in the following years. MTB A-03 is one of the wells supplying steam and brine for power plant unit 2 which is actively operating in July 2023. Wellhead pressure (WHP) and wellhead temperature (WHT) are stabilized at 2.8 Bar and 138 °C, respectively with 40% FCV opening. MTB A-03 has been continuously flowing with a neutral pH and no scaling issues since the middle of 2023. The estimated production of MTB A-03 is equal to ~1.5 MW at current WHP.

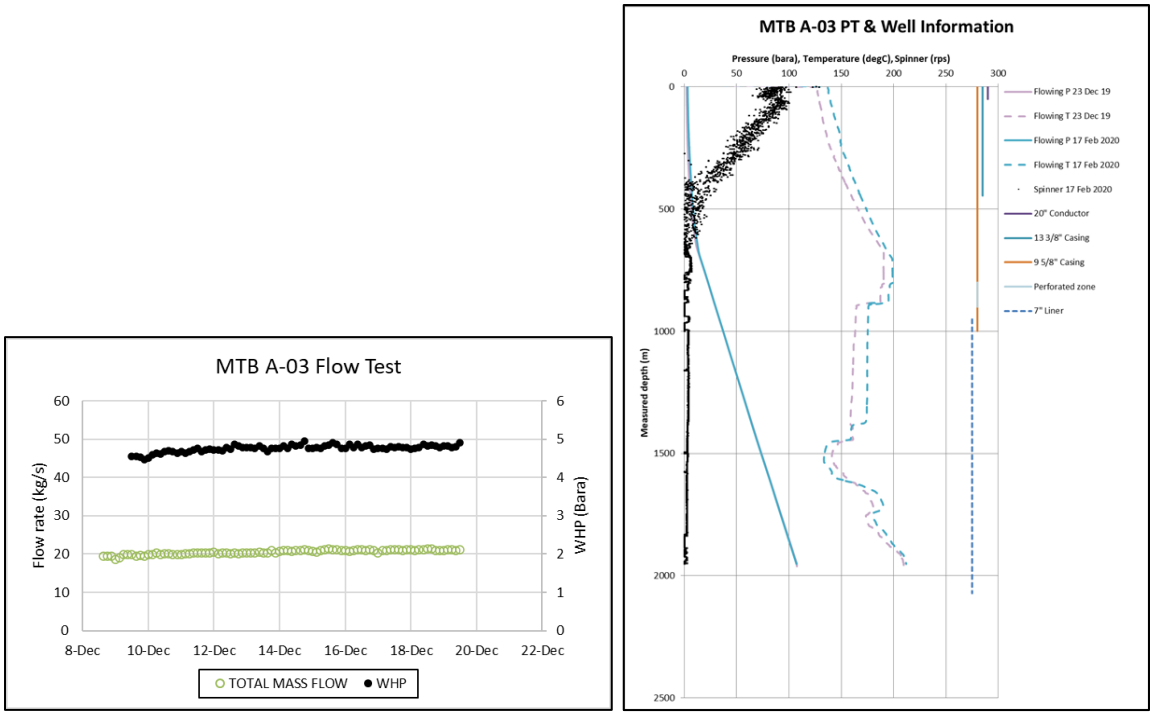

Figure 7: Flow test and PTS data of MTB A-03 Well in 2022.

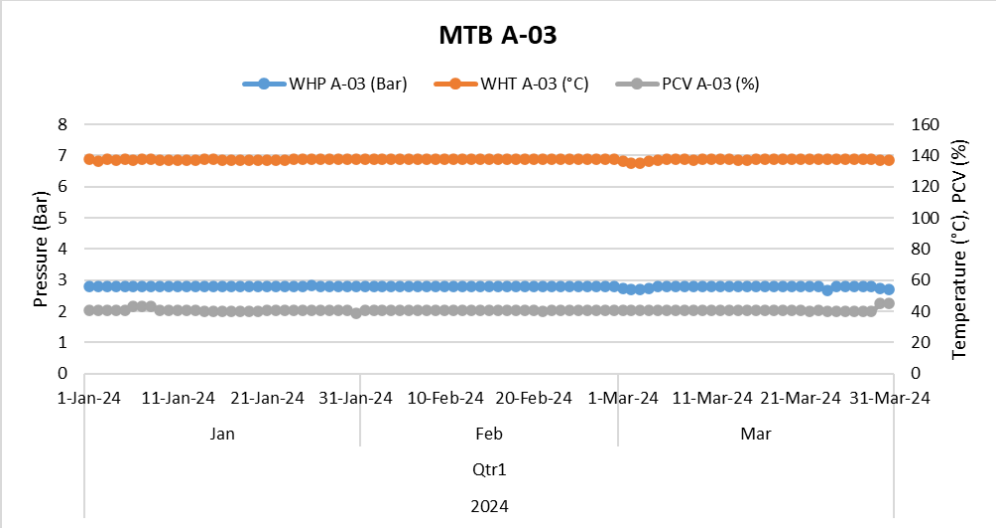

Figure 8: MTB A-03 well performance since online to system.

4. CONCLUSIONS

The conclusions that can be summarized from this study are as follows:

1. MTB A-03 well performance has progressed after carrying out several activities and analyses, mainly due to the perforation job that opens the production zone at shallow depth.
2. The resulting test in October 2019 showed an improvement in the Injectivity Index to 6.4 kg/s/bar or an increase 6 times larger than the previous injectivity index in March 2018.
3. MTB A-03 was discharged for the first time in December 2019. The well has an average WHP and total mass rate of 3.2 Bara and 16 kg/s respectively at 100% FCV opening.
4. The well appears to flow at a higher WHP (~4.8 Bara) and total mass rate (~21 kg/s), compared to the previous flow test (2019-2020). Discharge enthalpy is about 850 kJ/kg and pH after 10 hours flowing is 6.6 without caustic treatment.
5. The flow test result concluded no observable impact from A-03 discharge to the flowing WHP of nearby wells. The temperature was observed to have increased by 9 °C in the perforated zone and ~15 °C in the

production area (above 1400 mMD). Furthermore, there is a temperature deflection at the perforation zone (~800-900 m depth). Based on the analysis, flowing mass enthalpy is estimated at ~850 kJ/kg.

6. MTB A-03 has been continuously flowing with a neutral pH and no scaling issues since the middle of 2023. The estimated production of MTB A-03 is equal to ~1.5 MW at WHP 2.8 bar and WHT 138 °C.

Keywords: Brine pump, reliability, maintenance standard

ABSTRACT

Dieng Geothermal Field is a geothermal field with water-dominated reservoir characteristics where injection strategy plays a crucial role in maintaining operational continuity. One aspect of the injection strategy is preparing reliable brine injection equipment. Based on historical data, vertical pumps as brine injection equipment experience breakdowns at least 4 times a year. The primary objective of this paper was to conduct a comprehensive analysis of the factors impacting the reliability of vertical pumps. The study started by collecting preventive and predictive maintenance data, process review, and evaluating about maintenance standards. The vibration analysis data as a part of the predictive maintenance item shows that the most common problems identified are misalignment, bearing problem, bend shaft, unbalance and cavitation. Several improvements were taken to reduce corrective action and improve vertical pump reliability related to Dieng's Site characteristics. This study involved several improvements to enhance the reliability of a brine injection pump. Improvements that were taken included process limitation, design analysis, maintenance procedure, and precision installation process. Furthermore, this paper can become a reference for another geothermal field in order to resolve the brine injection pump reliability problem and make some improvements to achieve high effectiveness of maintenance action.

1. INTRODUCTION

Dieng Geothermal Field is located in the Dieng Plateu, which is geothermal working area managed by PT Geo Dipa Energi (Persero). Dieng Geothermal Field has potential of up to 400 MW. Currently, PT Geo Dipa Energi (Persero) operates two geothermal power plants, namely Dieng Unit 1 for 60 MW and Dieng Small Scale for 10 MW. Based on the steam characteristics in Dieng Geothermal Field, which has water-dominated steam characteristics, there are some brine managements that should be carried out to support stable power plant operation. One of the most critical equipment to ensure that system can run well is brine pump. The reliability of brine pump in steam field area will indirectly affect the overall electricity generation process. But the actual reliability still low, so there should be an analysis about what makes the brine pump reliability is low.

Brine management in Dieng Site mostly uses vertical pump type. Based on (Kurniawan et al., n.d.) maintenance data shows that the vertical pump reliability shows the most effective and efficient than horizontal pump type depending on the maintenance time and maintenance cost.

2. BRINE PUMP IN DIENG SITE

The injection well, which is higher than the production well, requires Dieng to carry out a pumping process so that the brine fluid can flow to the injection well. Strategy in brine management is important because maintaining smooth operations means you must be able to maintain pond levels to prevent overflow. If the pond overflows, environmental issues will arise, the consequences of which will mean having to lower the well opening, which will directly reduce the generating capacity of the power plant. In fact, if the brine gets out of control, it could result in well shut-in, which means there is no generation process at the power plant.

The complex condition of brine, which has a lot of mineral content, including silica which has the potential to cause surface facility brine management to become plugging, makes brine management a critical aspect in managing geothermal power plants in the Dieng. Brine management in Dieng Site need reliable pump for stable operation. Maintenance history shows that the breakdown event of vertical brine pump is still quite high. The lifetime of brine vertical pump is mostly not more than 3 months. There are many breakdowns of pump happened in every month. Data shows us the disbursement of the breakdown event in every month. This condition needs to be evaluated.

The condition of the vertical brine pump should be evaluated to reach better reliability. Maintenance strategies, like Preventive Maintenance, Predictive Maintenance and other type of maintenance should be evaluated. Proactive maintenance should be performed because of its low cost and great impact to the equipment.

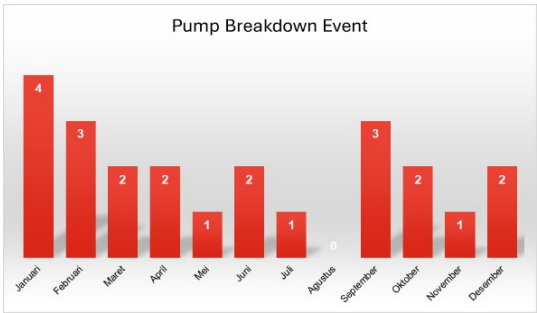

Figure 1: Existing Pump Breakdown Event Condition.

2.1 Probability Causes

Several cause that probably happen are cavitation, misalignment, bearing problem, bend shaft, unbalance, etc. All types of failure cause should be assessed to see which type of failure most contribute to pump breakdown, or pump short lifetime.

2.1.1 Unbalance and Bend Shaft

The vertical pump construction at the Dieng Site has a multistage impeller and long shaft construction. With multistage impeller construction, it increases the potential that unbalance could occur in more than 2 planes, especially if the number of stages is more than 2, such as at the Dieng Site, there can be 3, 4, 5 or 7 stages.

Unbalance occurs because there is excess mass on one or more sides, the amount of which is outside the established standards. Unbalance is a condition where a shaft's geometric centerline and mass centerline do not coincide. Each machine and type of use has different standards for unbalance. ISO 1940-1 is a standard that determines the amount of residual unbalance mass that is permitted according to its use. Unbalance is the most frequented abnormal vibration profile seen in rotating machinery and is instigated during assemblage, maintenance or fabrication (Spagnol & Wu, 2016).

With a long shaft construction, it is also possible for shaft deflection to occur, which if there is excessive external force, can result in shaft bending. This cannot be avoided considering that with a certain diameter and length, the shaft relatively has low rigidity characteristics.

2.1.2 Cavitation

Cavitation is a topic that is often discussed considering that it is a condition that is often found in centrifugal pumps. The condition of the brine, which still has a relatively high temperature, has the potential to cause bubbles to form when there is less flow in the suction area. Cavitation is a commonly natural phenomenon caused by local pressure being lower than the saturated vapor pressure, resulting in the formation of steam pockets. These pockets aggregate and collapse with the flow of fluid, not only disrupting the stable flow state but also generating considerable noise and causing damage to nearby surfaces (Xie et al., 2024). The design of the suction line also determines whether there are significant restrictions from the pond to the pump inlet, considering that the fluid being pumped also has the potential to cause the line to become a dead end after a certain amount of time in operation.

2.1.3 Misalignment

Cases of misalignment also often occur when installing motors and pumps but are more common in horizontal pumps. Horizontal pumps are generally equipped with a groove between the pump head connection and the motor, so that there is minimal misalignment. However, sometimes it needs to be verified further, considering that the surface flatness on the pump head could shift/out of tolerance.

This case of misalignment needs to be considered, especially if the coupling construction is a rigid coupling type. Moreover, most vertical pumps at the Dieng Site have a running speed of 3000 rpm, so based on ANSI/ASA standards the permitted tolerances are quite tight.

2.1.4 Bearing Problem

Bearings on vertical pumps are rolling bearings and plain bearings. Rolling bearings are usually used in motors and for upper pumps. Meanwhile, for the middle to lower part of the pump, which is in direct contact with the fluid, usually uses a plain bearing. The type of plain bearing material used for vertical pumps at the Dieng Site is carbon bushing.

2.2 Existing Maintenance Condition

In this paper, the writer collects all data about maintenance action that has been taken every day to solve or facing the vertical pump condition. As an illustration, the process of recording the performance of each equipment is still done manually, so that if a failure occurs, it will be difficult to detect the root cause, because the data availability is minimal.

2.2.1 Preventive Maintenance

Preventative (or periodic) maintenance where maintenance is based on the length of the operating period (Simm et al., 2016). The mechanical team has a preventive maintenance schedule for existing vertical pumps. Scheduled preventive steps include a daily visual check routine, clean up, tightening and painting if necessary. Then, given the existing conditions, an overhaul is scheduled every 3 months. However, this schedule often shifts, or is not implemented due to frequent breakdowns that occur.

2.2.2 Predictive Maintenance

Predictive maintenance strategies have led to the need for machinery condition monitoring. Condition monitoring can be defined as monitoring the physical parameters associated with the operation of the machine, such as vibration, temperature or pressure, to determine the operational condition of the machine (Simm et al., 2016). Predictive maintenance in Dieng Site is carried out only by taking the overall value from vibrations. Then, recording is done manually. This makes it difficult when data is needed at any time, because the data is spread across each worker. Then, trends cannot be carried out to evaluate whether there is an increase in vibration parameters, or anomalies in other parameters such as pressure, current and temperature.

2.3 Existing Process Condition

The current condition is that the only protection available is overload on the motor. The absence of other protection, such as level switches/sensors, pressure sensors, and vibration sensors makes it difficult to detect anomalous conditions early. This condition also allows the pump to run without liquid due to a low pond level, or the pump to continue running even though the vibration conditions are high, or even to continue running even though no pressure is produced.

3. ANALYSIS AND IMPROVEMENT ACTION

This analysis was carried out to find out what could possibly be improved to increase the reliability of the vertical pump at the Dieng Site. This analysis is based on the condition of existing equipment, maintenance procedures that have been carried out, design standards used, quality checks that have been implemented, as well as paying attention to operational requirements. Improvement actions taken are in accordance with financial capabilities and ease of realizing these improvements.

3.1 Review the Root Cause

Currently, the Dieng Site has a Vibration Analyzer, so it can be used to evaluate all rotating equipment in Dieng. The author has collected data as evidence to analyze the source of the problems currently occurring. The author has summarized and written down several findings that occurred at the vertical pump at the Dieng Site, and at this time the author only discusses the problems that mostly occur at the Dieng Site, where if most of these problems are resolved, hopefully, it can increase the reliability of the vertical pump at the Dieng Site significantly.

The author evaluated the pumps that were running and looked at the history of damage that had occurred and found that the majority of vertical pumps that were currently running experienced misalignment, bearing problems, bend shaft, unbalance and cavitation. The Pareto Chart can be seen in figure 2.

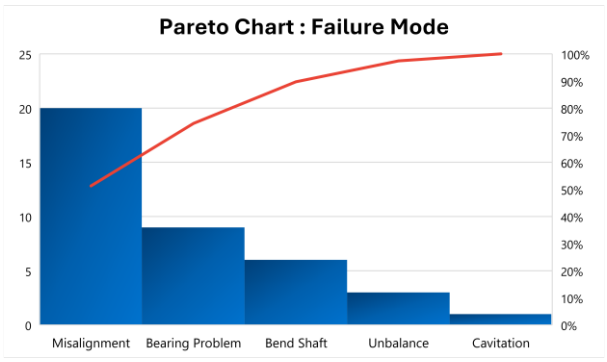

Figure 2: Pareto Chart Failure Mode Vertical Pump.

3.1.1 Misalignment

A common problem (estimated to cause over 70% of vibration problems in rotating machinery is shaft misalignment(Simm et al., 2016). The number of catastrophic cases at the Dieng Site, especially broken shafts in the coupling area, is an interesting aspect for analysis. The current condition is very detrimental because it has the potential for derating, and high repair costs will arise. Then, the vertical pump design in Dieng uses grooves, which rely on adjustments to the grooves between parts/components to ensure the straightness of the installation. With this design, the existing installation procedure does not require an alignment process when installing the coupling and installing the motor to the pump head.

Figure 3: Catastrophic Failure due to Misalignment.

However, with repeated incidents of damage, it provides chances for analysis as to whether the pump currently running is still in one axis (aligned) condition. So, with existing predictive tools, in the form of a vibration analyzer, an evaluation of the running condition of the pumps is carried out. Unfortunately, the author found that there were symptoms of misalignment in running pumps as much as 51%. One example of vibration reading results that show symptoms of misalignment can be shown in figure 4.

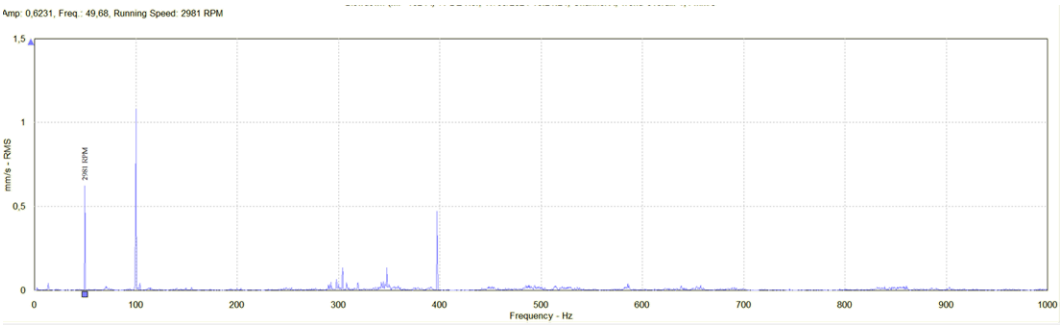

Figure 4: Vibration Spectrum Pattern of Misalignment.

After reviewing it, the condition of the groove used as a reference to ensure the installation process was carried out correctly, and that the results were straight between the coupling, pump and motor parts, had experienced wear. So, when installation is carried out without adjustments, it has the potential to cause misalignment.

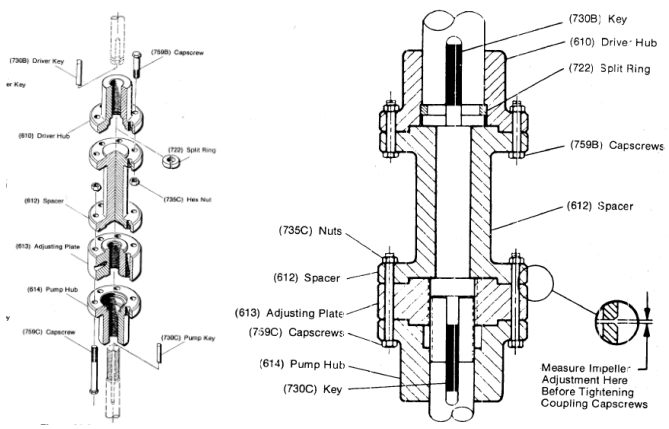

Figure 5: Vertical Pump Coupling Design.

Therefore, it is necessary to add an adjuster to carry out alignment, with worn conditions, meaning there is still space to carry out re-alignment. So, we no longer rely on existing grooves, but the alignment process is still carried out to ensure that the installation process complies with existing standards. The standard currently used is ANSI/ASA S2.75-2017, the maximum misalignment value is determined by the running speed and the type of coupling used.

An illustration of the clutch arrangement that may occur under existing conditions can be seen in figure 6. Where it is very possible for the clutch components to be installed not on one axis, which will cause misalignment and influence high vibration and low pump reliability.

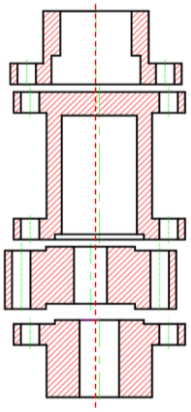

Figure 6: Coupling Misalignment Illustration.

Figure 7: Excessive Wear in Carbon Bushing Vertical Pump.

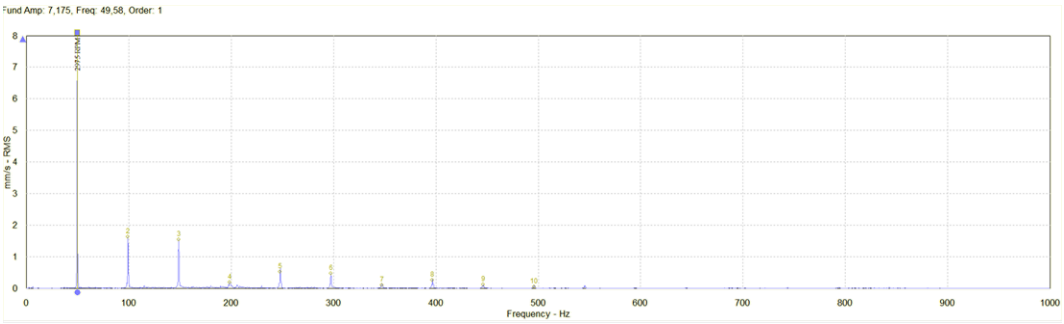

Figure 8: Vibration Spectrum Pattern of Rotating Looseness.

3.1.2 Bearing Problem

Vertical pump designs generally use plain bearings/bushings as bearings in the pump area. This is because this bearing will be in direct contact with fluid, where typical rolling bearings are not applicable for this function. The plain bearings/bushings used have several types of materials, such as bronze, carbon graphite, etc. In the vertical pump at the Dieng Site, the type of bushing material used is carbon graphite, where this material has resistance to very high temperatures, and produces low friction.

Considering the plain bearing/bushing used, clearance is an important parameter to test whether the bearing is still suitable for use or not. If there is excessive clearance, it will increase the space for the shaft to move, which will cause the pump to run with high vibration conditions. In vibration analysis, this can be categorized as mechanical looseness, where the characteristic is that there are harmonics at 1x the running speed. If over clearance is not detected, and there is no vibration sensor as protection, then this condition can have fatal consequences, namely

metal to metal contact can occur, when the carbon bushing is completely worn. If this is allowed to continue, it will result in catastrophic failure.

The author has carried out an evaluation for all pumps running in the Dieng Site area and found that there are several conditions where there is already over clearance for pumps that are still operating.

In this condition, a strategy is needed by carrying out routine monitoring, if over clearance has occurred, mechanical rotating looseness symptoms will arise, where the trend can be seen to determine the right time to carry out repairs.

3.1.3 Unbalance / Bend Shaft

Having a multistage impeller construction and long shaft construction, makes the vertical pump prone to unbalance or bending of the shaft. Ideally, each impeller should be balanced individually before assembly is carried out, then final balancing will be carried out after all the impellers have been installed. However, because it does not have balancing equipment, and demands that the pump must be ready to be installed again in a short time, the balancing process was not carried out.

With a long shaft, the potential for the shaft to bend due to excessive force when installing the coupling is also a factor that needs to be evaluated. Not carrying out run out on the shaft before, after the coupling shaft installation process, and after the assembly process means that the same quality for each pump cannot be always achieved.

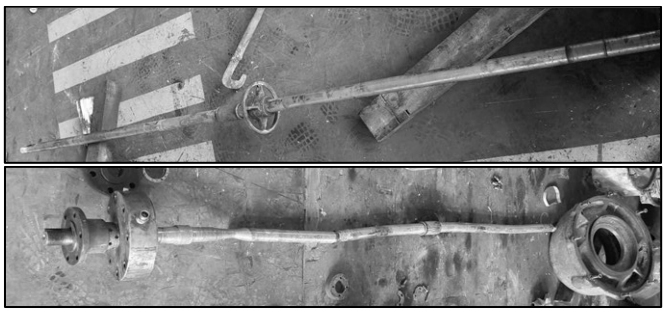

Figure 9: Catastrophic Failure due to Bend Shaft.

The author tried to evaluate the condition of the running pumps, and it was found that around 23% of the pumps operating at the Dieng Site experienced unbalance/bend shaft conditions with varying severity. The following is evident from one of the pumps operating in the steam field area.

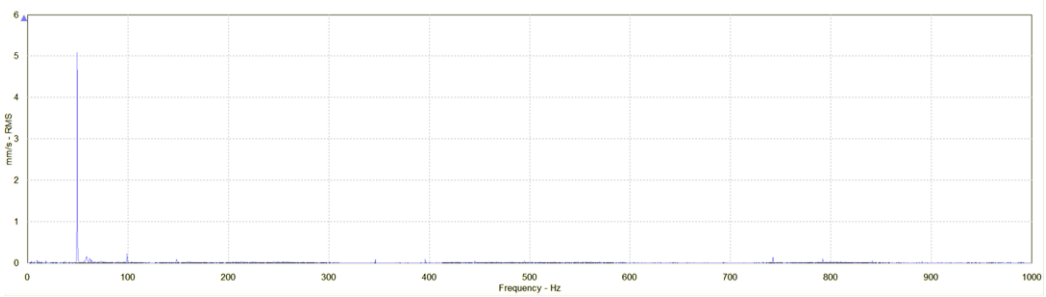

Figure 10: Vibration Spectrum Pattern of Unbalance/Bend Shaft.

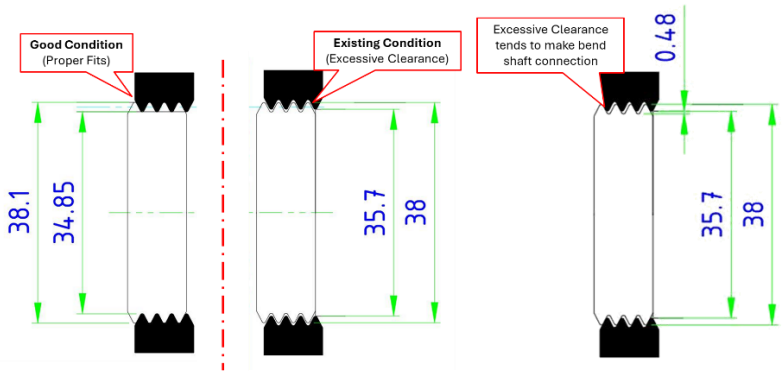

Figure 11: Shaft Coupling Thread Clearance Analysis.

Because the symptoms are the same, namely dominant at 1X running speed, so in the vertical pump it is difficult to distinguish whether there is an unbalance condition in the rotating part of the vertical pump, or whether a shaft bend is occurring. This can be minimized if we eliminate one of the symptoms. For example, if a run out has been carried out, and it is confirmed that the shaft is straight, then it can be ascertained that the condition that is occurring is unbalance in the pump's rotating part assembly.

Because there is no balancing machine, one of the actions that can be used for evaluation is the run out of the pump shaft, pump shaft coupling, and installation process. The author found that there was over clearance in the pump shaft coupling thread connection. Illustrations can be seen in figure 11.

Over clearance conditions in the coupling and pump shaft connections tend to cause the resulting pump shaft connection to become bent. This can affect the overall quality of the assembly, because if the coupling which should be able to connect the two shafts straight is not aligned, it will provide excessive force on the shaft itself, which will result in the shaft bending.

3.1.4 Cavitation

The condition of the brine content in the pond at the Dieng Site requires cleaning every 2 or 3 months, considering that the silica deposits that occur in the cooling pond are quite massive during that time. The open condition of the cooling pond, which is used as a suction pump, really allows restrictions to occur on the strainer, or even on the suction bell. The author found several incidents, where when the pump was damaged, and an inspection was carried out foreign material was found covering the suction bell as seen in the figure 12. So, this condition allows the pump to remain in running condition even though the incoming fluid is insufficient or even no fluid at all, considering that there is no other protection other than motor overload.

Figure 12: Foreign Material in Suction Bell Vertical Pump.

The author tried to evaluate the condition of the pumps that were running and found that there were several pumps that were running in cavitation conditions. Apart from foreign materials, manual operation sometimes increases the human error factor, in the form of allowing the pump to continue running even though the cooling pond is at a low level. One of the author's findings through vibration analysis can be seen in figure 13.

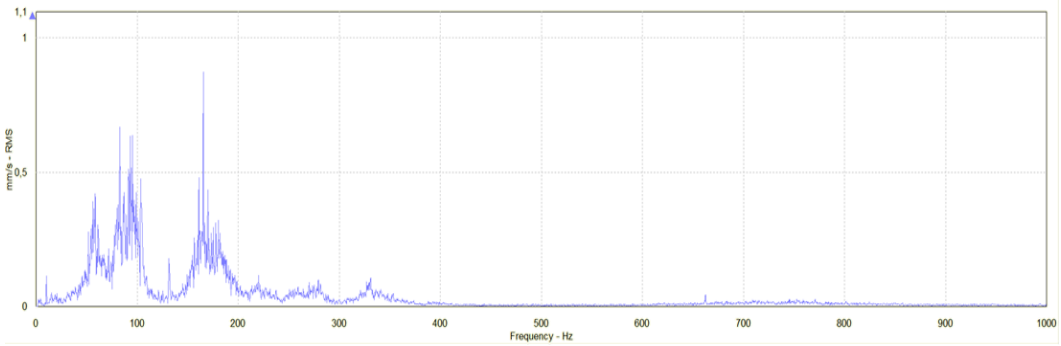

Figure 13: Vibration Spectrum Pattern of Cavitation.

So, under these conditions, there is a real potential for cavitation to occur due to the lack of flow in the suction bell and suction line. This needs to be of particular concern to the operations division which carries out routine patrol checks every day. If a cavitation condition is found, mitigation needs to be carried out to prevent the pump from continuously running in a cavitation condition, which will influence pump damage.

Some indications that can easily be recognized if cavitation occurs are the cavitation noise signal is random, and its spectral structure is unique. The liquid-loaded noise signal is promising for detecting cavitation (Liu et al., 2023), Then, there are pressure pulsations due to cavitation that can be easily seen on pressure gauge (Liu et al., 2023). Vibration increases in the blade pass frequency area and random noise increases (Liu et al., 2023). Then,

the level is in low condition, remembering that if there is a head decrease of 3% it increases the possibility of cavitation (Kazi et al., 2011)

3.2 Improvement Action

3.2.1 Alignment and Run Out Installation Procedure

Considering that the condition of the pump component grooves is worn, it is necessary to carry out an alignment procedure for each motor, pump and clutch installation. The current condition of the head does not have an adjuster to precisely adjust the position of the motor and pump. So, modifications have been made in the form of an adjuster installed on the pump head to regulate the straightness of the motor installation on the pump head.

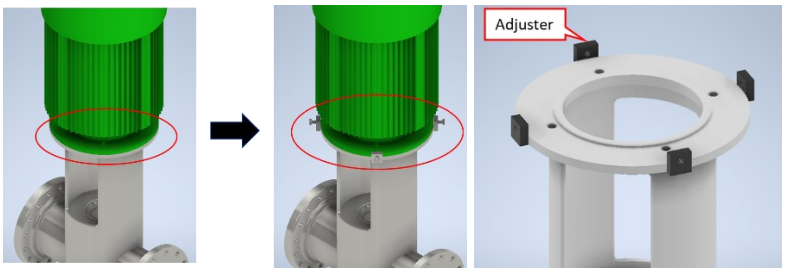

Figure 14: Adjuster Modification for Alignment Process.

Then, before alignment is carried out, several procedural steps need to be carried out, namely:

a. Run out of motor shaft and coupling
   This is done to evaluate whether the motor shaft is still straight or not. Then run out of the motor coupling also needs to be done, to determine whether the coupling is still in good condition and installed with the appropriate clearance. Because, if there is over clearance it will cause the center between the motor shaft geometry and the motor coupling to shift, and this will definitely affect the subsequent alignment process.
b. Run out of pump shaft and coupling
   This needs to be done when the pump is in good condition after full assembly has been carried out in the workshop. This is used to confirm whether the pump shaft and coupling are installed precisely. This can be done with a dial indicator while the pump is still horizontal. It is necessary to check the installation of the coupling and shaft, which is often found that the axis between the shaft and coupling has shifted due to over clearance and inappropriate feather key dimensions.
c. Alignment between pump head and motor
   This can be done after the head pump assembly has been installed in its place, and the motor has sat on the head pump. The alignment process is important considering that the groove between the pump head and motor has experienced wear and tear, which still provides enough space to shift, so that the position of the pump and motor axes are in the same axis/alignment.
d. Alignment between motor coupling and spacer
   The coupling alignment process needs to be carried out considering that the coupling arrangement used is a rigid type of clutch, and the running speed is quite high, namely 3000 rpm, so that if we refer to ANSI/ASA standards the tolerances are quite tight. If you review the existing design, the coupling arrangement is long, which involves spacers and adjusting nuts, so the coupling alignment process needs to be done with precision, because if one of the arrangements is wrong, it will affect the subsequent alignment process and the alignment process.
e. Axial play settings
   Axial play is used to ensure that the axial position of all rotating parts does not come into contact with static parts when operating. In vertical pump construction, there is an adjusting nut that can be used to regulate axial play precisely. This process can be carried out using a vernier caliper.
f. Coupling installation
   After the alignment process is complete, you can continue with the process of installing the clutch bolts. However, you need to pay attention to the order of tightening, remembering that the alignment process needs to be maintained so as not to change the settings that have been made.
g. Final run out checks
   After the coupling bolt tightening process is carried out according to the torque, the next step is to ensure that the entire alignment process has been carried out properly and correctly. So, it is necessary to carry out a final run out of the pump shaft, remembering that if the alignment process has been carried out correctly, it will produce a good run out too. However, if the alignment process is not carried out properly, it will result in the clutch arrangement and connections between motor and pump components resulting in run outs outside the standard (out of tolerance).

3.2.2 Re-design Pump Shaft Coupling

The thread in the pump shaft clutch connection uses a smooth thread design. The thread construction used is Whitworth which has a pitch design of 55° (Simmons et al., 2020). If you look in more detail, in thread construction there are major and minor diameters that need to be met. Considering that the threads currently used are not standard, it is necessary to carry out a detailed analysis of the major and minor diameters of the thread. When the analysis was carried out, minor and major discrepancies were found, so it was necessary to standardize the drawing thread to avoid bending of the shaft after connection.

Standard Shaft Coupling Thread Data		
Pitch Diameter	:	35,39 mm
Major Diameter	:	38,1 mm
Minor Diameter	:	32,68 mm
Pitch	:	2.54 mm

Figure 15: Standard Shaft Coupling Thread Data.

Standard shaft coupling data in figure 15 provide complete data for fabrication shaft coupling vertical pump in Dieng Site. It designs for better shaft connection, and avoid the bend shaft condition due to loose clearance between shaft and coupling shaft. Detail design can be viewed in figure 16.

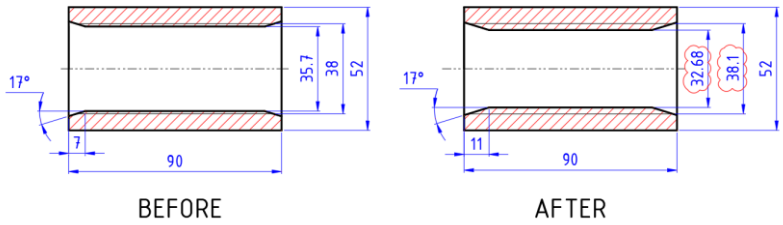

Figure 16: Standard Shaft Coupling Final Design.

Figure 17: Installation of Level Transmitter.

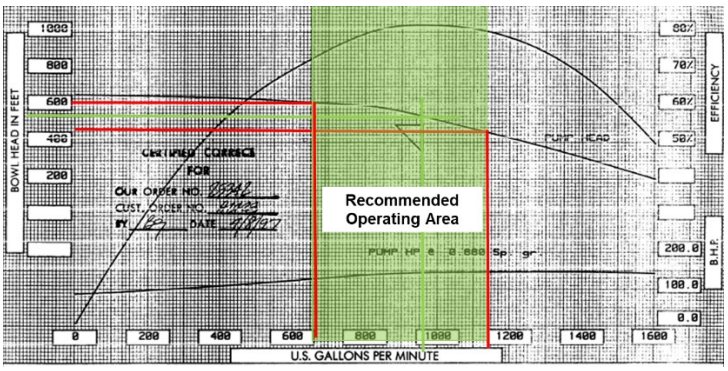

Figure 18: Recommended Operating Area based on Pump Performance Curve.

3.2.3 Installation of Level Switch/Level Transmitter and Process Limitation

To overcome the condition that the pump continues to run even without liquid conditions, which will result in cavitation conditions that will damage the pump, so one of the improvements that has been made is to install a level switch as additional protection when the pump is running in low level conditions.

Then, the operating process greatly influences the overall performance of the equipment, so it is necessary to review the process limitations for each pump. Several literatures say that the recommended pump operation is 70% - 120% of BEP. So, the author collects all pump performance curves, to ensure that the pump continues to work within permitted conditions.

3.3 Improvement Result

After implementing all the improvement actions in the discussion above, observations are then carried out within one year, which can be compared with the conditions before the improvement. The historical results show that there has been a reduction in breakdown events of up to 74%. In Figure 19, the trendline tends to decrease, indicating that there is a trend towards improving the reliability of the vertical pump.

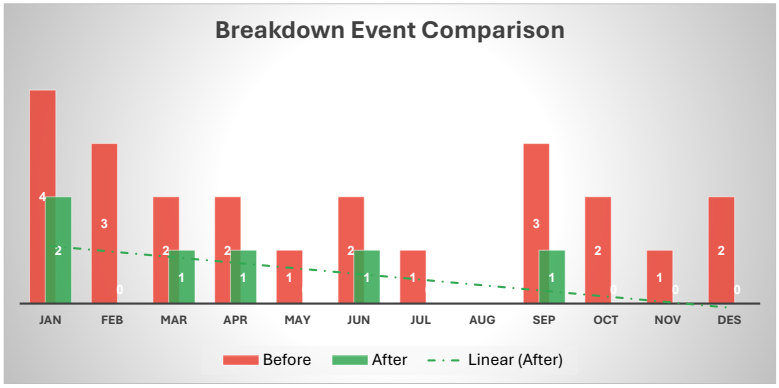

Figure 19: Breakdown Event Comparison After Improvement Action.

4. CONCLUSION

Based on data collection and maintenance history review, the biggest causes of damage are misalignment with 51%, bearing problem with 23%, bend shaft with 15%, unbalance with 8% and cavitation with 3%. Improvements that have been carried out are in the form of alignment assessments and applications, and run out checks for vertical pumps, re-designing threads of coupling shafts, adding level switches or level transmitters, as well as input for the operations team regarding process limitations in pump operation.

Keywords: reservoir characteristics, pressure transient analysis, pressure build-up

ABSTRACT

Kamojang, one of the biggest and oldest geothermal fields in the world, has been actively producing for more than 40 years. The key to maintaining productivity is to understand that reservoir characteristics change occasionally. One way to evaluate the change in the reservoir is through pressure transient analysis (PTA). A fall-off test (FOT) is performed during the completion test to acquire pressure transient data. Furthermore, since Kamojang is a single-vapor phase field, a pressure build-up test (PBU) is performed during the production phase to acquire additional pressure transient data and get more information about the reservoir. The pressure transient data is evaluated using commercial software to capture the changes in reservoir characteristics during the production period, such as transmissibility and skin factor, in each well.

1. INTRODUCTION

Kamojang is located in Ibun District, approximately 40 km from Bandung, West Java, with an elevation of around 1500 meters above sea level. The reservoir is classified as a single-vapor-phase reservoir. Currently, total vapor production is comparable to 235 MWe, complemented by six power plant units. Now, Kamojang has 97 wells along the production period from 1974 to 2024 (63 production wells, 9 injection wells, 16 monitoring wells, and 9 abandoned wells). With such high levels of output, reservoir management is essential for maintaining reservoir performance. One approach to reservoir management is to monitor the reservoir and determine its features using pressure transient analysis.

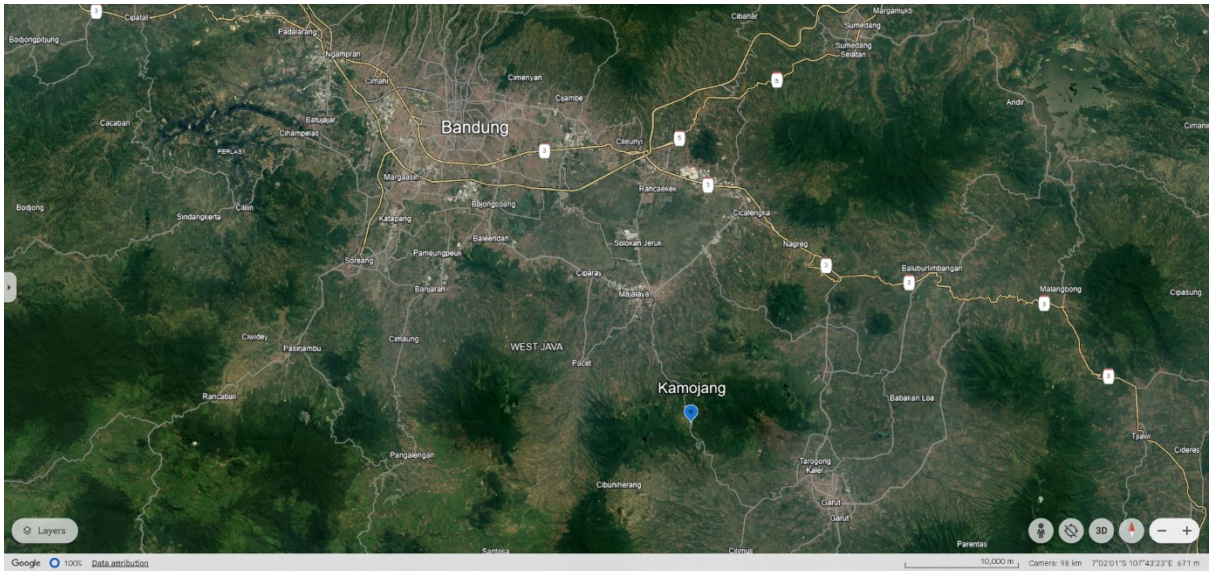

Figure 2: Kamojang Location from Google Earth (Google, 2024).

Pressure transient analysis (PTA) is the process of analyzing the resulting pressure and flow data set by matching the data to an analytical or numerical model of the well and reservoir. Data collection typically involves four types of tests: drawdown, build-up, injection, and fall-off tests (Zarrouk & McLean, 2019). However, with geothermal, only two types of tests are practicable to implement: build-up and fall-off tests, because thermal shock along the pipe does not occur during the test. A study was conducted to capture the reservoir parameters of a geothermal reservoir in Turkey utilizing both pressure build-up and fall-of-test methods (Aydin, Merey, & Akin, 2024). In this scenario, to monitor reservoir characteristics throughout vapor production in Kamojang, PTA is performed

on build-up test data, which can be repeated on a regular basis. To monitor reservoir parameters, it is preferable to use build-up test data rather than fall-of-test (FOT), which is often performed only once throughout the well completion test period. For those reasons, only build-up test data is used in this paper to depict the changes in reservoir characteristics in Kamojang during the production period.

The primary purpose of PTA is to gather reservoir data with some typical outcomes, including reservoir transmissivity (kh), skin factor (s), initial reservoir pressure (Pi), and other parameters indicating reservoir size and boundaries. This analysis plays a crucial part in reservoir management. For example, knowing the properties surrounding the wellbore, such as skin and permeability, can help with decision-making when developing a workover/well intervention strategy. Other than that, the characterization of the permeability system can also be helpful in determining the location of the new make-up well. With that being said, PTA takes a big part in taking care of reservoir management system.

In Kamojang, pressure build-up tests are conducted by shutting down the well after a certain amount of production time to allow the reservoir pressure to return to its static shut-in point if possible. From 2009 until 2023, pressure build-up tests were performed often, which necessitated a complete investigation of reservoir characterization. However, in this study, PBU tests were performed in most of production wells to provide a thorough understanding of reservoir attributes using the same pressure transient test method. However, not all of that data can be examined using pressure transient analysis due to pressure instability and other issues that may arise throughout the test. This study will provide PTA for some wells that can be evaluated because the tests were performed several times in previous years to capture more understanding of reservoir properties along the production period.

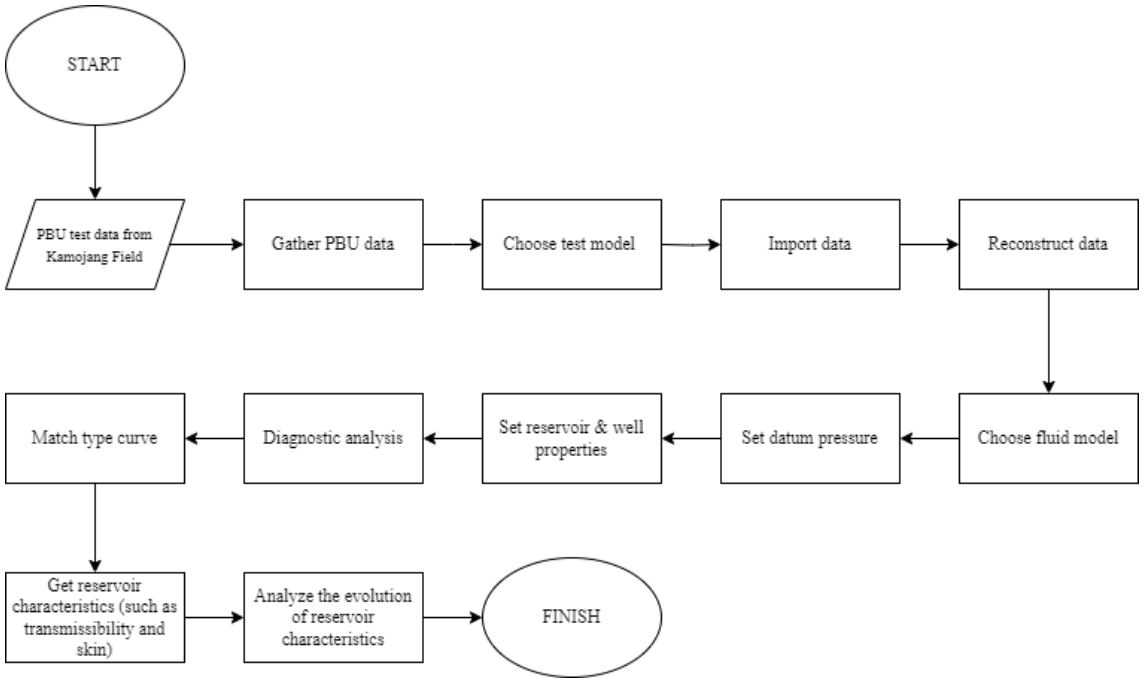

Figure 2: Methodology for the study.

2. METHODOLOGY

For this study, transient data sets were acquired by creating pressure disturbances in the production well through a shut-in method by monitoring wellhead pressure (pressure build-up test). The analysis will cover pressure transient analysis for several production wells, as these tests were conducted multiple times in previous years to track changes in reservoir properties over the production period. The employment of computers to match models to well-tested data was inevitable. Reservoir features can be approximated at an early age by utilizing software and inverse modeling to match transient data (Earlougher, R.C., & Kersch, 1972). With the development of PTA, in this study, reservoir characteristics will be modeled using existing well data with the aid of WellTest 2019.1 software (IHS Markit, 2019). A detailed description of the study methodology is illustrated in Figure 2.

After obtaining the transient data, the appropriate build-up test model will be selected, and then this data will be imported into the software. These datasets will be quite numerous (it can be more than 10,000 data points). Therefore, to ensure an optimal data volume of less than 5000 data points, data reconstruction is necessary using a data filtering method involving logarithmic points per cycle or arithmetic time steps tailored to meet the

requirement. If necessary, this data reconstruction allows adjustments to the shut-in period, which may differ from the well closure time data.

Fluid properties are important in reservoir characterization modeling because they apply to geothermal fluids at high temperatures, which might change their own properties and, as a result, pressure disturbance responses. Aside from fluid parameters, reservoir and well properties influence these responses. As a result, inputs obtained from PT survey monitoring data are critical, augmented as needed by assumptions tailored to reservoir conditions. These data inputs are essential to obtaining the right analysis of our reservoir characteristics.

Once all input data is consistent with reservoir conditions, additional analysis is required to ascertain reservoir characteristics. Following that, diagnostic analysis is performed to help detect several effects throughout the pressure transient: wellbore storage effects, reservoir radial flow, and boundary effects (pseudo-steady state). Understanding these phases aids in the early stages of type curve matching. Type curve matching can be aided by making alterations to predetermined parameters. Furthermore, automated matching methods can be done by iterating parameters like permeability, skin, wellbore storage, reservoir boundaries, and so on to ensure that they match the reservoir model. After all processes have been completed the reservoir parameters matched with the type curve will be used as outputs for subsequent analysis. This analysis will involve comparing data from the same wells across different years. These results will serve as the foundation for understanding the evolution of reservoir characteristics through PTA.

3. RESULTS AND DISCUSSIONS

Pressure transient studies were performed on 61 wells in the KMJ field, including FOT and PBU tests. Only 31 wells underwent the PBU test more than once. Wells with PBU data from two time periods, 2009-2012 and 2019-2023, were chosen for this study, totaling seven wells (which are KMJ-A, KMJ-B, KMJ-C, KMJ-D, KMJ-E, KMJ-F, and KMJ-G). This analytical constraint was designed to generalize the research findings and examine the impact of production on reservoir properties such as transmissibility and skin over a given time period.

The geological structure map of the Kamojang revealed that the wells are directed towards two structural fault boundaries, notably Kendang and Laksana faults. The PTA is used to identify the properties of these geological structural boundaries. The geological structure map of Kamojang shows that KMJ-C, KMJ-E, and KMJ-G are oriented toward the Kendang Fault. Meanwhile, KMJ-D and KMJ-F are pointing toward the Laksana Fault. Furthermore, KMJ-A is oriented toward the northeast, while KMJ-B is oriented toward the north. In Figure 3, a well distribution map of Kamojang is shown.

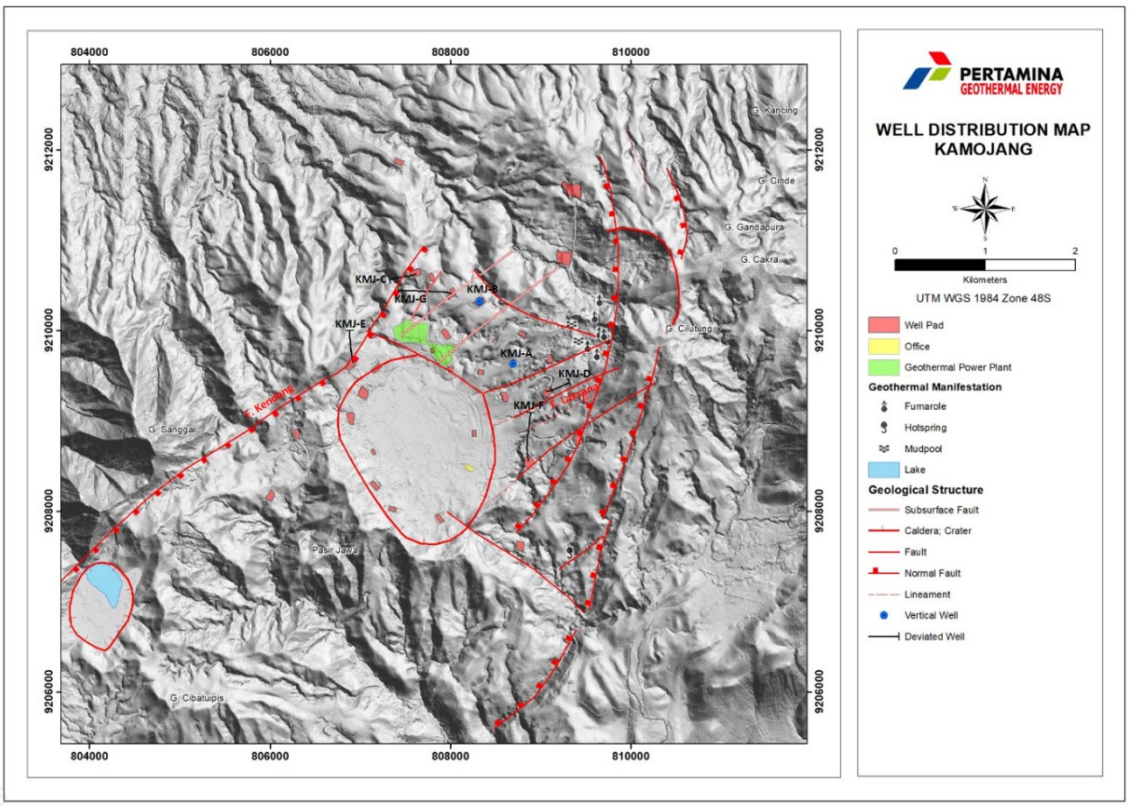

Figure 3: Well Distribution Map of Kamojang.

In the figures below (Figure 4, Figure 5, and Figure 6), log-log plots for the wells directed towards the Kendang Fault are presented. The analyses of these three figures indicate a similarity in reservoir characteristics, where the pressure transient characteristics still act as an infinite-acting reservoir. The pressure derivative plot at the late time reveals that the pressure response is constant, with no increase or drop. Based on this evidence, it may be argued that these wells do not respond to possible boundaries at the Kendang Fault, implying that the structure is still acting as a reservoir. Furthermore, it is also probable that the duration of the pressure build-up test was insufficient to see the boundary effects of the Kendang Fault.

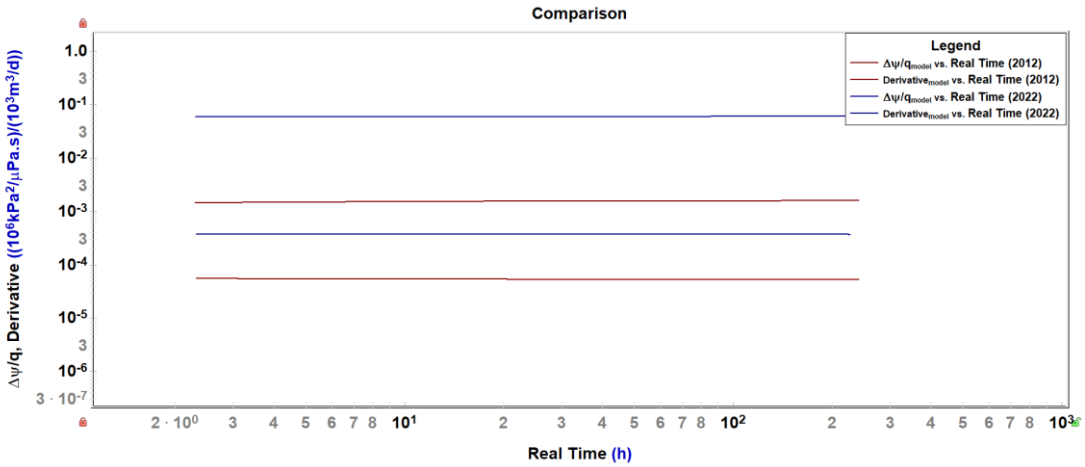

Figure 4: Pressure Build-Up (PBU) Comparison Plot in KMJ-C.

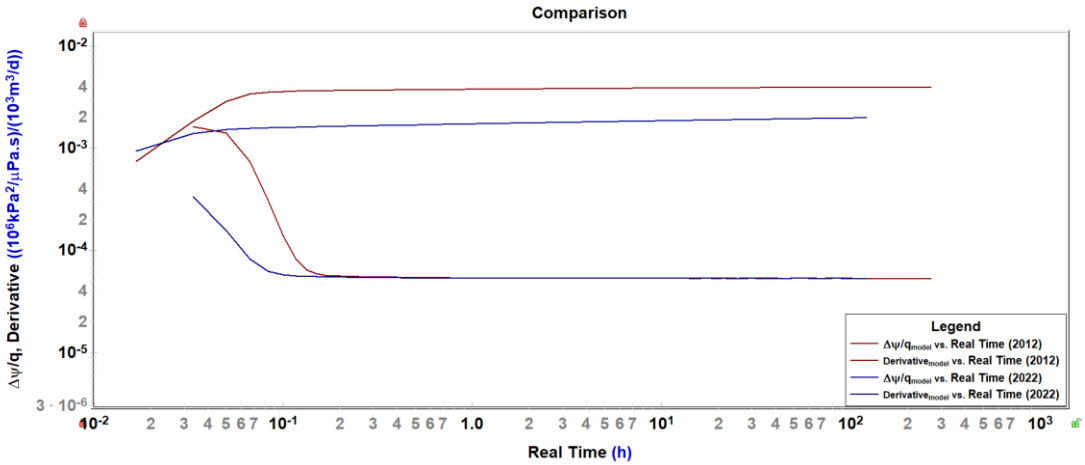

Figure 5: Pressure Build-Up (PBU) Comparison Plot in KMJ-E.

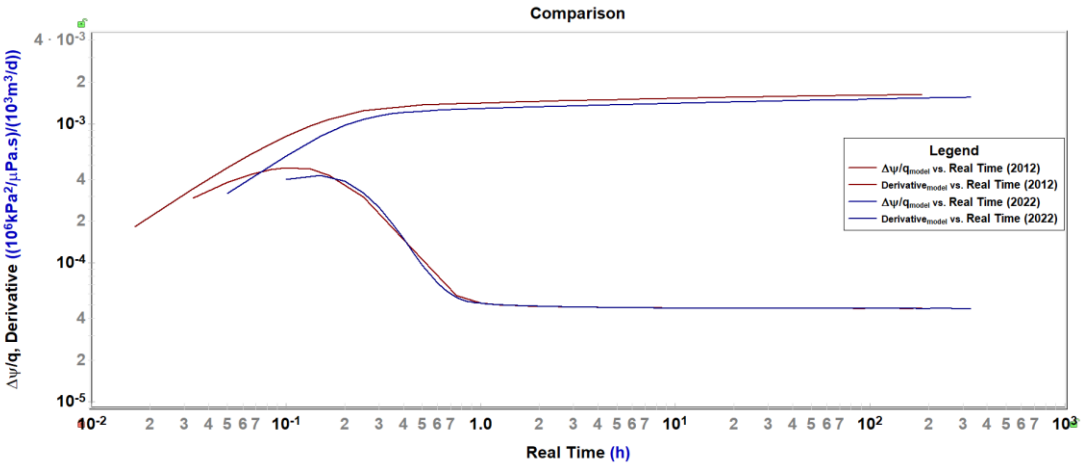

Figure 6: Pressure Build-Up (PBU) Comparison Plot in KMJ-G.

For the wells directed towards the Laksana Fault, the log-log plots are represented in Figure 7 and Figure 8. The PBU (Pressure Build-Up) results indicate the presence of a no-flow boundary for these wells, although it cannot be immediately confirmed due to the need for a drawdown test, which is essential for verifying the boundary characteristics (Zarrouk & McLean, 2019). However, conducting a drawdown test in a geothermal field is challenging due to issues related to thermal shock and the potential need for discharge stimulation to enable fluid flow from the wells. In well KMJ-D, the heat boundary can be relatively determined due to the presence of a radial flow pattern indicated by the pressure response on the pressure derivative plot before it rises. On the other hand, in well KMJ-F, the heat boundary is relatively difficult to determine because the radial flow pattern is not reflected before any disturbance to the reservoir pressure response occurs.

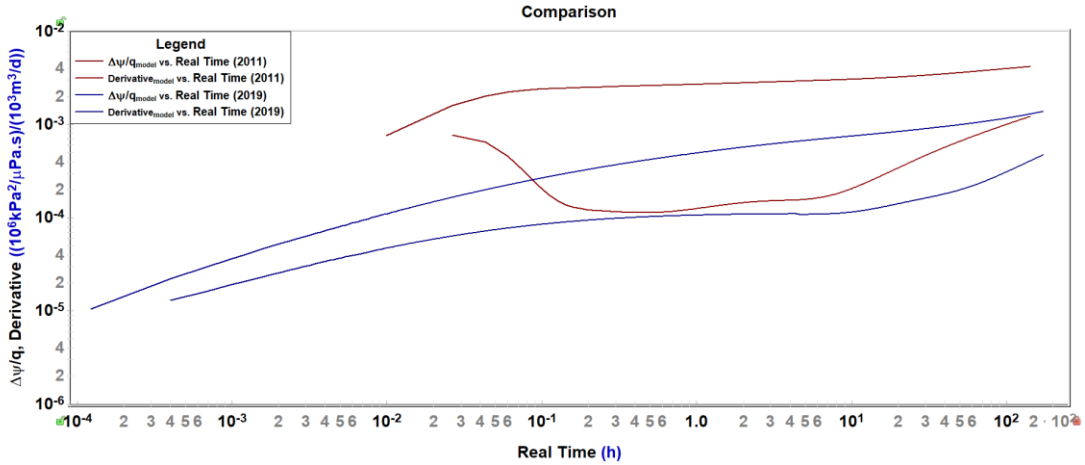

Figure 7: Pressure Build-Up (PBU) Comparison Plot in KMJ-D.

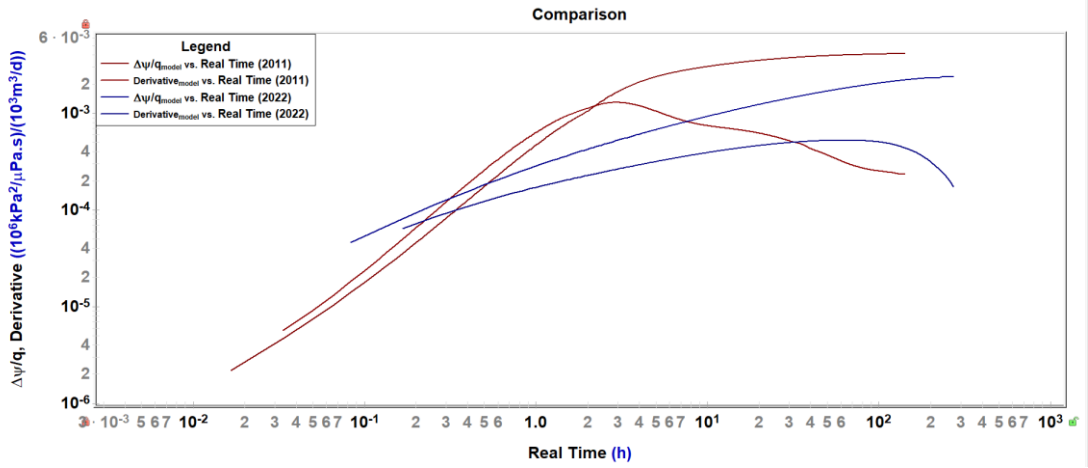

Figure 8: Pressure Build-Up (PBU) Comparison Plot in KMJ-F.

The log-log plot profile for well KMJ-A (Figure 9) shows a constant pressure boundary, which is a reservoir state in which the reservoir pressure remains constant at a set distance from the well (unaffected by production or injection). This boundary can be circular or linear with a constant pressure profile and a decreasing derivative profile. The pressure transient profile for well KMJ-B shows that pressure transients are controlled by flow within narrow and wide fractures (Figure 10). This signifies that the flow is linear, rather than radial. The width of the fracture will cause differences in the pressure and pressure derivative profiles. However, in order to further understand these features, additional pressure transient test are required (drawdown tests), which are typically difficult to implement in geothermal wells.

The results of the seven PTA for the seven wells are summarized in Table 1. From these results, it is observed that in the absence of significant changes in transmissibility during the production period, there is a numerical decrease in the skin value over approximately 10 years of production in these wells. This suggests that numerically, there appears to be an "improvement" in the near-wellbore condition. However, it cannot be conclusively stated that the decrease in skin value represents an actual "improvement" in near-wellbore conditions, as no well stimulation treatments were performed during this period. Instead, this could indicate that the decline in reservoir pressure is the main factor affecting the reservoir characteristics in the Kamojang field.

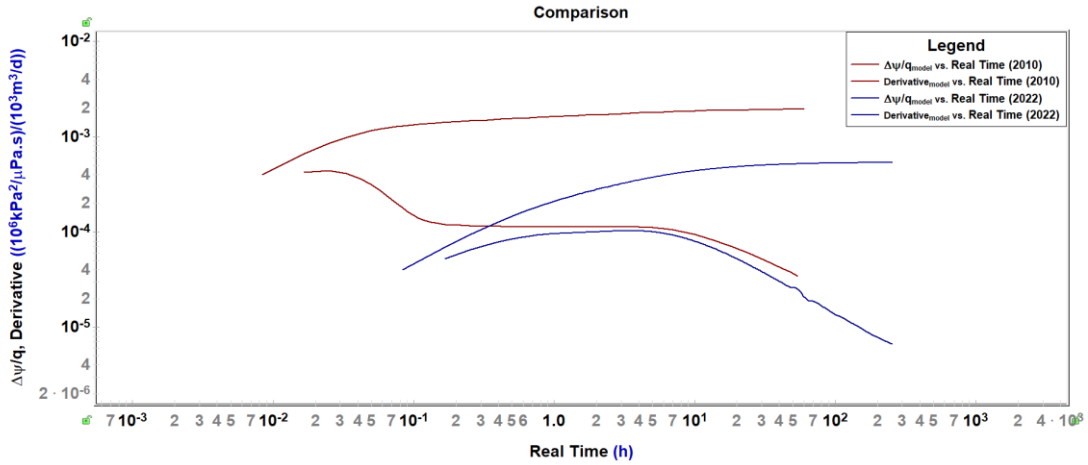

Figure 9: Pressure Build-Up (PBU) Comparison Plot in KMJ-A.

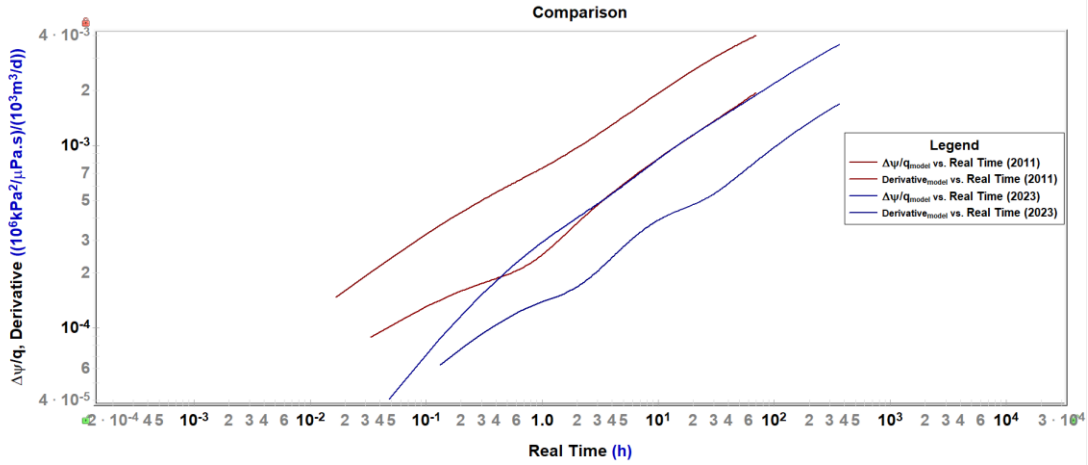

Figure 10: Pressure Build-Up (PBU) Comparison Plot in KMJ-B.

Table 1: Reservoir Characteristics Summary in Kamojang.

Well	First Period		Second Period	
	kh (D.m)	S	kh (D.m)	S
KMJ-A	2.7	2.5	2.7	-3.8
KMJ-B	1.03	-3	1.03	-3.93
KMJ-C	6	8	0.85	74
KMJ-D	2.8	7	2.8	-2.6
KMJ-E	6	30	6	12
KMJ-F	0.4	-3	0.35	-4.86
KMJ-G	6.3	9.8	6.3	8.75

4. CONCLUSION

Through pressure transient analysis (PTA), changes in reservoir characteristics at the Kamojang field have been observed over several years, specifically between the periods 2009-2012 and 2019-2023. PTA plays a crucial role in reservoir management by helping identify changes in factors such as transmissivity and skin factors.

The results of PTA on several wells showed a numerical decrease in skin value, which might indicate an "improvement" in near-wellbore conditions, even though no well stimulation treatments were performed. However, this decrease is more likely due to the natural decline in reservoir pressure over time.

The analysis also identified that certain wells are directed toward structural geological boundaries, such as the Kendang and Laksana Faults. Wells directed toward the Kendang Fault exhibit reservoir characteristics that still

act as an Infinite Reservoir, while wells directed toward the Laksana Fault suggest the presence of a possible no-flow boundary.

In summary, this study provides valuable insights into reservoir characteristics in the Kamojang field and highlights the importance of continuous monitoring and thorough analysis for effective reservoir management.

5. RECOMMENDATION

In the Kamojang region, it is essential to conduct tests on these wells to obtain comprehensive reservoir characterizations across the entire area. These tests should not only be performed but also be carried out correctly and with adequate time to ensure the accuracy and reliability of the data. This will enable a more accurate assessment of the geothermal potential and support informed decision-making for future development and management strategies.

Keywords: Gazsol, geothermal, production test, H_2S, zeolite

ABSTRACT

This initiative by PT Pertamina Geothermal Energy (PGE) addresses a critical issue in geothermal well testing within national geothermal industry, specifically in 2022. During this period, high-risk incidents in some companies (other than PGE) led to several fatalities and numerous medical treatment cases linked to hydrogen sulfide (H_2S) gas exposure. The project aimed to prevent such hazardous exposures by developing an effective, efficient, and standardized gas abatement system. The solution, termed Gazsol (Gas Abatement System using Zeolite and Sodium Hydroxide Liquid), is designed to neutralize the accumulation of toxic gases during geothermal well production test. The necessity for this system arises from regulatory directives by the Directorate General of New Renewable Energy and Energy Conservation (EBTKE), which mandates gas abatement systems in all geothermal well testing activities to prevent fatalities and serious incidents similar to past occurrences in Indonesia. Gazsol represents a modification and development of existing technology, utilizing specific materials to effectively neutralize toxic gases. The implementation of this system has demonstrated significant improvements. The complete elimination of H_2S exposure during gas release has been achieved, along with the reduction in operational cost, the punctuality of well testing schedule, the absence of TRIR–NoA incident, and the adherence of positive moral perception from the community and well testing operator. Gazsol has been standardized and recognized for its replicability, setting a new benchmark for safety and efficiency in geothermal energy production.

1. INTRODUCTION

Geothermal energy, a sustainable and renewable resource, has been gaining increased attention as a viable alternative to conventional fossil fuels. It offers a clean, low-emission source of energy that can significantly reduce our carbon footprint and combat climate change. However, the development and utilization of geothermal resources are not without challenges, particularly concerning the safety and environmental impact of production processes (Bertani, 2016). The recent events in Indonesia's geothermal sector underscore the need for rigorous safety protocols and advanced technological solutions to mitigate potential hazards.

In March 2022, PT. Pertamina Geothermal Energy (PGE) Kamojang's proposal for production testing was put on hold for several days by the Directorate General of New Renewable Energy and Energy Conservation (Ditjen EBTKE). This suspension was primarily due to the alarming number of Notices of Accident (NoA) and Total Recordable Incident Rate (TRIR), which included six fatalities and 89 medical treatment cases within the first three months of 2022. These incidents were attributed to toxic gas exposure during the activation of wells for production testing at PT. Sorik Marapi and PT. Geo Dipa Energi. The victims included both workers and local community members, highlighting the risks associated with geothermal operations (Upstream Online, 2022).

Non-condensable gases (NCGs) like hydrogen sulfide (H_2S) and carbon dioxide (CO_2) can accumulate in geothermal wells during a shut-in position due to natural geothermal reservoir dynamics. When the well is shut in, the flow of geothermal fluids stops, causing pressure to build up within the well. This pressure increase causes NCGs to migrate from deeper high-pressure zones towards the wellbore. Without fluid movement, these gases exsolve from the geothermal fluids and concentrate in the wellbore, reaching hazardous levels (Rodriguez et al., 2014). Figure 1 illustrates NCG accumulation scheme within a geothermal well compared with the Pressure-Temperature logging profile after a distinctive shut-in period in a vapor-dominated reservoir in Kamojang field.

In response to these incidents, in 2022 the Director General of EBTKE issued a circular mandating the use of gas abatement systems in all production testing activities. However, there is currently no standard, optimal, and measurable gas abatement system for geothermal wells in PGE or even in Indonesia. The dominant reasons for

this gap include the reliance on estimates for materials used, lack of accommodation for varying concentrations of toxic gases, and the design of gas abatement equipment based on individual user assumptions without considering specific formulations. Furthermore, there is an absence of specialized formulations or calculations that can effectively address the varying concentrations of toxic gases. Regarding to Rodriguez et al. (2014), effective gas abatement systems should incorporate precise formulations and calculations to handle the specific gas concentrations encountered in geothermal operations.

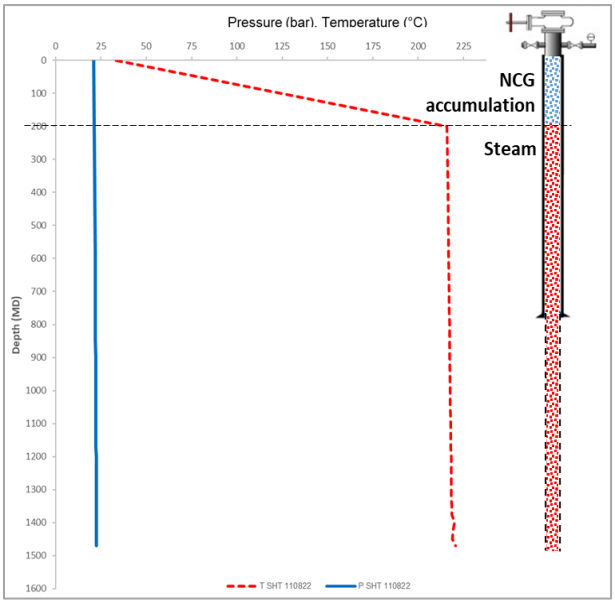

Figure 1: The illustration of the NCG accumulation scheme within a geothermal well compared with the Pressure-Temperature logging profile after a distinctive shut-in period in a vapor-dominated reservoir in Kamojang field.

The highlight of issues faced by PGE Kamojang prior to implementing innovations during gas abatement process was the unspecified quantity of NaOH used during the gas abatement, leading to ultra-excessive usage of NaOH. This excessive use not only resulted in the production of a substantial amount of liquid waste but also significantly increased the expenses due to the high cost of NaOH for geothermal industry purposes. Before the innovation, gas abatement process could add up the liquid waste as many as 2200 liters from post-NaOH usage. On other hand, the high amount of NaOH use could give the adverse effects of NaOH dispersion to the air, including black spots, itchy skin, and stinging eyes within a radius of up to 200 meters. This phenomenon could happen due to the absence of a standard gas abatement system, resulting in redundancy and ambiguity during the formulation of materials. Furthermore, the lack of a properly dimensioned gas abatement system led to the use of excessive amounts of NaOH, or in other circumstances (other than PGE), resulted in an inadequate amount of materials to absorb toxic substances from being released into environment.

The demanding need for a standardized gas abatement system in geothermal operations is definite. Such a system should be capable of handling different concentrations of toxic gases, ensuring the safety of both well testing operators and the surrounding communities. This paper aims to explore the current challenges in developing an effective gas abatement system for geothermal wells and propose potential solutions based on best practices from other industries. By addressing these issues, PGE Kamojang proposed Gazsol, a new system that combines natural zeolite and sodium hydroxide liquid with a specific abatement atmospheric flash tank. This formulation approach ensures the necessary amount of used material to respond to the different characteristics of geothermal wells effectively.

2. METHODS

2.1 Zeolite for H_2S Adsorption

Zeolites, due to their unique structural and chemical properties, have proven to be highly effective for the adsorption of hydrogen sulfide (H_2S), a toxic and corrosive gas. Structurally, zeolites are characterized by their three-dimensional microporous framework composed of silica (SiO_2) and alumina (Al_2O_3) tetrahedra, linked by oxygen atoms. This framework forms a crystalline lattice with a vast network of uniformly sized pores and cavities, providing an extensive surface area conducive to adsorption. The large surface area and high pore volume allow zeolites to trap and hold a significant amount of gas molecules, making them highly efficient at adsorbing H_2S (Georgiadis et al., 2021).

Natural zeolites are described with the following chemical formula (Coombs et al., 1998).

$$\left(M_x^+, M_y^{2+}\right)\left[Al_{(x+2y)}\ Si_{n-(x+2y)}O_{2n}\right] \times mH_2O \quad (1)$$

Where M_x^+ are monovalent values with stoichiometry x, M_y^{2+} are divalent values with stoichiometry y, [$Al_{(x+2y)}$ $Si_{n-(x+2y)}O_{2n}$] is structural cations, and *m* is the number of water molecules in the structure (Čejka and van Bekkum, 2005).

The mechanism of H_2S adsorption by zeolites involves both physical and chemical adsorption processes. In physical adsorption, H_2S molecules are attracted to the internal surfaces of the pores through weak van der Waals forces. When a gas stream containing H_2S passes through the zeolite, the H_2S molecules are drawn to the internal pore surfaces and become adsorbed. This process is facilitated by the uniformity of the pore sizes, which ensures selective adsorption of H_2S molecules while excluding larger molecules that may be present in the gas stream (Breck, 1974).

When impurities come into contact with a zeolite, the hydrogen sulfide molecules can react with these cations to form metal sulfides, effectively removing compound such as H_2S from the gas phase. The mechanism can be represented as follows:

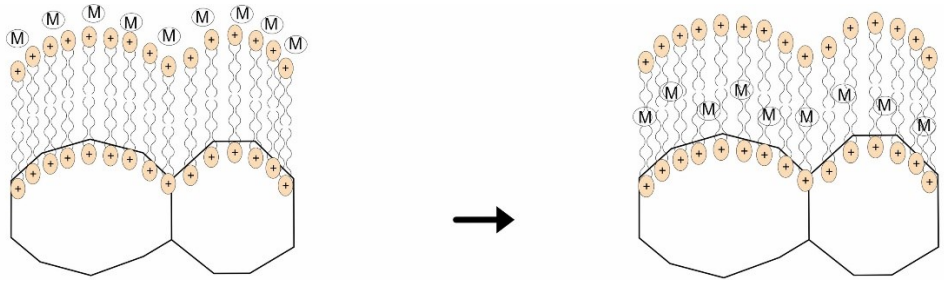

Figure 2: A scheme for principal mechanisms of adsorption of heavy metals with natural zeolites under electrostatic interaction (Velarde, L., et al., 2023).

One of the significant advantages of using zeolites for H_2S adsorption is their regenerability. After a zeolite becomes saturated with H_2S, it can be regenerated through various methods, such as heating or exposure to a vacuum. This regeneration process desorbs the adsorbed H_2S molecules, restoring the zeolite's adsorption capacity and allowing it to be reused multiple times. This regenerability not only extends the lifespan of the zeolite but also reduces operational costs and waste generation, making zeolites a sustainable choice for long-term use.

2.2 NaOH for H_2S Adsorption

The adsorption of hydrogen sulfide using sodium hydroxide (NaOH) is an efficient method for removing this toxic and corrosive gas from various industrial and environmental contexts. The mechanism involves a series of chemical reactions that result in the conversion of H_2S into harmless compounds. This process is primarily driven by the strong basic nature of NaOH, which facilitates the absorption and neutralization of H_2S (Rodriguez et al., 2014).

When H_2S gas comes into contact with an aqueous solution of NaOH, a neutralization reaction occurs. The hydroxide ions (OH^-) from NaOH react with the hydrogen sulfide gas (H_2S) in a two-step process. In the first step, H_2S dissolves in water to form hydrogen ions (H^+) and bisulfide ions (HS^-):

$$H_2S \leftrightarrow H^+ + HS^- \quad (2)$$

This reaction is an equilibrium process, meaning that it can proceed in both directions. The second step involves the reaction of bisulfide ions with hydroxide ions to form sulfide ions (S^{2-}):

$$HS^- + OH^- \rightarrow S_2^- + H_2O \quad (3)$$

The overall reaction can be represented as:

$$H_2S + 2NaOH \rightarrow Na_2S + 2H_2O \quad (4)$$

In this process, H_2S is effectively removed from the gas phase and converted into sodium sulfide (Na_2S) in the aqueous phase. The formation of water (H_2O) as a byproduct further contributes to the neutralization process.

The efficiency of H_2S adsorption using NaOH depends on several factors, including the concentration of NaOH, the temperature, the contact time between the gas and the liquid, and the pH of the solution. A higher concentration of NaOH increases the availability of hydroxide ions, thereby enhancing the reaction rate and the overall

adsorption capacity. The optimal pH for this reaction is typically above 10, where NaOH is fully dissociated, providing a high concentration of OH^- ions.

Temperature also plays a crucial role in the adsorption process. Higher temperatures generally increase the reaction rate, but extremely high temperatures can lead to the decomposition of Na_2S, thereby reducing the efficiency of H_2S removal. Additionally, sufficient contact time between H_2S and NaOH ensures that the gas has ample opportunity to dissolve in the aqueous phase and react with the hydroxide ions (Rodriguez et al., 2014).

The application of sodium hydroxide (NaOH) for hydrogen sulfide (H_2S) adsorption is widely utilized across various industries, including natural gas processing, wastewater treatment, and biogas purification. For instance, in natural gas processing, the removal of H_2S is crucial to prevent corrosion in pipelines and equipment, ensuring compliance with safety and environmental regulations. Similarly, in wastewater treatment, NaOH is used to eliminate H_2S odors and prevent the formation of sulfuric acid, which can damage infrastructure (Awe et al., 2017).

2.3 Considered Variables for Gas Abatement Formula Approach

To approach the required amount of material for H_2S abatement in a geothermal well, several key variables must be considered. Here's a detailed explanation of each variable:

2.3.1 Geothermal Well Casing Dimension

The dimensions of the geothermal well casing play a crucial role in determining the volume and pressure of the geothermal fluids being extracted. These dimensions include the diameter and depth of the casing:

- The diameter of the well casing affects the flow rate of geothermal fluids. A larger diameter allows for a higher flow rate, which can result in a greater volume of H_2S and other gases being extracted.
- The depth of the well influences the temperature and pressure of the geothermal fluids. Higher temperatures can increase the solubility and concentration of gases like H_2S in the fluid.

By understanding these dimensions, we can estimate the volume of geothermal fluid and the associated gas emissions, which is essential for calculating the amount of material required for H_2S abatement.

2.3.2 Gas Chemistry Ratio and Composition

The gas chemistry ratio and composition, particularly the ratio of H_2S to other gases, are critical in determining the abatement strategy. Common gases in geothermal wells include H_2S, CO_2, CH_4, and N_2. The ratio and composition can vary significantly between wells.

- H_2S Ratio: The proportion of H2S relative to other gases such as CO_2 and CH_4 must be determined. For instance, if the gas composition is 70% CO_2, 20% H_2S, and 10% CH_4, the abatement system must primarily target H_2S.
- Total Gas Composition: Understanding the total gas composition helps in designing the abatement system to handle not only H_2S but also other gases that may impact the efficiency of the abatement materials (e.g., NaOH and zeolite).

2.3.3 Concentration of NaOH and Zeolite

The concentration of NaOH (sodium hydroxide) and zeolite used in the abatement process is pivotal in ensuring the effective removal of H_2S from geothermal fluids. NaOH neutralizes H_2S through a chemical reaction that forms sodium sulfide (Na_2S) and water. The concentration of the NaOH solution must be sufficiently high to react with all the H_2S present. Typically, this concentration is determined based on stoichiometric calculations considering the amount of H_2S, with the required concentration calculated from the molar ratio of NaOH to H_2S.

Zeolite serves as an adsorbent material capable of capturing H_2S molecules. The concentration and quantity of zeolite required depend on its adsorption capacity and the volume of gas passing through it. Zeolite effectively traps H_2S molecules within its porous structure, making it an essential component in the abatement process. To ensure the effectiveness of zeolite in H_2S abatement, it is essential to conduct thorough material characterization to determine its concentration and actual presence within natural rock formations. Microscopic analysis and X-ray diffraction (XRD) are critical techniques used to obtain these data. The observation under microscope allows qualitative examination of rock samples to identify mineral composition and texture, while XRD provides precise information on the crystalline structure and quantitative mineralogical composition. Together, these analyses offer a comprehensive understanding of the zeolite content, ensuring its efficacy in the H_2S abatement process.

2.3.4 Design of Flash Tank

The design of the flash tank is integral to the effectiveness of the H_2S abatement process. The flash tank allows the geothermal fluid to depressurize, separating steam from liquid. Proper design ensures efficient contact between H_2S and NaOH.

- *Dimensions of flash tank*: the size and volume of the flash tank are crucial as they determine the residence time of the geothermal fluids and gases within the tank. Sufficient residence time is essential to ensure that NaOH has adequate opportunity to effectively neutralize H_2S. A properly sized flash tank allows for the optimal interaction between the NaOH solution and the H_2S gas, enhancing the efficiency of the abatement process.
- *Dispersion Pipe*: this part within the flash tank plays a vital role in uniformly distributing the NaOH solution throughout the tank. This uniform distribution ensures maximum contact between the NaOH solution and the H_2S gas. The design, placement, and configuration of the dispersion pipe directly affect the interaction efficiency, enabling thorough mixing and effective neutralization of H_2S.
- *Minimum amount of NaOH*: the dimensions of the flash tank and the flow rate of geothermal fluids are key factors in determining the minimum amount of NaOH required for complete neutralization of H_2S. The tank must be large enough to provide sufficient mixing and reaction time between the NaOH solution and the H_2S gas. Proper tank design ensures that the NaOH solution can interact effectively with the H_2S, ensuring complete abatement and preventing any untreated gas from escaping.

3. RESULTS

3.1 Zeolite Characterization

This section will discuss the results of characterizing natural zeolite rock using X-Ray Diffraction (XRD) and microscopic analysis. The graph in Figure 3 is a crucial component of the analysis, displaying the XRD pattern of the zeolite rock. The x-axis represents the 2-theta (deg) values, while the y-axis shows the intensity (cps) of the diffraction peaks. These peaks are indicative of the crystalline phases present in the sample. The superimposed red and blue lines highlight the peaks corresponding to specific minerals, with annotations for heulandite and mordenite clearly marked. The analysis results are summarized, confirming the identification of heulandite and mordenite as the primary zeolite minerals within the natural rock sample. This confirmation is crucial as it validates the presence of these minerals, which are known for their significant industrial and environmental applications due to their adsorptive properties.

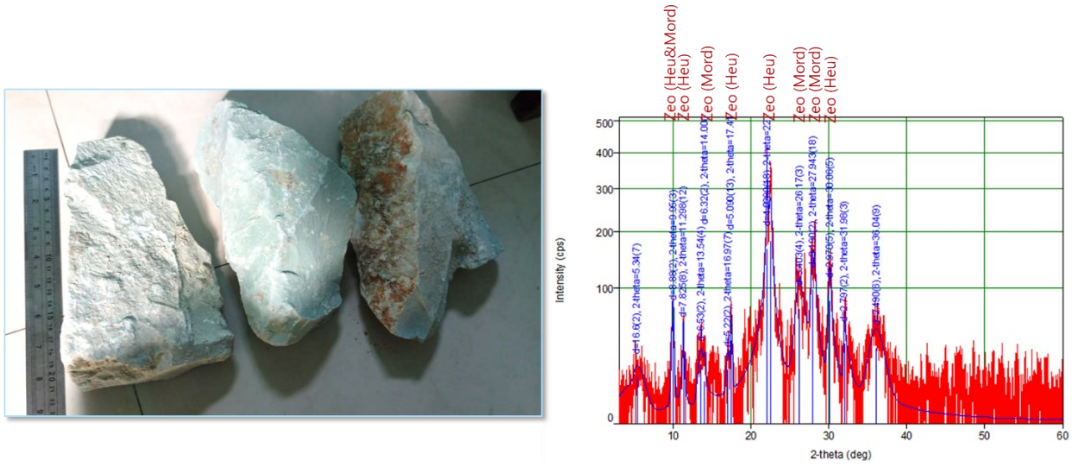

Figure 3: (left) photograph on the left side showcases the natural zeolite rocks that were selected for the study, providing a visual context for the material being analyzed; (right) the graph of XRD analysis result using graph method.

Figure 4 provides an in-depth analysis of the zeolitic rock under thin section observation using reflecting microscope. The primary focus is on determining the abundance and distribution of zeolite minerals within the rock sample. The microscopic analysis reveals that the base rock is identified as lithic tuff, a type of volcanic rock composed of consolidated volcanic ash and fragments. The findings indicate a significant alteration of the lithic tuff by zeolite minerals, transforming its original composition. The analysis confirms that zeolite minerals are prevalent in the rock.

Additionally, a comparator chart from the BC Ministry of Forestry (1997) is included, which serves as a reference for estimating the abundance of zeolite minerals within the thin sections. This chart provides visual aids for comparing different percentages of mineral abundance, assisting in the qualitative quantification of zeolite content, with an abundance ranging between 30-40%.

Overall, the microscopic analysis complements the previous XRD characterization by providing a visual confirmation of the zeolite minerals within the natural rock. The combined use of XRD and thin section offers a comprehensive understanding of the zeolitic rock's mineralogical composition, confirming the presence and

significant abundance of heulandite and mordenite. For further data processing, this data would contribute significantly in providing zeolite abundance data during formulation stage and calculation of required abatement materials.

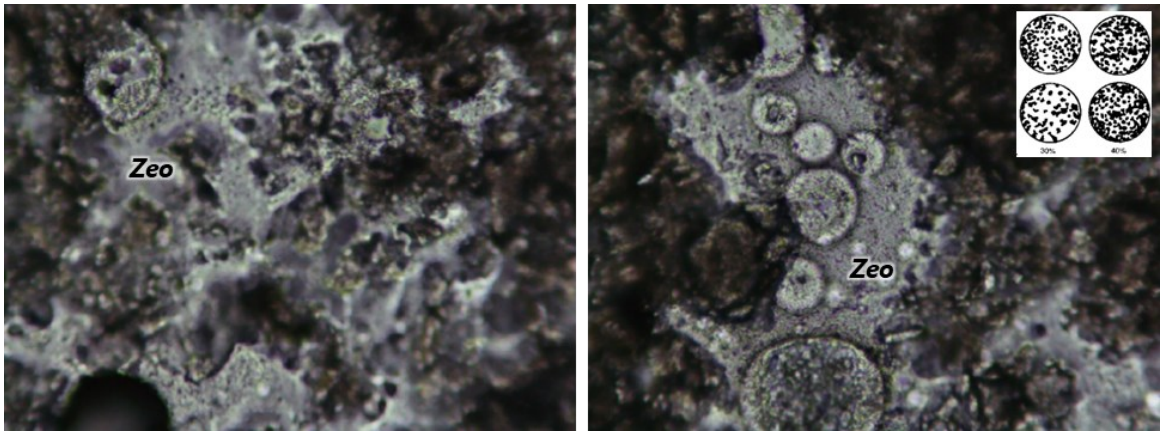

Figure 4: Photographs of zeolite rock under 100x magnification using reflecting microscope, zeolite mineral within the rock section provided by white greenish object with granulose texture.

3.2 Natural Zeolite Adsorption to H_2S: Experiment Result

The provided graph illustrates the relationship between the concentration of hydrogen sulfide (H_2S) over time in comparison to the background concentration of H_2S. Notably, the ratio between these concentrations begins to stabilize at around the 1300-second mark, indicating that the adsorption process reaches a point of equilibrium.

Based on the experiment, the ability of the zeolite to adsorb H_2S is quantified as 1667 ppm H_2S per square meter of zeolite area or equivalent with 2532.5 mg/Nm^3 per meter square of zeolite surface area. This high adsorbance capacity demonstrates the effectiveness of zeolite in capturing and retaining H_2S molecules, which is essential for applications in environments where H_2S buildup poses a risk. This high adsorption capacity underscores the remarkable effectiveness of zeolite in capturing and retaining H_2S molecules. Such a significant adsorbance capacity is particularly essential for applications in geothermal well testing activity.

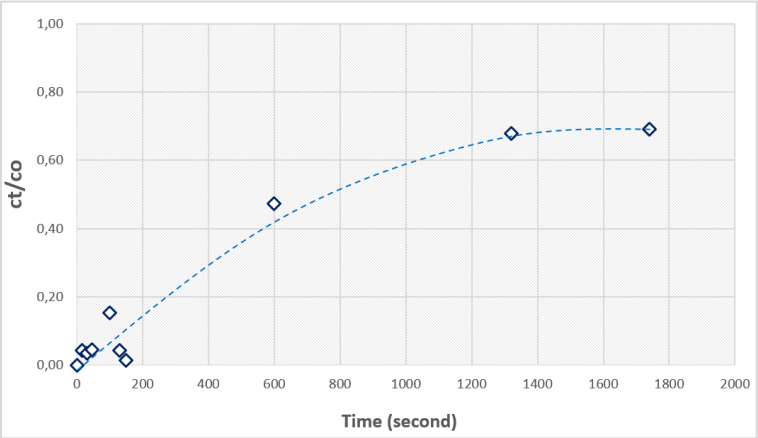

Figure 5: The image appears the graph related to the ratio between the concentration of H_2S over time compared to the background concentration of H_2S. Begins at 1300-second point, the trend of the ratio turned to stationary.

The stationary trend observed in the graph after 1300 seconds suggests that the zeolite has reached its maximum adsorption capacity under the given conditions. This information is vital for optimizing the use of zeolite in practical applications, as it helps to determine the appropriate amount and surface area of zeolite required to achieve desired levels of H_2S removal. Consequently, this contributes to more efficient and cost-effective gas abatement process.

3.3 Gazsol Technical Design

3.3.1 Configuration

The below image depicts the technical configuration of Gazsol application designed for gas abatement in Kamojang field, preceding geothermal well production test. The illustration highlights main setup that includes several crucial components starting from the wellhead and extending to Gazsol flash tank.

Figure 6: Technical configuration of Gazsol application for gas abatement process preceding geothermal well production test: (A) master valve, (B) top valve, (C) side valve, (D) tandem side valve, (E) casing head, (F) gas abatement pipe, (G) gas dispersion pipe, (H) main body flash tank, (J) steel wire rope, (K) hefty concrete cube.

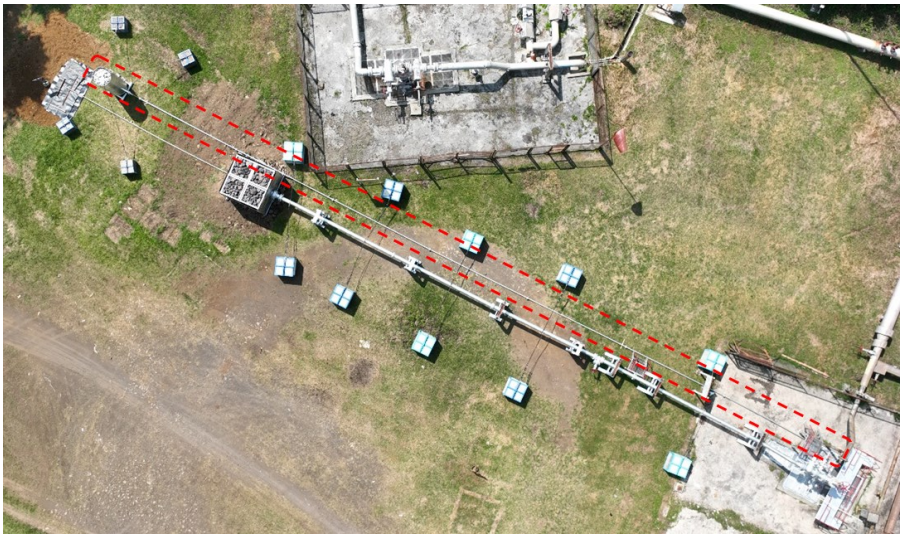

Figure 7: Bird's-eye view of Gazsol implementation in the Kamojang geothermal field for the purpose of geothermal well testing. The dotted red line outlines the real configuration of Gazsol, spanning from the wellhead assembly through the side valve, then being connected by gas abatement pipe into the Gazsol main body flash tank.

At the wellhead, the master valve (labeled A) is prominently featured. This valve plays a critical role in controlling the flow of geothermal steam and gas from the well. Above the master valve is the top valve (B), which provides an additional access into the well from the top side. The side valve (C) and tandem side valve (D) facilitate the diversion of gas from the main flow path. The casing head (E) serves as a transition point between the wellhead and the surface piping, ensuring a secure and stable connection. From the casing head, the gas abatement pipe (F) extends horizontally, acting as a conduit for the gas to be transported away from the wellhead.

The gas accumulation from the subsurface enters the gas dispersion pipe (G), which is connected to the main body flash tank (H). This tank is a critical component of the Gazsol system, designed to handle and neutralize the gas by allowing it to dissipate safely. The flash tank's robust structure ensures that the gas is contained and treated effectively. Supporting the system, a steel wire rope (J) is used to stabilize and secure the components, ensuring they remain in place during operation. Additionally, a hefty concrete cube (K) provides a solid foundation, preventing any movement or displacement of the equipment.

This configuration allows for the efficient accumulation and redirection of gas from the top part of the geothermal casing. The gas flows from the side valve into the gas abatement system, where it is safely managed and neutralized. This setup is essential for maintaining safety and efficiency during geothermal well testing, ensuring that any gas emissions are properly handled before production test begins.

3.3.2 Flash Tank

Figure 8 provides a detailed technical design for a Gazsol atmospheric flash tank, illustrating its main components and operational flow. The primary structure of the flash tank includes a main body, inspection ladder, inlet pipe, perforated dispersion pipe, NaOH drainage pipe, and the zeolite bucket.

The gas accumulation process begins at the inlet pipe, where the gas enters the flash tank. From there, the gas moves into the slotted dispersion pipe, which evenly distributes the gas within the tank. This dispersion ensures that the gas floats upward efficiently, passing through the slotted bucket base. As the gas ascends, it interacts with the zeolite rocks inside the bucket, initiating the adsorption reaction. The zeolite effectively captures and retains the H_2S molecules, demonstrating its high adsorption capacity. This process is crucial for environments where H_2S buildup poses a risk, as it ensures that harmful gases are adequately treated and removed. Besides that, zeolit stacks in the upper part of the tank also helps in retaining the NaOH dispersion effect to the air.

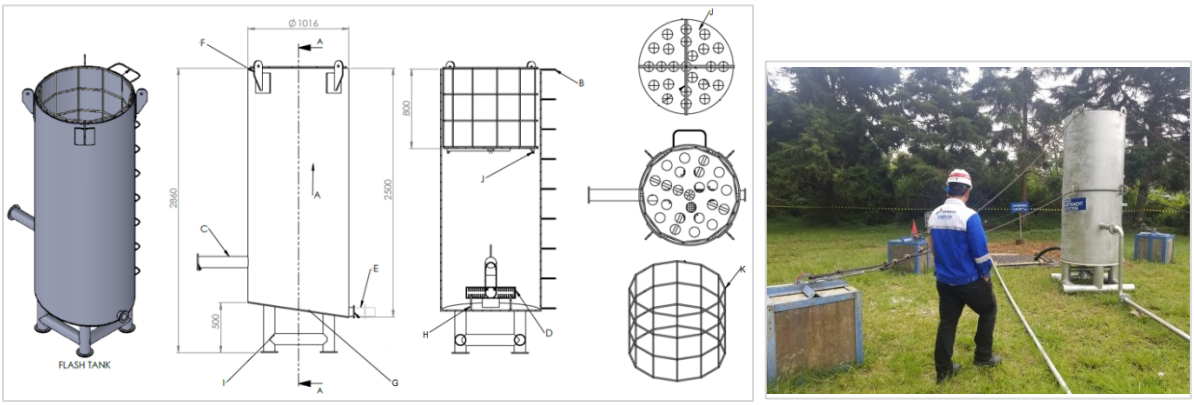

Figure 8: (left side picture) technical design for a Gazsol atmospheric flash tank: (A) main body, (B) inspection ladder, (C) inlet pipe, (D) perforated dispersion pipe, (E) NaOH drainage pipe, (F) zeolite bucket holder, (G) inclined-base, (H) support for dispersion pipe, (I) main body support, (J) enforced slotted metal for bucket base, (L) zeolite bucket; (right side picture) Gazsol has been applied for geothermal well production, anchored by hefty concrete cube, as it was being inspected by the EBTKE inspector (the man in the picture).

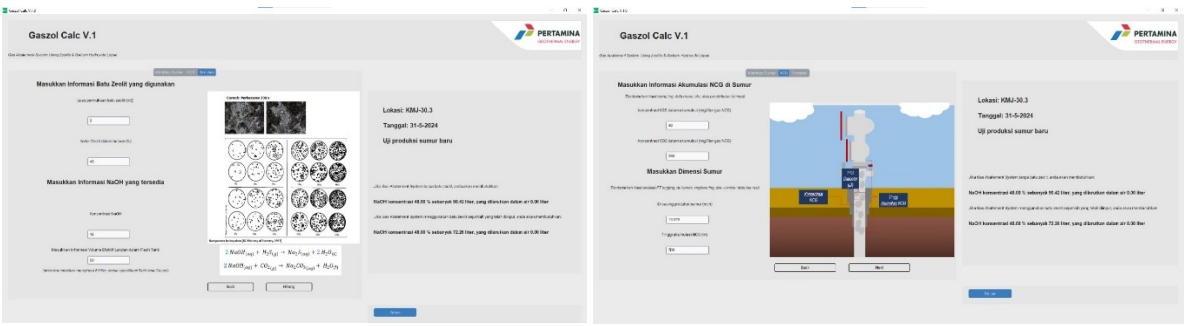

Figure 9: Gazsol Calc interface, a simple application to formulate the quantity of sodium hydroxide and zeolitic rock for gas abatement system.

The design also highlights key structural elements like the inclined base, which allows for the efficient drainage of NaOH after the abatement system has processed the gas. Additionally, the support systems for the dispersion pipe and the main body ensure the stability and proper functioning of the flash tank.

Overall, the design showcases the ample approach to gas treatment within the Gazsol flash tank, emphasizing the efficiency and effectiveness of its components in handling H_2S adsorption.

The flash tank was outlined by several assumptions and calculations for determining the flash tank's appropriate dimensions and operational parameters. Key parameters in the table include line pressure, enthalpy of steam, AFT pressure, steam velocity, steam dynamic viscosity, and water density, among other relevant physical properties and calculations essential for the apparatus's functionality. The flash tank detailed pressure design wall thickness according to ASME B31.1 Power Piping standards, regarding to weld joint quality factor, design temperature, weld joint strength reduction factor, material allowable stress, and manufacturing tolerances.

3.4 "Gazsol Calc": A Formulation to Quantify Abatement Materials

Figure 9 showcases the Gazsol Calc application, a simple tool meticulously developed through a series of sequential experiments by PGE using Python. This tool is designed to determine the precise quantities of materials required for an effective gas abatement system, focusing specifically on zeolitic rock and sodium hydroxide (NaOH). Both of these components are essential in the gas abatement process, which is critical for maintaining safety and efficiency during geothermal production test. The application integrates complex calculations and scientific principles to ensure accurate and reliable data, providing a significant advantage for professionals in the geothermal industry.

The Gazsol Calc interface is presented in a user-friendly manner, beginning with a introductory that outlines the purpose and capabilities of the application. Users are prompted to enter detailed well data, including the well name, date, relevant notes, and any specific conditions at the well site. This initial input form is crucial as it ensures that the subsequent calculations are tailored to the unique parameters of each geothermal well, allowing for highly customized and precise estimations. The interface also includes visual aids and detailed instructions to guide users through the data entry process, making it accessible even to those who may not be experts in the field.

One of the key capabilities of the Gazsol Calc is its ability to calculate the required amount of zeolitic rock based on its abundance at the site. This feature ensures that the use of natural resources is optimized, reducing waste and improving the overall efficiency of the gas abatement process. Additionally, the application can determine the necessary quantity of sodium hydroxide (NaOH) needed, if required, for the process. This is particularly important as NaOH is a critical chemical in neutralizing and managing gas emissions, and its precise measurement is essential for safety and effectiveness. Furthermore, the application computes the effective concentration of NaOH to be used, ensuring that the chemical is used in the most efficient manner possible, thereby minimizing costs and environmental impact.

3.5 Environment Monitoring During Gas Abatement Process Using Gazsol

Figure 10: Environment monitoring during gas abatement system in geothermal well X, the red dotted circle indicates the radii of observation during gas abatement process.

Observation point	Noise	H2S (ppm)	CO (ppm)	Dispersion effect of NaOH	Complaint	Observation point	Noise	H2S (ppm)	CO (ppm)	Dispersion effect of NaOH	Complaint
TP 1	70 dB	2	0	None	None	TP 4	65 dB	5	0	None	None
TP 2	8.7 dB	7	0	None	None	TP 5	45 dB	0	0	None	None
TP 3	63.6 dB	0	0	None	None	TP 6	45 dB	0	0	None	None

Figure 11: The recap of environment monitoring during well production test of geothermal well X, Kamojang Field.

The tabular data in Figure 11 provides a comprehensive recap of the environmental monitoring results. It details the observations recorded at each monitoring point, including noise levels, concentrations of hydrogen sulfide and carbon monoxide, the dispersion effect of NaOH, and any community assessment. For instance, at TP-1, noise

levels were recorded at 70 dB, with H2S concentration at 2 ppm and CO at 0 ppm. There were no noted effects of NaOH dispersion or community complaints at this point.

Similarly, at TP-2, noise levels were significantly lower at 8.7 dB, but CO levels were higher at 7 ppm, while H_2S remained at 0 ppm. Like TP-1, no dispersion effect of NaOH or community complaints were reported. At TP-3, noise levels were measured at 63.6 dB, with both H2S and CO concentrations at 0 ppm, and again, no issues with NaOH dispersion or community concerns. Further observation points, TP-4, TP-5, and TP-6, show varied noise levels, with TP-4 recording 65 dB and TP-5 and TP-6 both at 45 dB. At TP-4, H2S levels were 5 ppm, while CO remained at 0 ppm. Neither TP-5 nor TP-6 showed any significant levels of H_2S or CO, nor any impact from NaOH dispersion or community complaints.

Overall, this detailed monitoring effort provides crucial data that helps in evaluating the environmental impact of the gas abatement system using Gazsol in place at geothermal well. The consistent documentation of noise levels, gas concentrations, and community feedback plays an essential role in ensuring the environmental safety and operational integrity of the geothermal field activities, especially during gas abatement process using Gazsol.

4. CONCLUSION

The formulation and technical engineering design for gas abatement system in Kamojang field that further being implemented and termed as “Gazsol” has led to significant benefits within the geothermal operation. The combination of zeolitic rock and sodium hydroxide, packed in distinctive design and dimension of flash tank, then being formulated under quantitative approach derived from some steps of experiments, can result in notable five points of view:

- Quality: the use of the Gazsol system led to the reduction of hydrogen sulfide (H_2S) emissions from >500 ppm to 0 ppm (under STP), significantly enhancing air quality in the geothermal field and eliminating serious health and environmental risks.
- Cost: operational costs associated with the gas abatement process were drastically reduced from approximately Rp61.25 million per year to Rp3.2 million per year, reflecting a 95% savings. This reduction was achieved by optimizing the amount of NaOH used, avoiding unnecessary expenditure, and making the process much more cost-effective.
- Delivery: project deliveries improved as the new gas abatement system eliminated delays caused by the lack of preparedness in managing gas emissions. The implementation of a standard system with clear material formulations led to projects being completed on time and on schedule, demonstrating enhanced efficiency and reliability.
- Safety: the gas abatement process safety has been improved vastly with Gazsol. The amount of NaOH waste was reduced from 2200 liters to 75 liters, a 96.7% reduction. The system also eliminated adverse effects of NaOH dispersion, within a 200-meter radius, significantly enhancing the work environment's convenience.
- Moral: 100% of personnel now feeling safe and comfortable while performing their duties, compared to 71% feeling unsafe previously. This increase in morale is a direct result of the improved safety and working conditions brought about by the new gas abatement system.

For further development, it is recommended to conduct comprehensive observations of the zeolitic rock under various physical conditions such as temperature and pressure to understand their impact on various geothermal environment. Additionally, further studies should focus on optimizing the flash tank design to enhance its efficiency and effectiveness. The development of the Gazsol Calc application should also be advanced, taking into consideration the need for an improved user interface, better replicability, and wider accessibility, ensuring that the application is user-friendly and can be easily adopted across different geothermal sites.

Keywords: geochemistry, geoindicator, kamojang, vapour dominated, superheat

ABSTRACT

The Kamojang Geothermal Field, located in West Java Province, Indonesia, is the oldest and one of the most significant steam-dominated geothermal fields in the country, managed by PT. Pertamina Geothermal Energy (PGE). Since the first exploration in 1918 by the Dutch East Indies government, the field has undergone extensive development, culminating in a current installed capacity of 235 MW. This paper evaluates the efficiency of reinjection processes in the Kamojang field, employing gas and isotope chemistry data collected since 2017. Reinjection is critical for maintaining reservoir pressure and ensuring sustainable production. Since 2019, reinjection has been conducted through 6 reinjection wells, However, wellbore issues have led to the cessation of reinjection in KMJ-21 and KMJ-55, reducing the number of active reinjection wells. This reduction requires efficient management strategies to optimize reinjection volumes and maintain reservoir stability.

The reinjection process will affect the composition of the production well fluid due to differences in the composition and temperature of the reinjection fluid compared to the reservoir fluid, ultimately altering the production well fluid. Therefore, monitoring these geoindicators, including isotopes and superheat, helps assess the effectiveness of reinjection in production wells and aids in optimizing reinjection strategies. The study concludes that while reinjection processes influence gas fractionation and isotope distribution in the Kamojang field, the reduction in reinjection wells has not yet led to matrix steam production. However, current reinjection levels are insufficient to prevent superheat increases, indicating the need for enhanced reinjection strategies. Continuous monitoring and targeted management are essential for optimizing reinjection efficiency and sustaining geothermal energy production in the Kamojang Geothermal Field.

1. INTRODUCTION

Kamojang Geothermal Field is located in Bandung and Garut Regencies, West Java Province. Owned by PT. Pertamina Geothermal Energy, it is the oldest geothermal field in Indonesia. This field is also one of the steam-dominated geothermal prospects in Indonesia. The first efforts to explore geothermal energy sources in Indonesia were conducted in the Kamojang Crater area by the Dutch East Indies government in 1918, with the drilling of five shallow wells. One of these Dutch exploratory geothermal wells, known as Kawah Kareta or well KMJ-3, which has a depth of approximately 60 meters, still emits steam to this day.

During the period from 1971 to 1979, a collaboration between Indonesia and New Zealand led to the drilling of 14 wells (KMJ-6 to KMJ-20) in the Kamojang Geothermal Prospect. The geothermal potential of Kamojang was proven to be viable for electricity generation, marked by the operation of a small-scale Mono Block turbine of 0.25 MW, utilizing steam from a single production well, KMJ-6. This Mono Block marked the initial momentum for the utilization of geothermal energy for electricity generation in Indonesia. The development period of Kamojang geothermal energy continued into the commercialization stage, signified by the commercial operation date (COD) of Unit 1 in 1983, with a capacity of 30 MW, followed by the COD of Units 2 and 3 in 1987, each with a capacity of 2 x 55 MW. This was achieved through a Steam Sale and Purchase Agreement (PJBU) business scheme between Pertamina and PT. Indonesia Power, a subsidiary of PLN.

Pertamina has continuously conducted further exploration to optimize the utilization of geothermal potential in Kamojang, successfully increasing capacity and constructing Geothermal Power Plant (PLTP) Unit 4 with a capacity of 60 MW in 2008 and Unit 5 with a capacity of 35 MW in 2015. These developments were implemented through a Total Project Electricity Sale and Purchase Agreement (PJBL) business scheme between PT. Pertamina Geothermal Energy (PGE) and PT. Indonesia Power. Thus, the Kamojang PLTP has been operating for more than 40 years and currently has an installed capacity of 235 MW with five generating units, supported by approximately 97 geothermal wells consisting of 63 production wells, 9 reinjection wells, 16 monitoring wells, and several abandoned wells.

Figure 1: Location Map of Kamojang Geothermal Field.

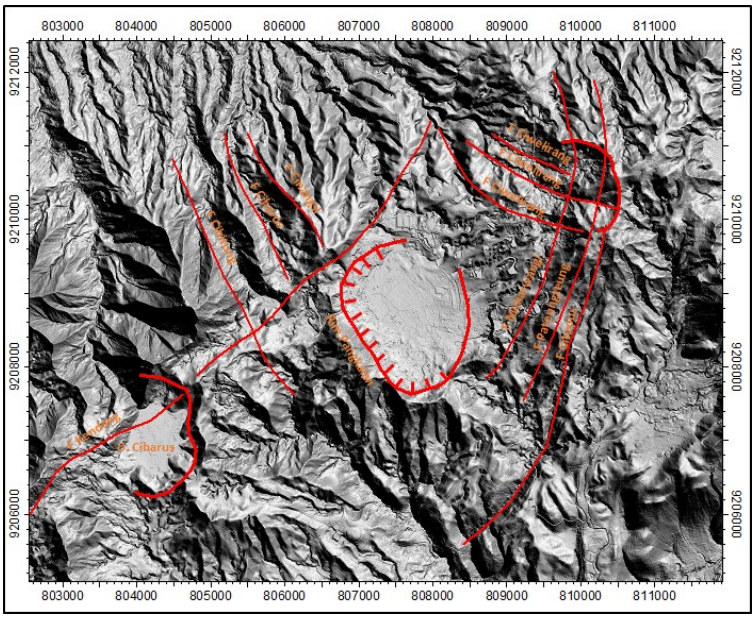

Figure 2: Geological Structure Map of the Kamojang Geothermal Field.

2. THE GEOLOGY OF THE KAMOJANG GEOTHERMAL FIELD

The Kamojang area is situated at the center of a volcanic mountain range oriented WestSouthwest-EastNortheast (WSW-ENE) Regionally, volcanic activity in this area has occurred since the Pleistocene era. Volcanic eruptions along fracture lines are associated with the WSW-ENE fault system. The sequence of volcanism from the oldest (WSW) to the youngest (ENE) includes Mount Rakutak, the Ciharus Complex, the Pangkalan Complex, the Gandapura Complex, the Masigit Complex, and the Guntur Complex. The reservoir rocks in the Kamojang Geothermal Field consist of interbedded pyroclastic and andesitic lava with some basaltic andesite and lacustrine tuff (Utami, 2000). Information from production wells indicates that the subsurface geology of the Kamojang Field is composed of altered andesite, altered pyroclastic rocks, and altered basaltic andesite, as demonstrated by the analysis of core samples and cuttings from the observed wells.

The geological structures in the Kamojang Geothermal Prospect are identified based on satellite image analysis, subsurface data from drilling, and geophysical measurements. Generally, the structures in Kamojang consist of:

- Circular collapse structures, such as the Pangkalan rim/caldera and other smaller circular structures seen at Lake Ciharus and around the summit of Mount Rakutak.
- The Ciharus Block Structure group, oriented NW-SE.
- Normal faults, oriented NE-SW to nearly north-south, including the Mekarwangi Fault, Citepus Fault, and Pateungteung Fault, located in the eastern part.
- The Ciwelirang normal fault, oriented NW-SE, located in the northern part of the Kamojang Geothermal Prospect.

In general, the wells drilled around the Pangkalan Caldera structure, the NW-SE normal fault structure in the Ciharus block, and the nearly north-south structures in the KWK area, such as the Mekarwangi Fault, Pateungteung Fault, and Citepus Fault, are productive wells. Good permeability in the younger NE-SW to nearly north-south faults is also indicated by the presence of massive manifestations such as craters, fumaroles, and hot springs in the NE area associated with these faults

3. GEOCHEMICAL CHARACTERISTICS OF KAMOJANG GEOTHERMAL FIELD

As previously mentioned, Kamojang is a steam-dominated geothermal field, so unlike two-phase fields, geochemical monitoring in this field is more focused on gas observations in wells. Sampling in Kamojang is conducted three times a year, and the analysis is carried out in the internal PGE laboratory located in the Kamojang area. In this paper, the discussion of geochemistry and monitoring of Kamojang will only use data obtained since 2017.

Kamojang itself has a relatively low gas/steam ratio, averaging less than 1% wt or 10,000 ppmW, and this ratio is evenly distributed throughout the Kamojang area. High NCG values are found in several wells at the edge of the field, assumed to be caused by condensation, and in the eastern part, assumed to be related to the production of fresh matrix steam with a higher gas content. The main gas composition in NCG in Kamojang is CO2, which reaches more than 80% dry gas, followed by H2S. This composition is not much different from other PGE-owned geothermal fields. In the ternary diagram plot of N2-Ar-CO2, the wells in the Kamojang field do not have magmatic influence because the plot position is not on the magmatic line and tend to originate from brine with neutral fluids.

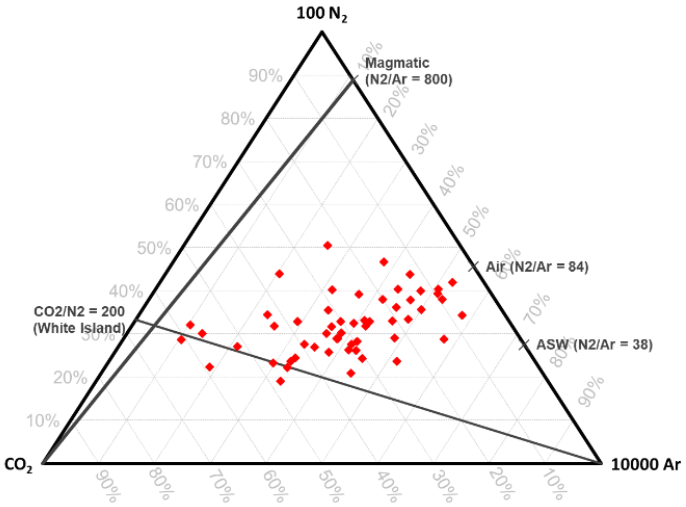

Figure 3: The ternary diagram of N2-CO2-Ar for production wells in the Kamojang field shows that the wells in the Kamojang area are not affected by magmatic fluids.

The manifestations of the Kamojang field consist of fumaroles and hot springs, mostly located in the northeast part and associated with the NE-SW to nearly north-south trending Pateungteung fault. Hot springs are also found on the rim of the Pangkalan caldera and in the southeast part of the Kamojang field. The hot spring manifestations in Kamojang consist of sulfate water and bicarbonate water. Bicarbonate water appears in the southwest (Ciharus) and southeast (Citepus) areas, assumed to be associated with the outflow zone. The Ciharus manifestation is associated with the Kendang Fault, and the Citepus manifestation is linked to the Kamojang recharge zone.

4. REINJECTION IN THE KAMOJANG FIELD

Since 2019, reinjection in the Kamojang Field has been carried out through 6 reinjection wells: KMJ-20, KMJ-21, KMJ-32, KMJ-35, KMJ-39, and KMJ-55, which are distributed throughout the Kamojang Field and are expected to cover the entire area. The fluid re-injected at Kamojang consists of condensate from the six power plants in the area, with the current total injection rate averaging around 4,000 liters per minute, or approximately 240 tons per hour. These reinjection wells are crucial for maintaining the overall mass balance within the Kamojang reservoir because vapor-dominated systems are characterized by tightly sealed reservoir boundaries, so the natural recharge of liquid tends to be minimal. Ensuring a balance between the fluid extracted and re-injected into the reservoir is vital to prevent excessive depletion in certain production zones, which could disrupt the long-term sustainability of the reservoir

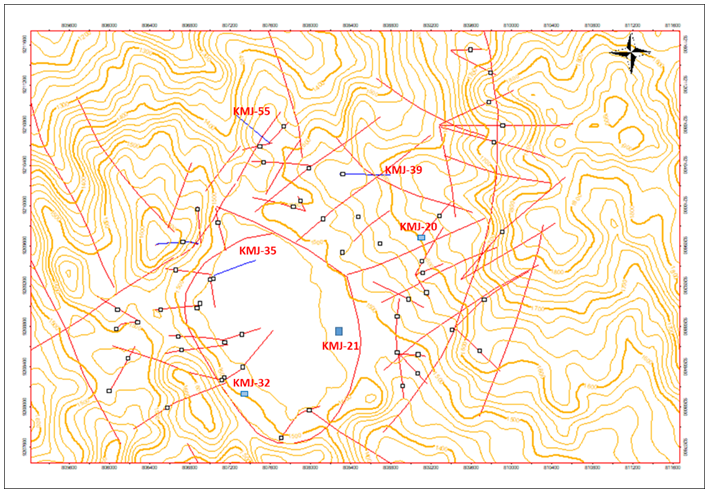

Figure 4: Map of Reinjection Wells in the Kamojang Geothermal Field.

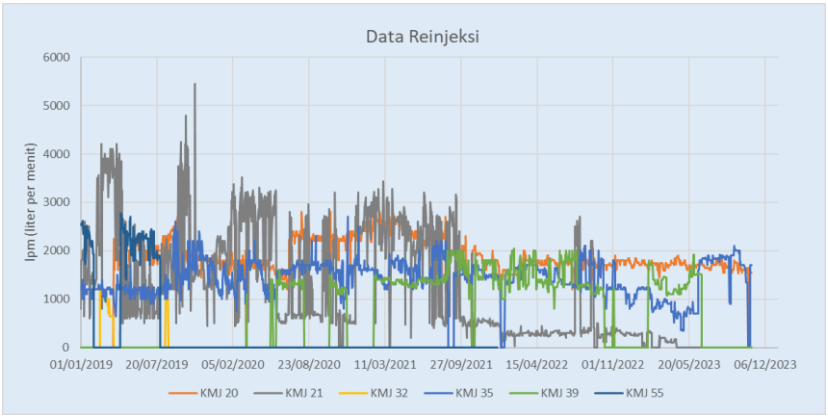

Figure 5: Graph of the reinjection volume of reinjection wells in Kamojang showing the dynamics of reinjection volume and the active reinjection wells in Kamojang from 2019 to 2023.

The dynamics of reinjection volumes in the Kamojang Field can be seen in figure 5. At the end of 2019, KMJ-32 and KMJ-55 stop operating due to wellbore issues as evidenced by their sudden drop to zero reinjection rates. Initially, KMJ-21 had the highest reinjection volume among all wells, but starting in 2021, its volume gradually declined due to wellbore problems that reduced the well's reinjection capacity. This trend is visible as a consistent decrease in KMJ-21's reinjection rate. Currently, the operating reinjection wells in the Kamojang Field are KMJ-20, KMJ-35, and KMJ-39 underscores the need for targeted management strategies to optimize reinjection efficiency and maintain reservoir pressure effectively.

5. GEOINDICATOR DYNAMICS DUE TO THE REINJECTION RETURN PROCESS

The reinjection process in geothermal fields significantly influences the chemical composition as well as chemical geoindicators, which are critical for understanding reservoir behavior. Reinjection of cooled geothermal fluids, especially condensate in steam-dominated geothermal fields, back into the reservoir not only helps maintain pressure but also affects various geoindicators such as temperature and chemical composition since condensate has a different chemical composition compared to the reservoir fluids. These changes can provide insights into the reservoir's response to reinjection, highlighting areas of enhanced permeability and potential thermal breakthroughs. Monitoring these geoindicators allows for the optimization of reinjection strategies, ensuring efficient resource utilization and long-term stability of geothermal energy production. In the Kamojang Geothermal Field, the strategic placement of reinjection wells and continuous monitoring of geoindicators are essential practices for maintaining reservoir health and optimizing energy output. With the reduction of reinjection wells in the Kamojang Field, monitoring these geoindicators becomes increasingly important to assess whether the remaining reinjection wells and their reinjection volumes are sufficient to maintain the Kamojang reservoir, or if the effects of the reduction in the number of reinjection wells have started to appear in Kamojang.

5.1 Superheat

Superheat occurs when the fluid's temperature exceeds its saturation temperature at a given pressure, specifically the pressure at the time of measurement. In a geothermal system, superheat conditions are assumed to arise when the reservoir is depleted of liquid, causing the existing steam to be continuously heated by a heat source above its boiling point. An increase in the superheat value of a well indicates a deficiency in reinjection mass. If this condition persists, the continuous loss of steam mass will result in a detrimental loss of pressure support. Additionally, superheat conditions can lead to various wellbore issues, including an increased risk of corrosion and scaling. Therefore, superheat is a crucial parameter monitored during geothermal field activities, especially in Kamojang. With the reduction in reinjection wells in Kamojang, superheat has become an essential indicator to determine whether a well is receiving sufficient mass from reinjection. Additionally, the overall adequacy of reinjection in the Kamojang field can be assessed by observing the trend of superheat over the years.

Superheat measurements have been carried out in Kamojang since 2016. The superheat measurements conducted are surface superheat measurements. This method is chosen because it is more efficient and can be performed periodically. Additionally, flowing PTS surveys were also examined to assess downhole superheat and compare it with wellhead superheat measurements. Generally, the review indicated that wellhead superheat data reasonably represented the level of superheat occurring in the field. Although monitoring has been conducted since 2016, the intensive increase in superheat began in 2019 and has continued to rise until now. The trend shows that the highest measured superheat values generally occur in the western and central areas of the field, which have experienced the longest production history and greatest pressure drawdown. The highest superheat observed is above 15 degrees. In 2021, superheat expanded to the southwestern part, even though this area contains the injection well KMJ-35, indicating that the support from reinjection fluids is no longer sufficient to maintain the reservoir in this zone. As of 2023, superheat in Kamojang has shown a continuously increasing trend, particularly in areas with superheat above 15 degrees, which has extended toward the northeast following the decrease in reinjection fluid volume in well KMJ-21. This indicates that the reduction in reinjection wells in Kamojang has had a negative impact on wells connected to the reinjection wells that have ceased operation.

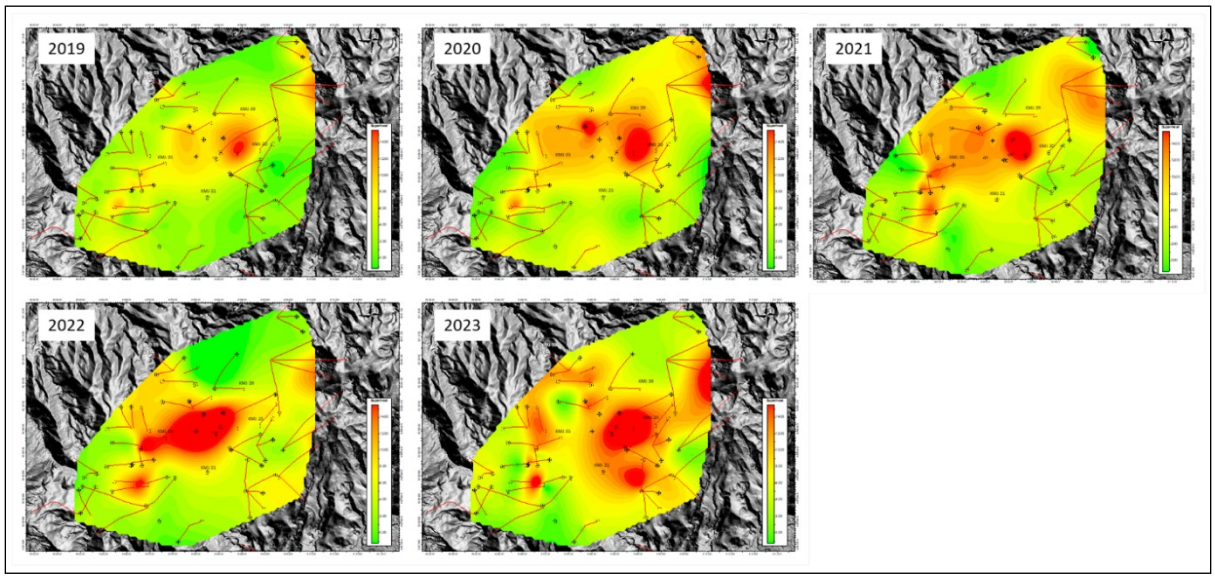

Figure 6:. Superheat Distribution Map in the Kamojang Geothermal Field. It is evident that over the years, the area affected by superheat has progressively expanded.

Unlike other parts of the field, the northeast area has a shorter production history. Additionally, due to the location of these wells along the structural alignment, it has resulted in low to moderate superheat production. The southeastern area of the field has the highest measured reservoir pressures and consistently shows some of the lowest observed superheat values in the field, typically less than 5 °C. The pattern of sustained low superheat values in the southeast supports the interpretation that this area may partly be producing fresh reservoir matrix steam from the east. Another area of sustained low superheat is observed in the southwestern margin of the field, which is likely related primarily to the influence of injection fluids and potentially minor recharge along the Kendang fault zone.

5.2 Gas Equilibrium

At equilibrium, concentrations of gases in reservoir steam and liquid are different because gases partition strongly into the steam. If reservoir liquid vaporizes during production and this steam mixes with the original reservoir

steam, gas concentrations in the mixture will not correspond to equilibrium in either liquid or steam (Truesdell, 1993). However, the fractionation of the original reservoir steam present in the produced fluid (represented as Y), which has mixed with vaporized liquid, can be determined by combining gas equilibrium and gas solubility equations on opposing axes. This approach not only provides the Y value but also determines the temperature of the fluid. The Y value, or fractionation, ranges from 0 to 1, where Y = 0 indicates that the entire sample originated from the boiling of reservoir liquid, while Y = 1 signifies that the sample represents pre-existing reservoir steam

In the Kamojang field, the steam fraction is calculated using the D'Amore gas geothermometer, which involves reactions where CH_4 and H_2O combine to produce CO_2 and H_2, a process known as the Fischer-Tropsch (FT) reaction and also the reaction where H_2 and H_2O combine with pyrite (FeS_2) to form H_2S and magnetite, represented as HSH. There are three equilibrium states considered in this reaction, known as HSH1, HSH2, and HSH3. However, in the Kamojang area, we will only use FT-HSH2, as it is the most applicable and provides the most accurate temperature readings for this field.

Based on the plot of the FT-HSH2 geothermometer grid, the Y values in the Kamojang field range from 0.02 (indicating fluids mostly composed of recently boiled liquid) to 0.3 (indicating fluids mixed with reservoir steam). Wells with the highest Y values are located in the southeast, which indicates more production of original matrix steam, in comparison to wells in the west and the early-developed central parts of the field, which yield lower Y values, indicating depletion of the original matrix steam and production from reservoir liquid. Additionally, the gas geothermometer values from the Kamojang wells can be determined, which range between 250-275°C.

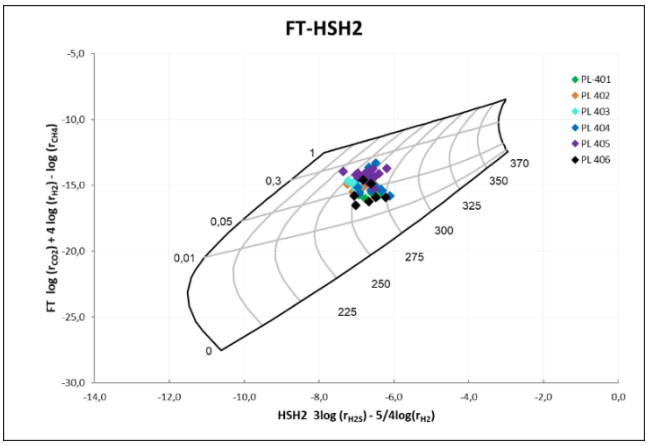

Figure 7: Gas geothermometer FT-HSH 2 for wells in Kamojang shows that the wells in Kamojang have varying Y values and temperatures ranging from 250 to 275°C.

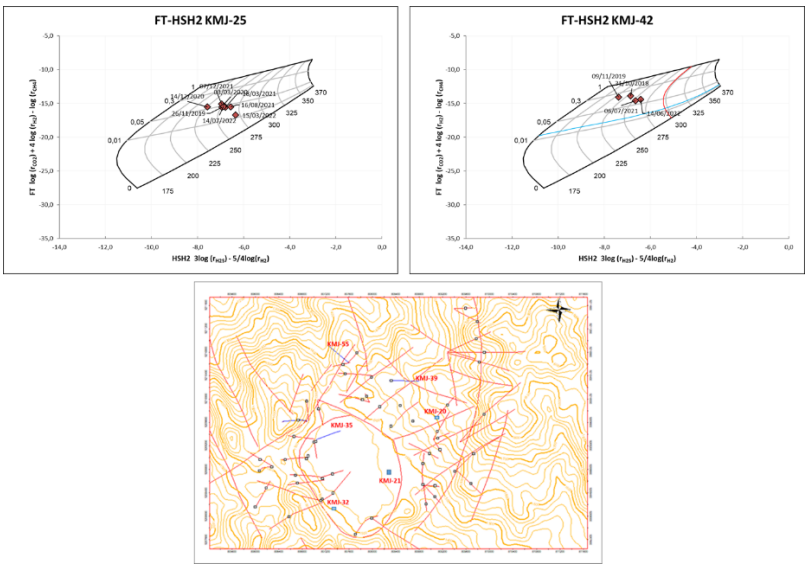

Figure 8: Geothermometer grid FT-HSH 2 from wells KMJ-42 and KMJ-25 experienced changes in gas fractionation throughout 2017-2023. These changes are assumed to be due to condensation, either by recharge fluid or reinjection condensate.

During the exploitation process, changes in Y values can occur due to the reinjection process, which causes the reinjection fluid to be produced in greater quantities, resulting in an increase in vaporized liquid and a decrease in the percentage of reservoir steam. Alternatively, the process of reservoir dry-up can reduce the vaporized liquid and make the original reservoir steam more dominant. Considering these factors, monitoring of Y values in the Kamojang Field is conducted to observe whether there are changes in these values in the wells in Kamojang.

Based on the monitoring results of all wells in Kamojang, only two wells exhibited a shift in Y values, indicating a change in gas fractionation in the produced wells, namely KMJ-42 and KMJ-25. In well KMJ-42, an increase in temperature was observed alongside a decrease in the Y value. This phenomenon is assumed to be caused by the production of more vaporized liquid, while the temperature increase itself can be attributed to the oxidation conditions of H2S. Well KMJ-42 is located on the western edge of the Kamojang Field, which is a recharge zone for this field, suggesting that the change in gas fractionation in this well is likely influenced by natural recharge.

In contrast, well KMJ-25 is not situated on the edge of the field but is very close to the injection well KMJ-39. The Y value in this well also experienced a decrease to 0.01, which is characteristic of a fluid mostly composed of recently boiled liquid. Additionally, the well's temperature showed an increase, attributed to the oxidation of H2S. Based on the analysis of this graph, it is assumed that well KMJ-25 is significantly influenced by the injection fluid from the nearby injection well, KMJ-39.

Apart from these two wells, there have been no significant changes in gas fractionation in the wells of the Kamojang Field, whether caused by condensation or the dry-out process. Therefore, it can be concluded that the reduction in the number of injection wells and the volume of injection fluid has not yet caused the wells in Kamojang to produce greater percentage of matrix steam.

5.3 NH_3

One of the key parameters for identifying injection returns is the trend of rising NH_3 levels in dry gas. This is also observed as an increase in NH_3 compared to less soluble gases like CO_2 and H_2S. The rise in NH_3 levels is linked to the increased production of boiled injection fluids. Due to NH_3's high solubility in liquid water, it is likely that some of this gas dissolves in condensing steam in the wellbore and then remains in the steam condensate as it cools at the surface before reinjection. Therefore, samples with a high proportion of "injectate" would exhibit higher NH_3 concentrations than the typical well fluid (Lowenstern, 1999).

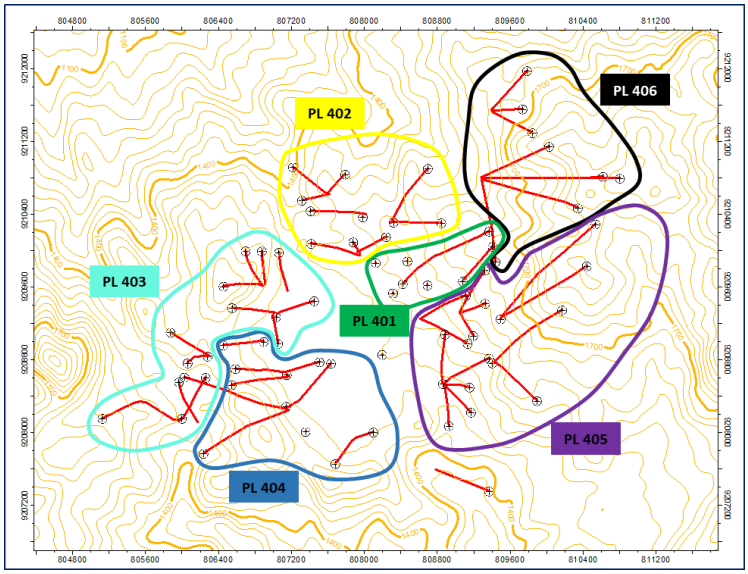

Figure 9: The wells in Kamojang are divided into several clusters based on the turbines they support. Unit PL 401, PL 402, PL 403, and PL 404 support PLTP Units 1, 2, and 3, while PL 405 supports PLTP Unit 4, and PL 406 supports PLTP Unit 5.

PL-402 wells exhibit the strongest signatures of injection-derived steam while wells in the PL-401 area, near the fumaroles and several injection wells, display a range of NH3 signatures. This suggests that wells in this region are sensitive to the injection strategy used for the numerous nearby injection wells. In the western part of the field (PL-403 and PL-404), wells show moderate to strong injection return signatures. This is expected due to the area's long production history and the lowest reservoir pressure. Many wells in PL-403 and PL-404 with more moderate NH3 signatures are offset from the Kendang fault, while those with the strongest NH3 signatures are located closer to the fault.

Wells in the PL-405 area, especially on the eastern side of the sector, show the lowest impact from injectate in the field, indicated by the lower NH3 distribution. Wells in PL-405 generally produce very low injection tracer returns. This is interpreted to be due to the higher pressures in the PL-405 sector. Tracer injected in wells on the boundary of PL-405 (such as injection well KMJ-21) might preferentially travels parallel to the primary NE-SW fracture direction, or towards areas of lower pressure once in the vapor state.NH3 signatures in PL-406 show two distinct clusters. Most wells exhibit stronger NH3 signatures, but two wells in the south end of the PL-406 sector (KMJ-88 and KMJ-89), which have a trajectory to the northeast, show distinctly lower NH3 signatures similar to those in the PL-405 area. This may be due to the proximity of KMJ-88 and KMJ-89 to the higher pressures in PL-405 and their location further off the structural strike from the injection wells. Based on NH3 monitoring, it can be determined that the reinjection fluid reaches the wells in Kamojang to varying degrees. Compared to the previously discussed superheat pattern, the NH3 signature shows a correlation between reinjection fluid and superheat values. PL-402, which has a high NH3 signature indicating a strong connection with the reinjection well, shows a lower degree of superheat compared to other areas. Similarly, PL-403 and PL-404 initially exhibited low superheat and high NH3 signatures, although superheat in these areas eventually increased. An exception occurs only in the PL-405 area, where the low superheat is more due to the support from the original matrix steam rather than reinjection support.

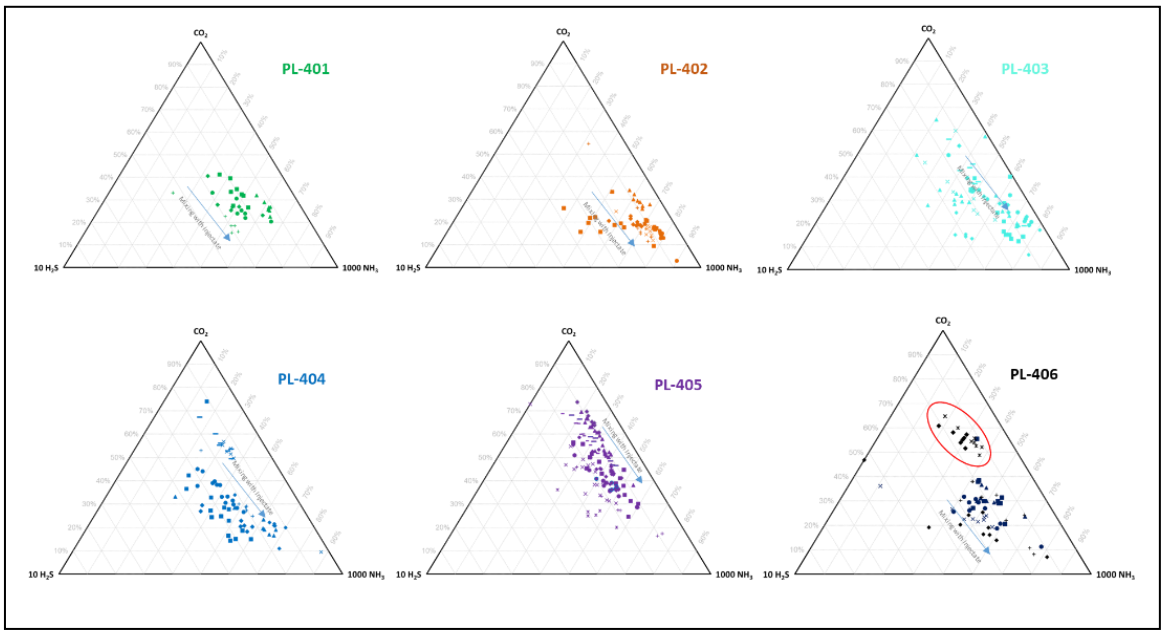

Figure 10: Ternary diagram showing the distribution of soluble gases including H2S, CO2, and NH3, with trends of increasing NH3 attributed to breakthrough of injection fluids. The red circles indicate wells KMJ-88 and KMJ-89, which have a slightly different pattern compared to other wells in PL-406 due to their closer proximity to the PL-405.

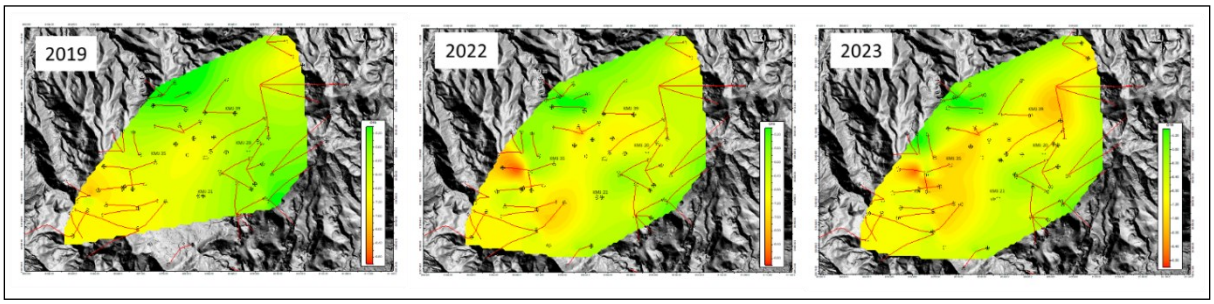

Figure 11: Isotope Distribution Map in the Kamojang Geothermal Field.

5.4 Isotope

Stable isotopes, particularly oxygen-18 (^{18}O), are valuable parameters for monitoring geothermal systems. This is because changes in stable isotope values can reflect the ongoing processes in geothermal fluids. It is well-known that the ^{18}O isotope in geothermal fluids tends to be more enriched compared to local meteoric water. This enrichment occurs due to water-rock interactions, where oxygen exchanges between rocks and fluids, leading to a higher concentration of the isotope in the liquid phase. When geothermal fluids mix with meteoric water, the

isotope values can be affected. Since meteoric water generally has lower ^{18}O values, any mixing would result in a lower ^{18}O value in the geothermal fluid compared to its original value. In addition to natural recharge mixing, reinjection breakthrough is another factor influencing isotope values. The reinjection water, typically condensate from the cooling tower, has undergone evaporation, making its isotope values highly enriched. If a well is affected by reinjected fluids, its ^{18}O isotope values will be significantly more enriched compared to surrounding wells. Given these characteristics, stable isotopes are essential parameters in the geochemical fluid monitoring process conducted in the Kamojang Area.

Generally, the ^{18}O isotope patterns in the Kamojang Geothermal Field for the years 2019, 2022, and 2023 are closely related to the active injection wells at the time the data was collected. The ^{18}O isotope pattern in 2019 differs slightly from that in 2022, with the central part of the field appearing more depleted than in the following years. This difference is because the injection well KMJ-39, located in the central part of the field, only began operations in 2020, and the enrichment pattern only becomes apparent in the maps for 2022 and 2023. Based on the ^{18}O isotope distribution maps above, it is evident that enriched isotopes are present in wells with good connectivity to the injection wells, while depleted isotopes are found on the edges of the field, associated with a supply of fluid more depleted in isotopes, such as natural recharge or areas not connected to the injection wells. Additionally, the isotope patterns in the Kamojang field also seem to correlate with the superheat pattern, where areas with enriched isotopes, such as PL-402 in the northwest, PL-405 in the southwest, and areas around the injection wells, also have lower superheat compared to surrounding areas. In contrast, areas with depleted isotopes, such as the central part of the field, also correlate with higher superheat values. An exception occurs in the western and southwestern parts, where depleted isotopes correlate with recharge influence associated with the Kendang fault. From this observation, it can be concluded that the ^{18}O isotope can be used to monitor the reach of reinjection fluids in the wells of Kamojang, as it closely matches the superheat pattern in this field.

5. CONCLUSION

Superheat measurements indicate a significant increase beginning in 2019, with the highest values observed in the western and central areas, correlating with prolonged production and substantial pressure drawdown. Superheat values have continued to rise, particularly in areas with superheat above 15 degrees, which has extended toward the northeast following the decrease in reinjection fluid volume in well KMJ-21. This suggests that the reduction in reinjection wells in Kamojang has negatively impacted wells connected to the reinjection wells that have ceased operation.

However, based on gas equilibrium, this has not yet caused the Kamojang wells to produce higher matrix steam, indicating that the Kamojang reservoir can still support field exploitation. The connectivity between reinjection wells and production wells is actually quite good, as evidenced by monitoring of NH3 and 18O isotopes, which shows a strong correlation between some areas and reinjection wells, marked by a strong NH3 signature and enriched isotopes in the PL-402, PL-401, PL-403, and PL-404 areas. Nevertheless, these areas have still shown an increase in superheat, indicating that the rise in superheat is more likely due to a lack of reinjection fluid rather than poor connectivity with reinjection wells.

ABSTRACT

Geothermal well targeting can be challenging due to the unpredictable nature of subsurface conditions, which may lead to drilling unproductive wells. To address these uncertainties, implementation of advanced technology and refinement of subsurface models are essential. This study aims to highlight the possibility of using a density model based on gravity data measurement to improve the targeting of geothermal makeup well drilling, particularly when aiming for steam cap reservoir. Implementing this method is expected to increase efficiency and cost-effectiveness, as demonstrated in the Salak field.

Microgravity/precision gravity has been measured in Salak from 1994 to 2020 for routine reservoir surveillance conducted every 3 to 4 years. Our methodology involved refining Free Air Gravity (FAG) measurements using radial basis functions and applying microgravity inversion techniques to develop density change models spanning from 2005 to 2020. Reservoir boundaries and water level elevation data serve as constraints for the microgravity inversion process. Outside the designated reservoir boundary and beneath estimated water levels, adjustments during microgravity inversions were limited, allowing only for minor perturbations. It is believed that the detectable density changes observed by microgravity surveys primarily originated from fluid phase alterations in two-phase geothermal fields induced by geothermal exploitation activities.

To effectively target wells, it's important to identify the "sweet spots" within the reservoir. This requires combining data on reservoir properties with a conceptual understanding of the reservoir itself. One of the important “sweet spots” characteristics in targeting steam cap reservoir is steam cap distribution. The distribution of steam cap can be obtained from the Pressure Temperature (PT) dataset but limited spatially to the distribution of existing wells in Salak. The density change model generated based on microgravity inversion can be useful in areas where there is high uncertainty due to lack of PT data. By interpreting gravity decline, which is largely due to density changes resulting from the development of the two-phase zone in Salak, the 3D density change model can identify areas of steam cap development, delineates zones with potential interconnected fractures and relatively favorable mass depletion rate. Such insights are pivotal for guiding decision-making processes regarding the targeting and development of steam wells in Salak Field. This model has also been shown to have good correlations with steam cap pressure, well production/injection data, and tracer test results, which validates its accuracy and reliability.

1. INTRODUCTION

The Salak geothermal field, with an installed capacity of 381 Mwe, is located in West Java, Indonesia, approximately 70 kilometers south of Jakarta (Figure 1). This location places the field within a region known for its geothermal potential due to its tectonic and volcanic activity. The geothermal field benefits from this geologically active setting, which is conducive to the development of geothermal resources. The Salak field has been in operation for 30 years, making it one of the longest-running geothermal projects in Indonesia. During these three decades, the field has undergone numerous development and optimization efforts to ensure its productivity and sustainability.

The Salak geothermal system is a high-temperature water-dominated reservoir with benign chemistry and low-to-moderate NCG content (Acuña et al., 1997). With its 30 years of operation, the Salak reservoir currently shows distinctive attributes across its eastern and western sectors: Eastern Salak region is noticeably characterized by a developed steam cap zone allowing most of the producing well in this region to be steam dominated, whereas western Salak area is characterized by liquid-dominated production wells.

The process of managing the reservoir to sustain the required generation possesses challenges, particularly in geothermal makeup well targeting. The main challenge is the unpredictable nature of subsurface conditions, which can lead to the drilling of target wells that do not yield the expected result. Addressing these challenges requires the integration of advanced technology and more reliable subsurface models. Modern advancements in

geophysical methods, data processing, and computational modeling offer new approaches to better understand and estimate subsurface conditions.

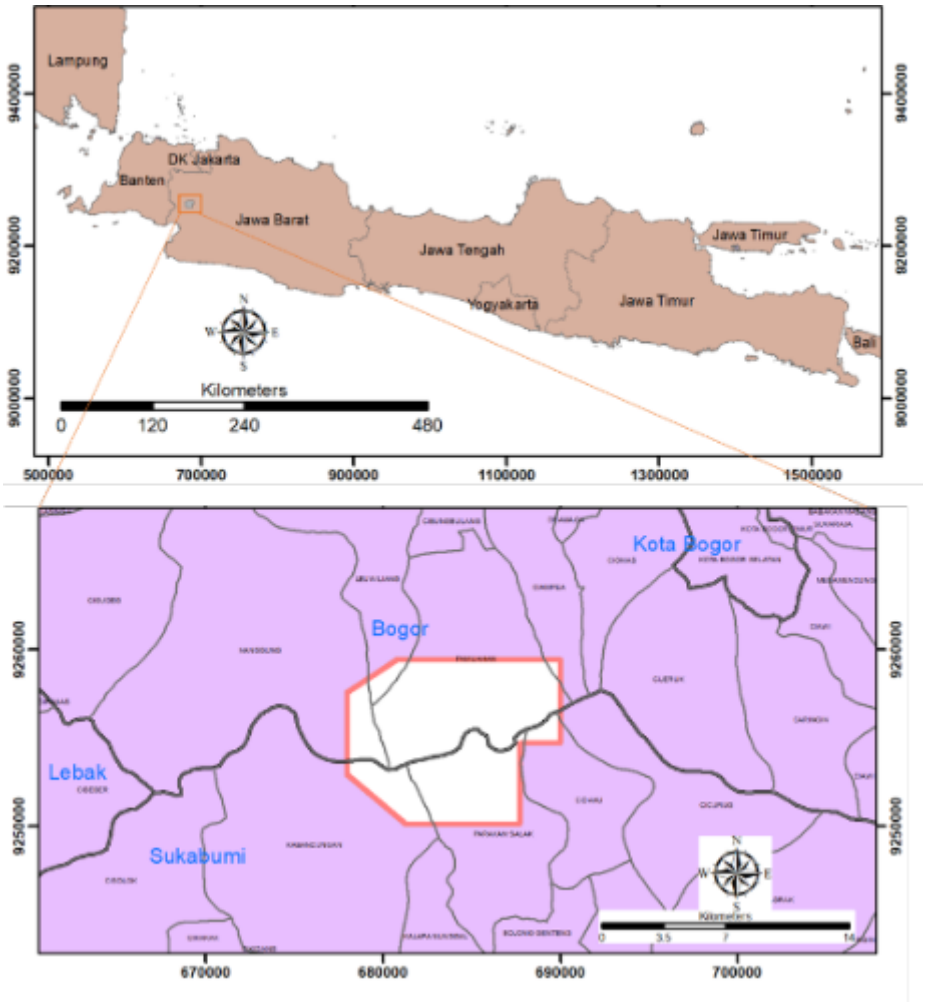

Figure 1: Location of Salak Geothermal Field Working Area (within red polygon).

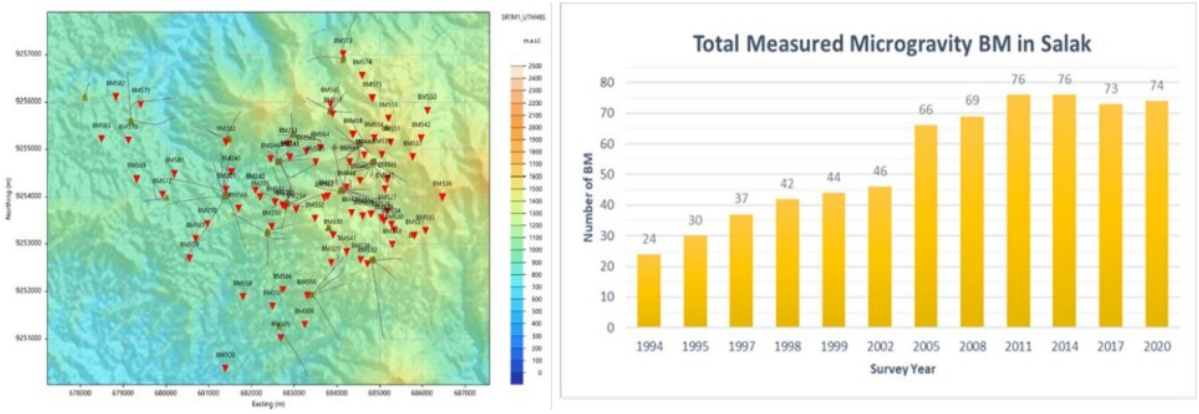

Figure 2: Benchmarks location in Salak Field (left) and the number of measured BM in each survey (right).

One of common geophysical techniques for reservoir monitoring is precision gravity and leveling survey which aim to measure subtle changes in the Earth's gravitational field inferring the changes in the reservoir net mass over particular time intervals. This survey is conducted by measuring variations in the Earth's gravitational field at distributed surface points called benchmark or BM (Figure 2) (CGG, 2021), revealing changes in subsurface mass distribution. Such variations are particularly useful in geothermal fields, where the extraction and reinjection of fluids can cause changes in subsurface density. From 1994 to 1999, precision gravity and leveling survey were

conducted annually, however since then, considering the rate of changes in the measured gravitational acceleration, the interval was optimized to be conducted every 3-year interval (Figure 2).

This study investigates the potential of using a density model to support the targeting of geothermal makeup well drilling, with a focus on steam cap well target. By refining subsurface models with detailed density data, this study aims to reduce uncertainty in well placement, thereby increasing the likelihood of intersecting productive zones and optimizing resource extraction.

2. METHODOLOGY

The methodology employed in this study involves refining Free Air Gravity (FAG) measurements, performing 3D inversion on the microgravity data and interpreting the inverted density change model. FAG measurements provide initial gravity data corrected for the elevation of the measurement point. In this study, Radial Basis Functions (RBF) were utilized to smooth the FAG data, minimizing the effect of outliers.

Following the refinement of the FAG data, microgravity inversion techniques were applied to develop detailed three-dimensional density change models. Microgravity inversion process inverts surface gravity measurements into subsurface density distributions. The 3D modeling mesh is of regular 100m x 100m x 100m cell size extending from 1,600 to -4,100 mASL elevation. A homogeneous density changes values of zero is used as the starting model (CGG, 2021).

For time windows of density change models, it was decided to use the delta density during 2005–2020 and 2011–2020 for investigation. The 2005 and 2011 surveys are used as baseline for these two time-windows, respectively, in accordance with BMs number and distribution.

To ensure the accuracy of the density change models, several constraints and assumptions were incorporated. Reservoir boundaries and elevation of steam-water contact in the reservoir were used as primary constraints during the inversion process. Outside the designated reservoir boundary and below estimated water levels, adjustments during microgravity inversions were limited to minor perturbations. The primary driver of the detectable density changes observed in the Salak field is believed to be fluid phase changes within the two-phase geothermal reservoir. As a typical two-phase system, Salak reservoir consists of both liquid and steam zone. The extraction, injection, and natural recharge processes in a producing geothermal field can lead to changes in the proportions of liquid and steam phases, altering the overall density of the reservoir rocks. These changes in density are detectable at the surface using sensitive gravimetric instruments. In the Salak field, the observed density changes are thought to be induced by geothermal activities, such as fluid extraction and reinjection, which alter the distribution and behavior of fluids within the reservoir.

The interpretation of the model includes how density change model correlates with other data, validate whether this model supports previous findings from other studies in Salak and how to utilize this model to support well targeting.

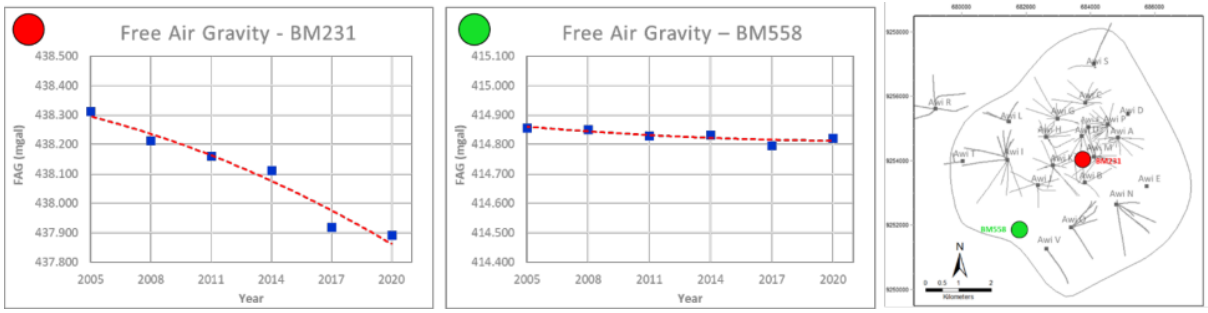

Figure 3: FAG trend overtime in region impacted by Salak production activities (BM 231) and region with minimum impact from Salak production activities (BM558).

3. RESULTS AND DISCUSSION

The observed decline in gravity measurements within the Salak geothermal field has been interpreted as a result of density changes primarily associated with the development of a two-phase zone. The development of such zones typically leads to a reduction in liquid saturation within both the rock matrix and the fracture network which decreases the overall density of the subsurface materials and eventually detectable as a decline in gravity measurements. In Salak Field, highest gravity decline is observed in BM 231 (Figure 3) which is located in the center part of reservoir between Awi M and Awi B pad. This part of the field is presumed to experience largest reservoir compaction due to continuous mass extraction from Salak producing wells. In contrary, BM that is

located far from production area, BM558, very low decline in FAG was observed suggesting no significant impact from Salak production.

Figure 4 and Figure 5 show density change occurring in Salak at 200 mASL. Over time, the density evolution model delineates three distinct zones: (1) areas characterized by a decrease in density attributed to production activities such as mass extraction leading to phase changes denoted by blue to red region in the map (e.g., water to steam, generally occurred in shallow reservoir section), with minimal influence from mass recharge sources; (2) areas exhibiting a slight increase in density due to the influence of mass recharge sources, notably injection activities and marginal recharge processes involving mass influx and cooling (denoted by greyish region in the map); and (3) areas where no density change is observed (denoted by white region). The latter is presumably associated with the following reasons: the absence of phase changes, insufficient extraction or recharge to change the density, resultant of both extraction and recharge nullifying each other's impact, other reason would possibly be related to data unavailability due to the lack of BM in this region. Understanding the reservoir process happening in Salak would assist in determining the more accurate explanation when interpreting this region.

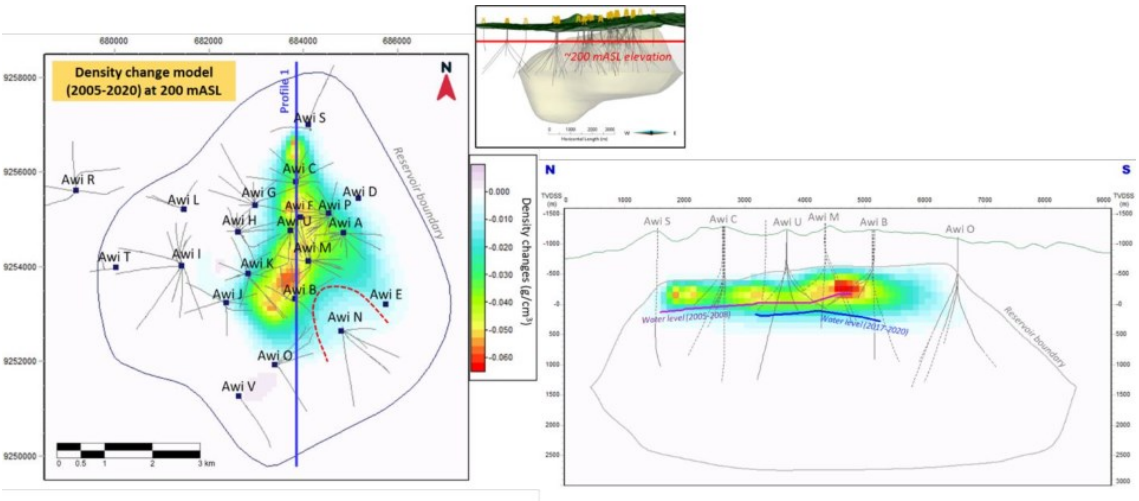

Figure 4: Density change between 2005-2020 at 200 mASL elevation and the north-south cross section relative to water level from different period.

Density changes model between 2005 and 2020 is shown in Figure 4. The most significant density decline occurred near AWI M and AWI B, likely due to continuous extraction since the early stages of production in the eastern part of the Salak field. Another substantial decrease in density is observed in the northern area following extraction from AWI C wells. The widespread density decrease in the eastern, northern, and central production wells of Salak indicates that mass extraction exceeds recharge rates, thereby could not sufficiently compensate for the total mass loss produced by the wells.

Between 2011 and 2020 (Figure 6), the most significant and noticeable decline in density occurred in the northern part of the Salak field near AWI C. The relationship between high mass extraction rates and density changes was also examined (Figure 7). Analysis of cumulative extracted mass during 2011-2020 indicates that AWI C extracted a greater amount of mass compared to other well pads. However, despite the high cumulative production, AWI A and AWI P exhibit relatively low-density changes. This anomaly suggests that well AWI A and AWI P receives substantial pressure support from potentially marginal recharge and injection breakthrough from the southeast injectors, specifically from wells AWI N and AWI O, which mitigate the density reduction that would typically accompany high mass extraction.

These findings signify the sensitivity of the density model to the field's operational dynamics. In both models, the decrease in density does not extend westward in Salak, as the impact of production from western wells was counterbalanced by additional mass injection from AWI I. Furthermore, a distinct "bent feature" (red dashed line) observed in the southeastern part of Salak suggests two possible causes: impact from injection operations at AWI N and O, and/or the absence of production wells in that specific area. Tracer tests conducted in Salak (Figure 7) confirm the occurrence of injection breakthrough from injection wells reaching and affecting production wells in the field.

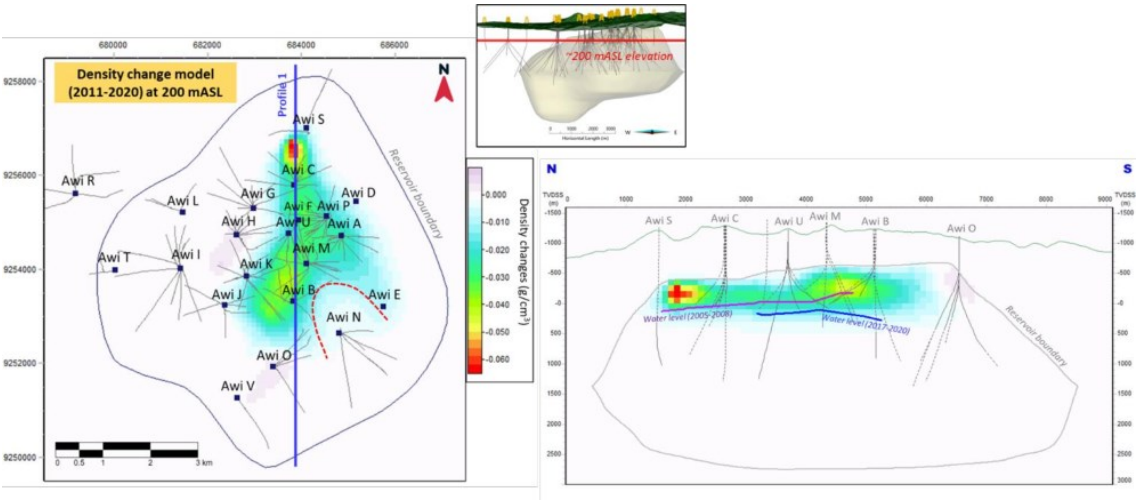

Figure 5: Density change between 2011-2020 at 200 mASL elevation and the north-south cross section relative to water level from different period.

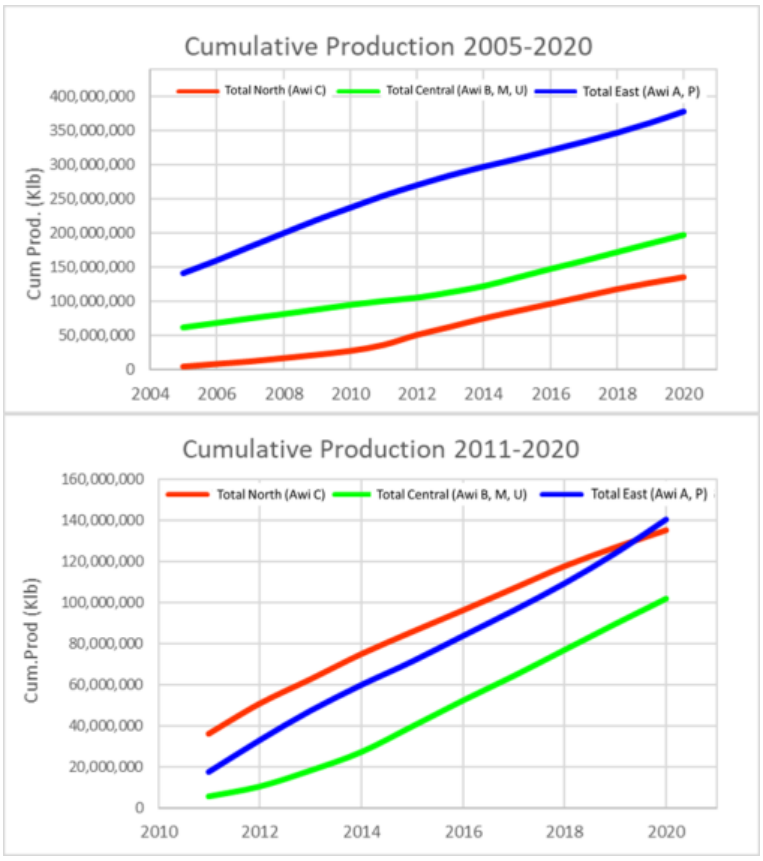

Figure 6: Total cumulative production of Pad Awi C (northern part of reservoir), Pad Awi B, M, U (central part of reservoir) and Pad Awi A, P (eastern part of reservoir) within different time windows.

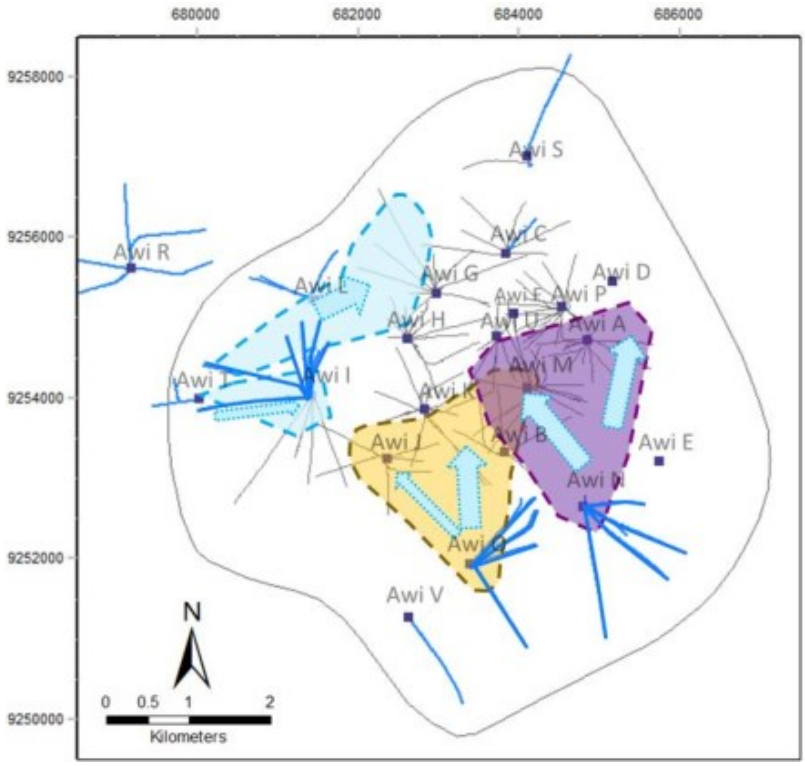

Figure 7: Illustration of 2009 Salak Tracer Test study results, modified from Abdurrachman et., al. (2014).

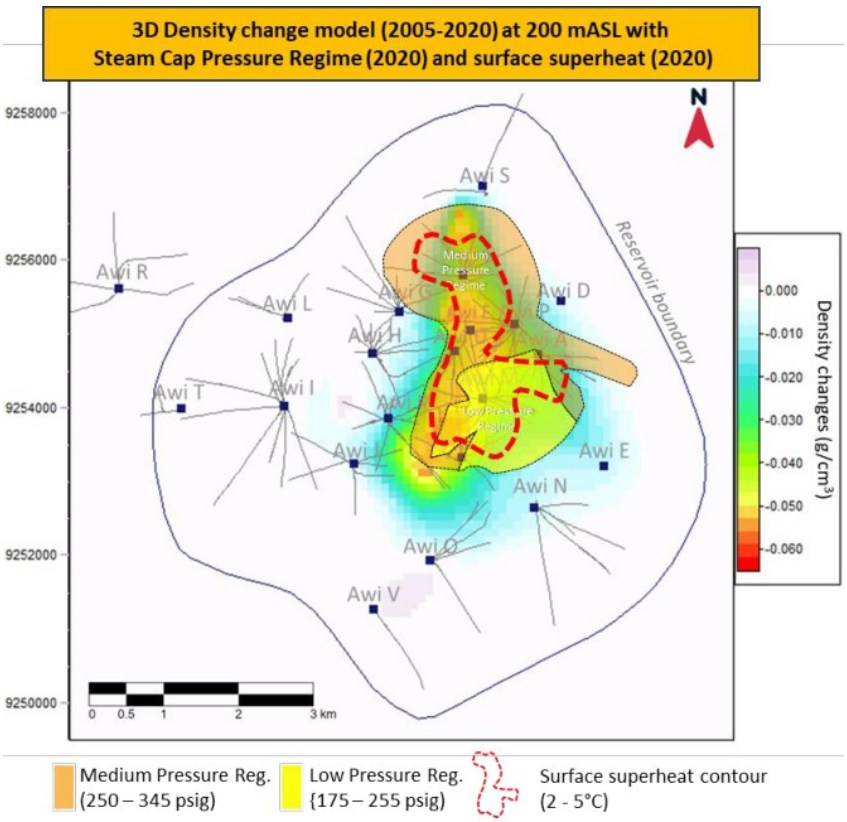

Figure 8: Density change model relative to steam cap pressure regime and surface superheat data in Salak.

Negative density changes observed through microgravity surveys exhibit a strong spatial correlation with areas subjected to steam cap pressure regimes and recorded surface superheat (Figure 8). The maximum observed changes in density are notably located within zones identified as having low and medium steam cap pressure

regimes, indicating significant fluid extraction and phase change activities in these areas. The surface superheat map identifies areas where surface temperatures exceed their saturation levels. Although not perfectly aligned, these regions of surface superheat correspond fairly with the areas showing density decreases as detected by density model. Confirmation of these correlations requires the availability of downhole superheat data.

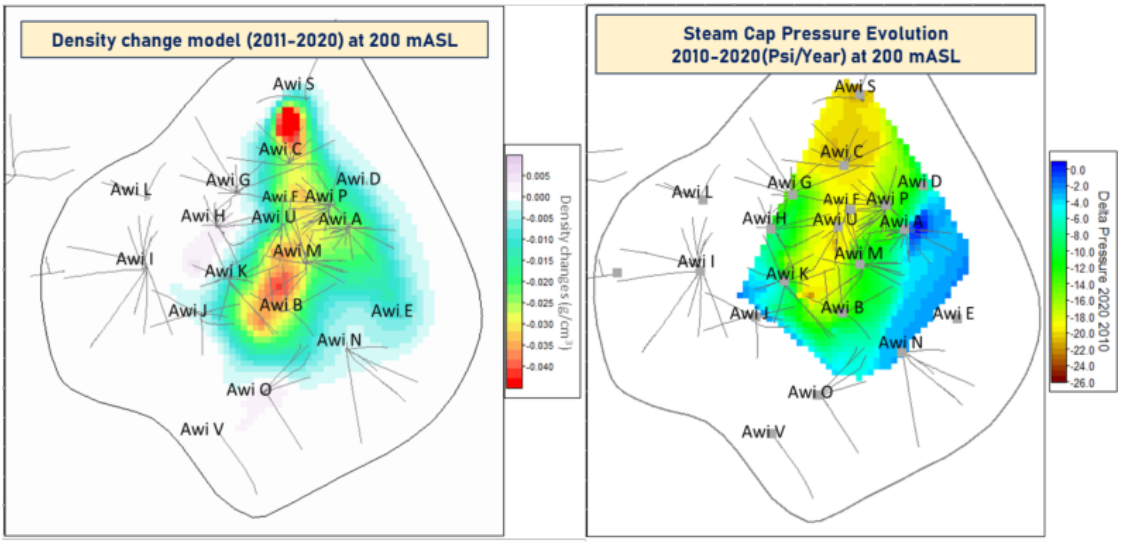

Figure 9: Density change model in comparison with steam cap pressure evolution showing relatively similar trend.

Further analysis of density changes over a shorter period, specifically from 2011 to 2020, reinforces the observed correlation between density changes and steam cap pressure evolution (Figure 9). The comparison suggests that the areas experiencing the most significant density reductions correspond well with the regions undergoing steam cap pressure evolution from numerical model. The density change model shows good correlation, in which during 2010 to 2020, steam cap pressure decline map shows major decline in both Awi C and north of Awi B.

Effective geothermal well targeting necessitates the identification of "sweet spots" within the reservoir. These zones are particularly favorable for drilling due to their high permeability, pressure, and temperature conditions. Identifying these zones requires a combination of detailed data on reservoir properties and a robust conceptual understanding of reservoir dynamics. One of the critical characteristics of these sweet spots, especially when targeting steam cap reservoirs, is the distribution of the steam cap itself.

Data on steam cap distribution can be derived from various sources, including Pressure Temperature (PT) datasets. PT data provide valuable information on the pressure and temperature conditions within the reservoir, which can be used to infer the presence and extent of steam caps. The density change model generated from this study is particularly useful in areas with high uncertainty due to a lack of direct PT data. With the help of density change models, a more comprehensive representation of areas where steam caps are likely to be present in the reservoir can be generated.

Regions exhibiting significant decreases in density are presumed to denote highly productive areas with extensive interconnected fractures. These areas have experienced substantial fluid extraction, leading to a pronounced reduction in subsurface mass. Such regions are typically less impacted by injection or marginal recharge (IB/MR), making them prime targets for further development. The higher density decrease in these zones indicates their potential for sustained production due to the presence of a well-connected fracture network facilitating efficient fluid flow. Nevertheless, targeting areas for makeup well should always consider the sustainability of targeted well production. Avoiding areas with highest density decline but still showing interconnected fracture to promote sustainability and balance out the extracted region would also be a good option to consider.

Areas with increasing density features should be approached with caution as they are potentially impacted by mass recharge sources, including injection and marginal recharge. The increased density in these areas suggests that the natural or artificial recharge processes are replenishing the reservoir, which may hinder the steam cap development.

It is important to note that areas lacking significant density decreases do not necessarily indicate an absence of productive potential or interconnected fractures. Such regions might still possess the capability to become productive but may currently exhibit less extraction activity or be influenced by mass recharge processes. The

presence of less density decrease could be attributed to lower extraction rates, indicating that the area has not yet reached its full production potential.

4. CONCLUSION

The insights gained from this study suggest that the density change model could serve as a robust indicator for identifying steam cap development areas, delineating zones with potential interconnected fractures and relatively favorable mass depletion rate. Such insights are pivotal for guiding decision-making processes regarding the targeting and development of steam wells in Salak Field. This model has also been shown to have good correlations with steam cap pressure, well production/injection data, and tracer test results, which validates its accuracy and reliability.

ABSTRACT

Papandayan geothermal field in West Java is one of Indonesia's Geothermal Field with a mean estimated potential output of 21 MW. An assessment of the Papandayan resource using a new numerical model including uncertainty quantification is presented in this study. Following the method developed by the Geothermal Institute at the University of Auckland, a new 3D geological model was constructed based on public sources and data from The Directorate-General of New Renewable Energy and Energy Conservation in Indonesia (EBTKE). The construction of the 3D geological model involved the integration of geology, geophysics, geochemical and spatial data through Leapfrog Energy. The 3D geological model illustrates the aspects such as the geological structures, rock types, water level and thermal features. Using an integrated modelling approach, the new digital conceptual model was used to create a new reservoir model following best practices.

The natural state model was simulated using both AUTOUGH2 and Waiwera to assure compatibility with industry standard TOUGH2 while also enabling quick calibration and uncertainty quantification through cloud computing. To calibrate the model, the permeability distribution of the rocks and the deep flow boundary condition are adjusted. For uncertainty quantification, a large number of models (1000 samples) were generated and run. The parallelized geothermal simulators like Waiwera which was developed by the University of Auckland in cooperation with GNS science (Croucher A. , et al., 2020) can accelerate this process dramatically. The next step is to condition each natural state model using the temperature distribution based on the clay cap and applying an Approximate Bayesian Computation Method (ABC). Once the ensemble of models had been filtered, a novel method was used to run maximum potential scenarios for each model. in this research, future production assumed a binary power plant for 25 years. The results of this resource assessment give the mean estimate (P50) of net power output potential for Papandayan at 18.5 MW, the P90 at 12.3 MW and the P10 at 28.4 MW.

1. INTRODUCTION

Geographically, Mount Papandayan is a stratovolcano that rises from 1,100 to 2,665 meters above sea level. The site is at 107.44'00" east and 7.19'00" south between Bandung and Garut District, West Java province. The last eruption of Mt Papandayan was in 2002, making it an active volcano. (Sulastri et al., 2014). Papandayan geothermal studies started in the late 1990s with geology and geochemistry research. The study covered lithology mapping, geologic structure, and alteration. Additionally, it involved locating, collecting, and examining fluid from thermal features (Nasution, 2008). Thermal features include solfataras, fumaroles, mud pools, steaming ground, hot springs, and large alteration zones, ranging in temperature from 55 to 260 °C, mostly being SO_4-type waters (Nasution, 2008). Several Geophysical surveys have been conducted to complement geothermal studies, as recorded in several publications (Nasution, 2008; Nurhasan, 2012; Geology Institution, 2018; Diba, 2021). In 2019, the Indonesia Geological Agency assessed the geothermal potential in Papandayan using the stored heat method, resulting in in a mean estimate of 21 MW of geothermal power. Considering these findings, Papandayan presents a promising prospect for geothermal energy.

The Indonesian archipelago has 40% of the world's geothermal reserves. Approximately 23.36 GW of geothermal potential is estimated by the Directorate General of Geology and Mineral Resources, with utilization only reaching 10% (Alhusni, 2022). Indonesia has a longstanding ambition to increase geothermal energy production to achieve the country's energy sustainability goals. According to the National Energy General Plan 2021-2030, Indonesia aims to produce an additional 870 MW of geothermal power by 2025, and by 2021-2030, geothermal power capacity is expected to reach 3,355 MW. Supporting these projections requires a comprehensive and robust exploration phase of green fields, which include the Papandayan. According to Nugraha (2017), the geothermal potential at Papandayan is quite attractive due to its location in West Java, an area with significant geothermal potential. The region's geological and tectonic conditions, along with successful nearby geothermal projects like Kamojang and Darajat, enhance Papandayan's appeal for development. These factors suggest that the existing exploration data for Papandayan should be examined more closely to capitalize on its potential.

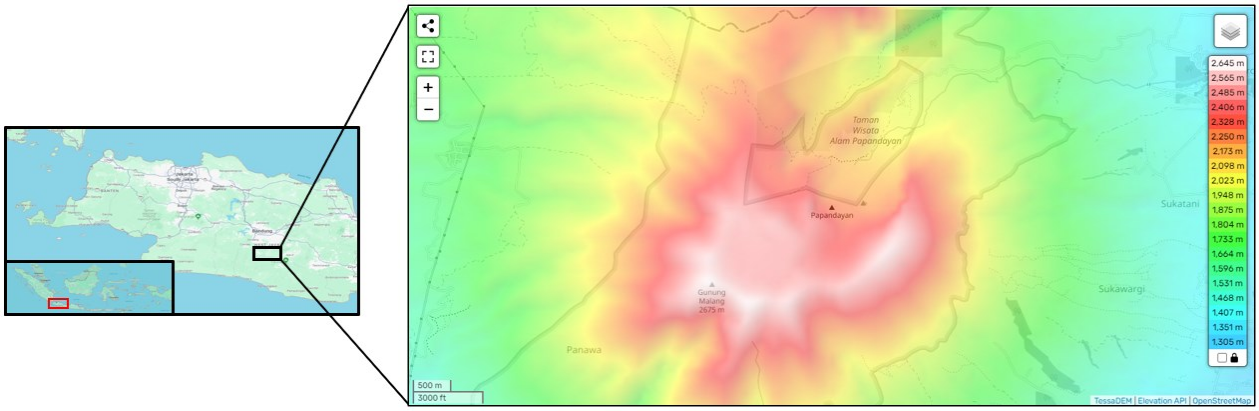

Figure 1: Location and topography map of Papandayan area modified from Google maps and topographic-map.com/Papandayan.

To advance beyond the current exploration stage, a better understanding of the Papandayan geothermal system is necessary. The process involves developing a 3D digital conceptual model and a numerical reservoir model. A 3D digital conceptual model visually represents the Papandayan geological system and geothermal system, while a numerical reservoir model provides a better understanding of Papandayan subsurface conditions. The numerical reservoir model calibration process can test different conceptual representations despite limited subsurface data. Additionally, numerical models of reservoirs developed during the exploration can be enhanced with downhole data as it is acquired. A numerical model calibrated with the downhole data provides invaluable insights for supporting drilling and well-testing operations. Nevertheless, resource assessments remain valuable at any stage of a geothermal project, particularly during exploration.

The first stage of this research was to create a 3D digital conceptual model of the Papandayan field using Leapfrog Energy. The 3D digital conceptual model was designed based on the relevant structural features, types of rocks, and thermal features of Papandayan. Papandayan's conceptual model provides the basis for 3D geological and reservoir models. The conceptual model combines geological, geophysical, and geochemistry data (3G) to describe physical mechanisms influencing fluid and heat flow in the Papandayan geothermal system. A 3D geological model was then used to generate a numerical reservoir model. This numerical model captures the natural state of the system and provides a starting point for a simulating the future production of the reservoir before exploitation. The clay cap can be interpreted from geophysical studies, is used to calibrate the numerical reservoir model with the reservoir assumed to be approximately 190-200°C at this location.

The numerical reservoir model is simulated with AUTOUGH2, while Waiwera is used for quick calibration and uncertainty quantification through cloud computing. Both geothermal simulators are utilized to ensure compatibility with the industry standard TOUGH2. To calibrate the numerical modelling, adjustments are made to the permeability and porosity of rocks and the mass flow. For uncertainty quantification, a large number of models (1000 samples) are generated and run. Parallelized geothermal simulators like Waiwera, which the University of Auckland developed in cooperation with GNS science (Croucher A. , et al., 2020), accelerate this process by exploiting cluster compute nodes. The next step is to condition the steady state model and temperature for the clay cap. In this process, the Approximate Bayesian computation method (ABC) is used. Following the acceptance of the steady state model based on geophysical data, a novel method was used to estimate and run maximum potential production scenarios. For this research, a future production scenario of a typical binary power plant was projected for 25 years.

2. GEOLOGICAL SETTING

MT Papandayan Volcanic Area is categorized into quaternary volcanic systems, identified by the presence of quaternary volcanic deposits in the vicinity of the eruption center (Sulastri, 2014). There are three geological structures on Mt. Papandayan: area morphology, fault structure and crater structure. Firstly, morphology of this area is characterized by steep slopes and mountains which dominate the landscape (Figure 2). Secondly, fault structure which most fault structures were found near Tegal Alun-Alun Crater, Mt. Nangklak, Mt. Walirang, Mas Crater, and on the volcano's northwest and southeast slopes (Figure 3). There are two normal faults with fault directions of NW-SE and NE-SW, respectively. In addition, there are three attributes that characterize normal faults: topographic lineaments, brecciation, and crushed zones. Lastly, several craters exhibit this structure, including Brungbrung Crater, Manuk Crater, Mas Crater, Tegal Alun-Alun Crater, Nangklak Crater, and Baru Crater (Sulastri, 2014).

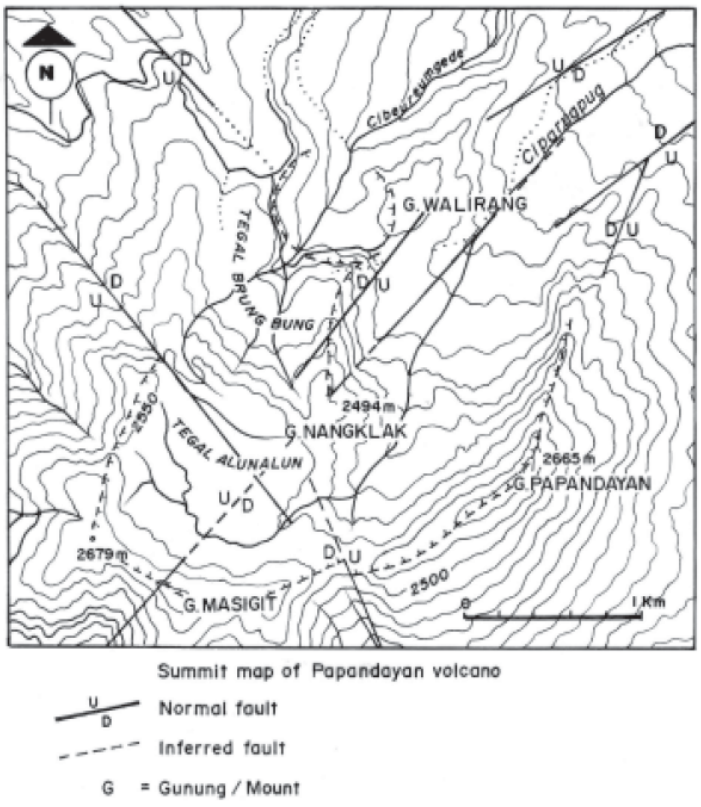

Figure 3: Geological Structure in Mt Papandayan and surrounding Area (Sulastri, 2014).

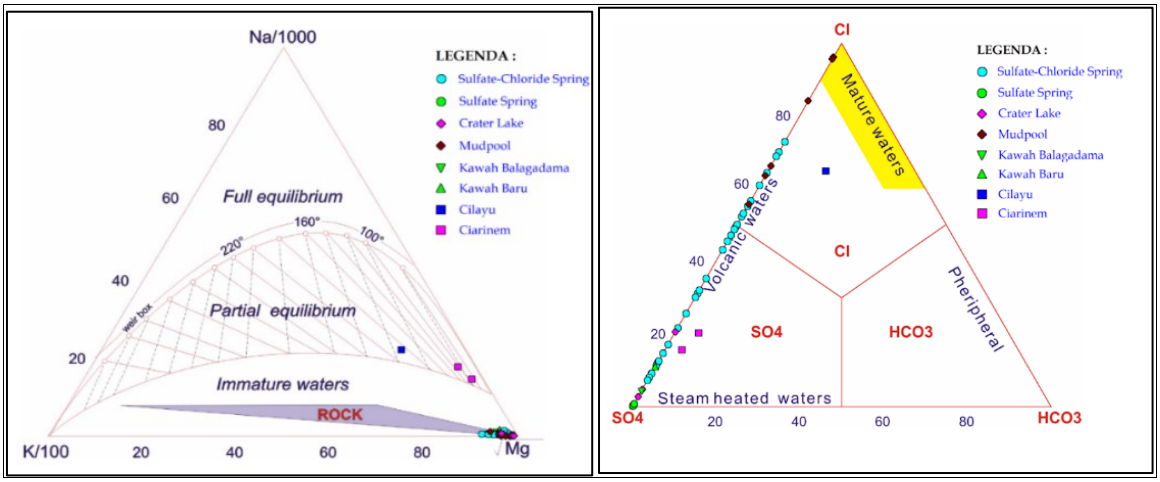

Figure 4: Water chemistry analysis.

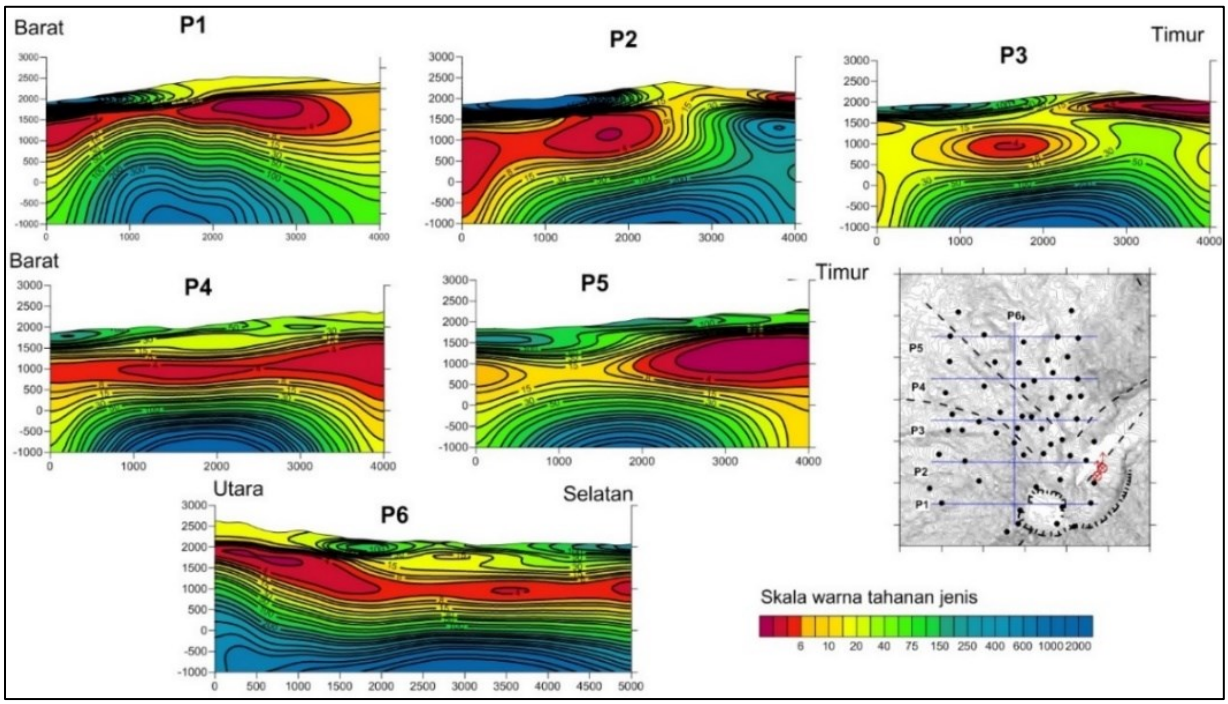

Figure 5: Magnetotelluric cross section maps of Papandayan (Geology Institution, 2018).

3. GEOCHEMISTRY STUDY

In accordance with geochemical analysis, Papandayan lava has a silica content of 55% (Sulastri, 2014). Accordingly, the values of SiO_2 variation in volcanoes are classified as medium-K andesite (Maitre, 1989). With regards to water chemistry analysis, Cl-SO_4-HCO_3 triangle diagram has been plotted showing that all water samples in the Papandayan area are located in volcanic waters which show manifestations that appear on the surface associated with Papandayan volcanic activity. Except for the Cilayu and Ciarinem, Volcanic water or steam heated waters in water samples indicate surface or near-surface steam interaction. Hot spring which are in the steam heated water zone (located far to the south outside the Papandayan prospect area). Meanwhile the Mg content in The Na-K-Mg triangle diagram shows that the appearance of water manifestations in the Papandayan complex is strongly influences by surface water. Additionally, Gas geothermometry result of Papandayan Reservoir is 240 -250 ℃ (Geology Institution, 2018; Maitre, 1989).

November 2002 was marked by an explosive eruption. The result was the formation of Kawah Baru. Volcanic eruptions that occurred up to 2002 tend to be more explosive. South-to-north displacement centres of eruption are controlled by structure. There are five large craters on Mount Papandayan that contain active thermal manifestations of fumaroles and springs. Several fumaroles and hot springs are active within the craters of Mount Papandayan. Fumarole discharges range in temperature from 90°C to 260°C, primarily containing H2O, CO2, and H2S (Sulastri, 2014).

4. GEOPHYSICAL SURVEY

Low resistivity anomalies (from Magnetotellluric survey) associated with altered rocks are distributed in the south-southeast (Tegal Alun), east (hot springs – Papandayan crater) and central areas. In Tegal Alun area, low resistance altered rocks of < 8 ohm begin to be modelled at a depth of around. 500 – 1500 m. In the eastern area or around the Papandayan craters, this altered rocks layer begins to be modelled from the surface to a depth of around 500 m. Meanwhile, in the middle area, the new altered rocks are modelled at a depth of around 800-1500 m. The low-resistivity rock < 8 ohm is thought to be clay cap for the Papandayan geothermal system (Geology Institution, 2018).

The clay cap is modelled with varying dimension but generally has a thickness of around 500-1000 m. The distributions pattern is based on lateral and vertical result starting from the southern area of Tegal Alun, the eastern area (Papandayan crater) and the central area of the investigation, meanwhile the low values in the north-northeast are not yet definitely part of clay cap based on its geological setting (Geology Institution, 2018).

The rock layer with a medium resistivity value ranging from 10-50 ohm is estimated as a reservoir rock layer. This layer lies beneath a low-resistivity rock layer, which is a type of impermeable rock, likely serving as clay cap. The peak of this reservoir rock begins to appear at depth at around 1400-1500 m in the southern (Tegal-Alun) and central part. Meanwhile, in the eastern area (Papandayan crater), this medium resistivity type of rock layer is modelled to be shallower, namely 500-750 m (Geology Institution, 2018).

5. CONCEPTUAL MODEL

A hydrothermal conceptual has been developed (Geology Institutional, 2018) as an initial concept for creating 3D conceptualizations. A detailed structural and geophysical study was incorporated with the previous model to represent the whole system. The new conceptual models as can been seen in Figure 6.

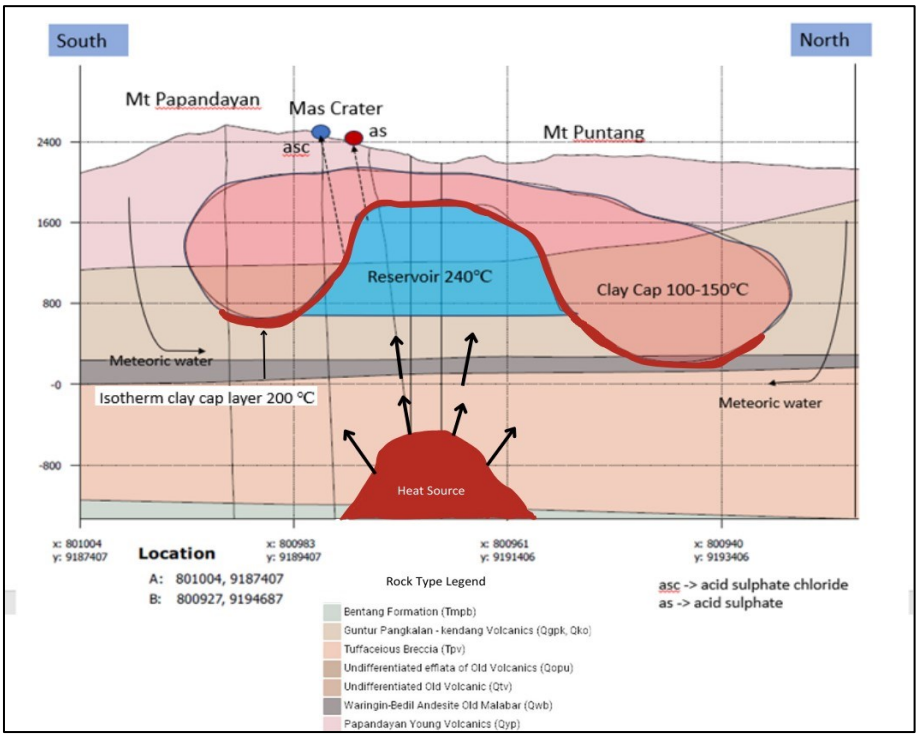

Figure 6: Conceptual Model of Papandayan Geothermal Field.

Papandayan geothermal power, sourced from ongoing volcanic activity, presents a notable volcanic risk. This is supported by magnetotellurics (MT) measurement data showing high resistivity values (> 200 ohm-m) extending continuously to a depth of over 3 km beneath the Mas Crater (Institution Geology, 2018). The heat source from magma chamber raises the temperature of the overlaying permeable rocks. This hot rock interacts with both deep, hot fluids and meteoric water. Fault structures and fractures act as pathways for this fluid movement, allowing it to rise towards the surface (Mahzari, 2021).

Magnetotellurics (MT) data indicate the presence of geothermal reservoirs with resistivity values ranging from 10 to 100 ohm-m and thicknesses of 750 to 100 m. Based on geological conditions, the reservoir rock is likely fractured volcanic rock, similar to the Darajat Reservoir, with estimated temperatures reaching up to 240°C

(Geology Institution, 2018). The reservoir age is believed to date back to the Quaternary Pleistocene and consists of efflata and andesitic-to-basaltic lavas. MT data suggests the reservoir depth varies from 500-750 m in the eastern part (Papandayan Crater) to 1400-1500 m in the southern part (Tegal Alun) (Geology Institution, 2018).

The geothermal fluid is concentrated in the Mas Crater and are characterized by an acidic water and acidic sulphate-chlorite composition (Mazot, 2008). These acidic surface manifestations, exhibit temperatures ranging 23°C to 91°C with an average 57°C (Birdina, 2018). The acidity likely originates from oxidation of hydrogen sulphide (H_2S) gas and the reaction of sulphur dioxide (SO_2) with water vapor. While the full origin of the fluids remains under investigation, the presence of altered rocks and cold water with a pH of 4 suggest ongoing geothermal activity in the Papandayan area (Geology Institution, 2018).

Steam-heated alteration are evident on the surface around the Mas Crater. These white-coloured rocks, composed kaolinite and illite clays, reflect them influence of acidic fluids interacting with magmatic fluids (Geology Institution, 2018). Additionally, low resistivity values low values (< 10 ohm-m) measured at the bottom of Tegal Alun, from a depth of 500 m to1500 m, suggest the presence of clay minerals (likely smectite) formed by hot fluid alteration of the surrounding rocks (Geology Institution, 2018).

6. 3D DIGITAL CONCEPTUAL MODEL

A 3D digital conceptual model of Papandayan was developed utilizing Leapfrog Energy. The model in this study is constructed using information, as shown in Table 1. The 3D digital conceptual model as was developed by specifying both rock formation units and fault structures, and an alteration model was constructed based on and geophysical data. The altered and unaltered volumes of the two models were then combined into a new 3-dimensional model as and be seen in Figure 8.

Table 1: An overview of data for 3D Digital Conceptual Model of Papandayan.

Type of Data	Function	Remark

7. NUMERICAL MODELLING

7.1 Reservoir Model Grid Setup

In this stage of the project, the AUTOUGH2 grid is implemented in Leapfrog Energy using a 3D Geological model. 49,112 blocks make up the AUTOUGH2 grid, which measures 15.8 km by 16 km (Figure 10). The blocks are 800 m x 800 m with a vertical thickness varies between 500 m at the base and decreasing to 100 m closer to the surface. The grid is refined more in the potential area (Papandayan) with blocks 200 m x 200 m. By using this grid as the reservoir setting up, a natural state condition will be simulated. Leapfrog Energy automatically assigns rock types, saving significant effort by eliminating the tedious task of manually inputting lithology data into the reservoir model. In addition, each time the geological model is modified, Leapfrog Energy instantly updates AUTOUGH2.

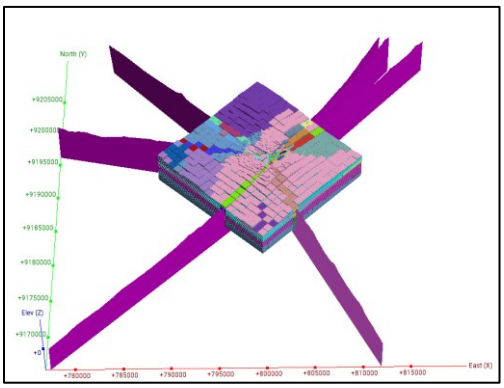

Figure 11: 3D view of Reservoir grid with orientation follows faults direction.

7.2 Boundary Condition

7.2.1 Top Boundary

At top of the model, Ground Surface is assigned as top of model. At this case dry atmospheric conditions are assigned at the top surface of field with the pressure of 1 bar and range temperature 12-28.2 °C. An annual rainfall of Papandayan area 3321 mm/year (Weather and Climate, 2020) and an infiltration rate of 10% are used in the analysis. High permeability was applied to the block's surface to facilitate rainwater flow to lower elevations because of the topography. The equation of state of water and air (EOS 3) is used in this case.

7.2.2 Side Boundary

No-flow boundary condition at the side was used as the model considers the entire convective geothermal system without side flows. It's assumed that the boundaries are far enough away that the flows at the boundary do not affect the flows of the geothermal system.

7.2.3 Base Boundary

80 mW/m^2 is the background heat flux at the base boundary. This heat flux indicates the up-flow zone under MT Papandayan. In addition, hot mass was fed into 12 blocks with a total up flow of 44 kg/s and enthalpy 1400 KJ/kg located under NW-SE faults which cross Mt Papandayan.

8. NATURAL STATE MODEL PAPANDAYAN

The natural state model was run using AUTOUGH2 geothermal simulator and successfully calibrated based on the bottom clay cap temperature isotherm of 200℃. The propylitic alteration zone occurred at the temperatures between 200°C - 300°C and produced altered rock including chlorite, epidote, quartz, pyrites, carbonate, and zeolites including prehnite and wairakite. As shallow formations cool below 230°C, argillic alteration occurs. Clay cap minerals are formed, including smectite, illite, and mixed smetite-illite clays (Mielke, Prieto, Bignall, & Sass, 2015). Natural state model ran for approximately 5x10^{13} seconds. The model reaches steady state at this point. Temperature consistency is evident in the dome area of the clay cap. The dome structure is of primary interest for drilling since it implies that the dome structure enables geothermal fluid to accumulate, making it more concentrated and accessible.

Papandayan Geothermal when reaching steady state. The calibrated model applied a deep up flow condition at the bottom of the model with a total mass flow rate 44 kg/s and an enthalpy of 1400 KJ/kg. The deep up flow in the calibrated model was focused along NW-SE faults which is consistent with the conceptual model as described in Figure 6. In the NW-SE direction as can be seen in Figure 12, three faults serve as the main heat transfer conduit from the depth to the reservoir and enable wider clay cap formation. Meanwhile, faults in the NE-SW directions also affect the Papandayan geothermal system. These faults mainly act as barriers to prevent fluid from flowing in the SE direction. This is necessary since naturally fluid preferentially due to topography changes.

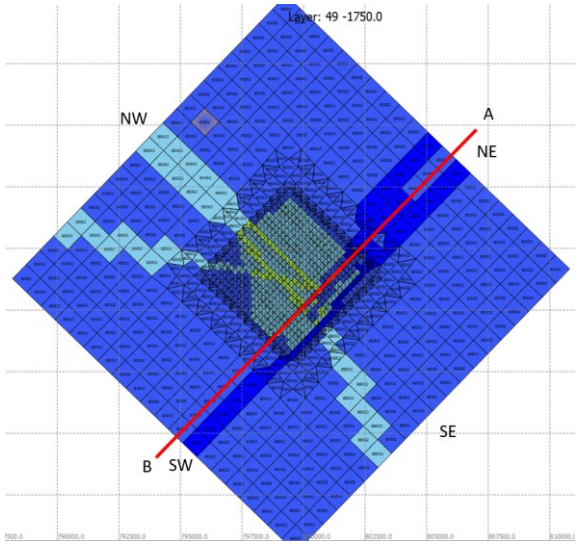

Figure 12: Fault Structure at bottom layer of reservoir grid (Visualization in Tim).

Permeability values for each rock type are calibrated parameter and values are within the range set by publication (Mielke, Prieto, Bignall, & Sass, 2015). The adjusted permeabilities are ensured to follow the geological rule. The clay cap was set at layers 6 to 36 based on the 3D Magnetotellurics Survey, with permeability ranging between 0.1 and 0.3 md. Meanwhile, the reservoir zone beneath the Caprock consists of Quaternary Holocene Papandayan Young Volcanics, Quaternary Pleistocene Guntur-Pangkalan and Kendang volcanics, Quaternary Pleistocene Waringin-Bedil Andesite old Malabar, and Tertiary Pliocene Tuffaceous Breccia Rocks. A range of 0.5 md to 300 md has been assigned to the permeability of reservoir rocks. Reservoirs generally have high permeability so that hot fluids can flow from deep formations and meteoric water can recharge. For the faults, permeability along the faults is greater than permeability across the fault. Vertical permeability (k3) is always set higher than k1 and k2 for the intersection part. In addition, the permeability of the rocks outside of the reservoir is designed to be lower than the reservoir area to confine the heat and prevent it from escaping.

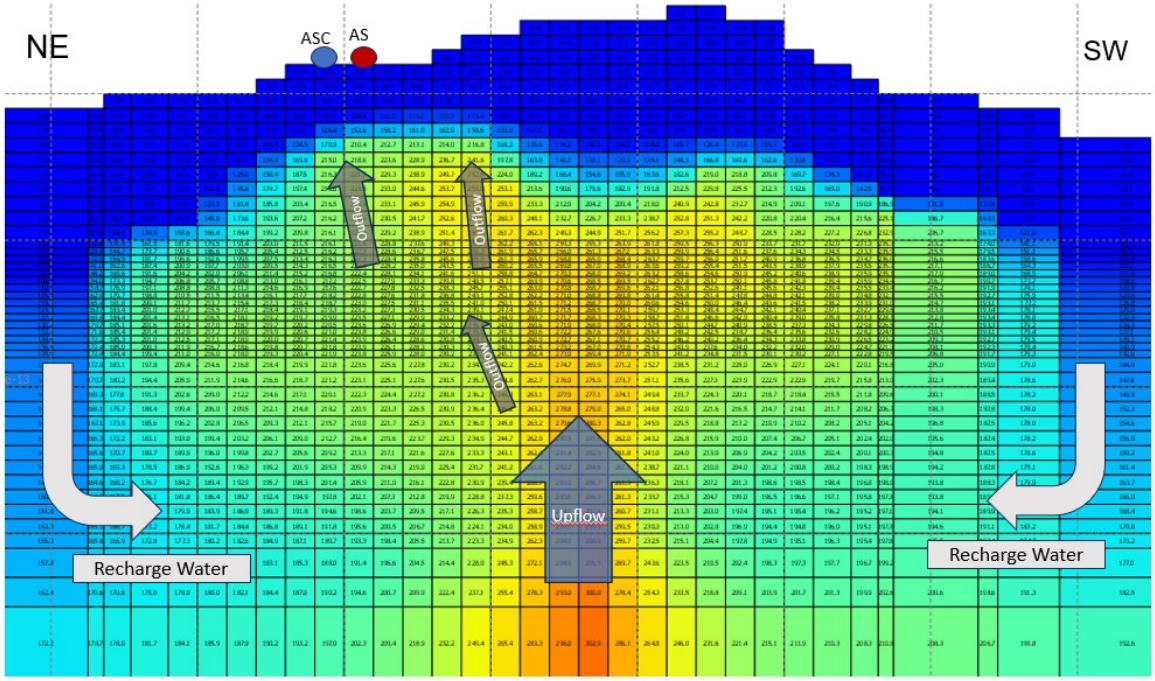

Figure 13: Temperature distribution for steady state for natural state simulation (Visualization in Tim). The slice is taken from Point A to B as per figure 12.

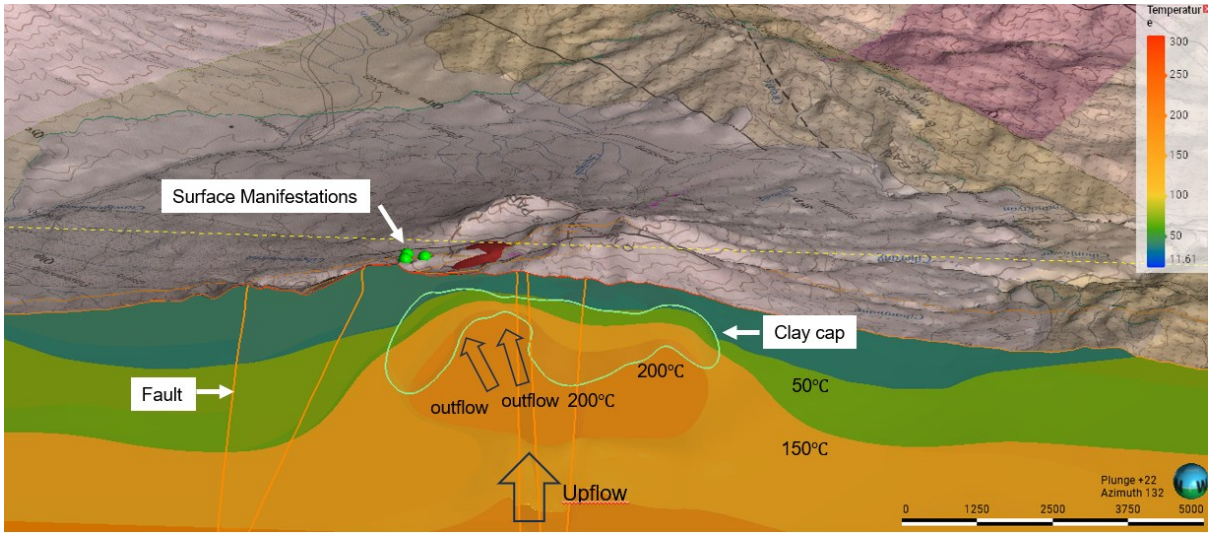

Figure 14: Temperature distribution for steady state for natural state simulation (Visualization in Leapfrog).

9. RESOURCE ASSESSMENT

9.1 Model Generation for Uncertainty Quantification

Model generation for uncertainty quantification are based on geology, structural setting, alteration data, and potential locations of deep up flows (Dekkers, et al., 2022). Based on a random distribution of parameters, the resources assessment method generates unconditioned sample models (prior distribution) that are predefined within a reasonable range of their permeability and porosity as well as their magnitudes of up flow. A probability density function was used to sample the total up flow, with the calibrated-up flow as the mean, as shown in Figure 15. In the first trial, a mean value of 44 kg/s total up flow was obtained by manually calibrating the natural state model, which is used for the uncertainty quantification. Selected blocks by the model calibration are then placed at faults in the bottom layer to distribute the total up flow according to a Gaussian distribution. Figure 16 illustrates variations in total up flow sources at bottom layer of model samples (-1750 masl).

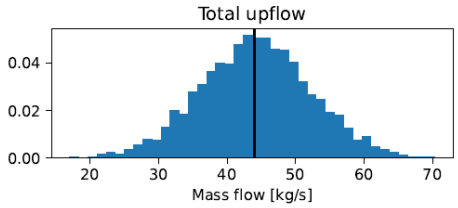

Figure 15: Total Up flow Distribution.

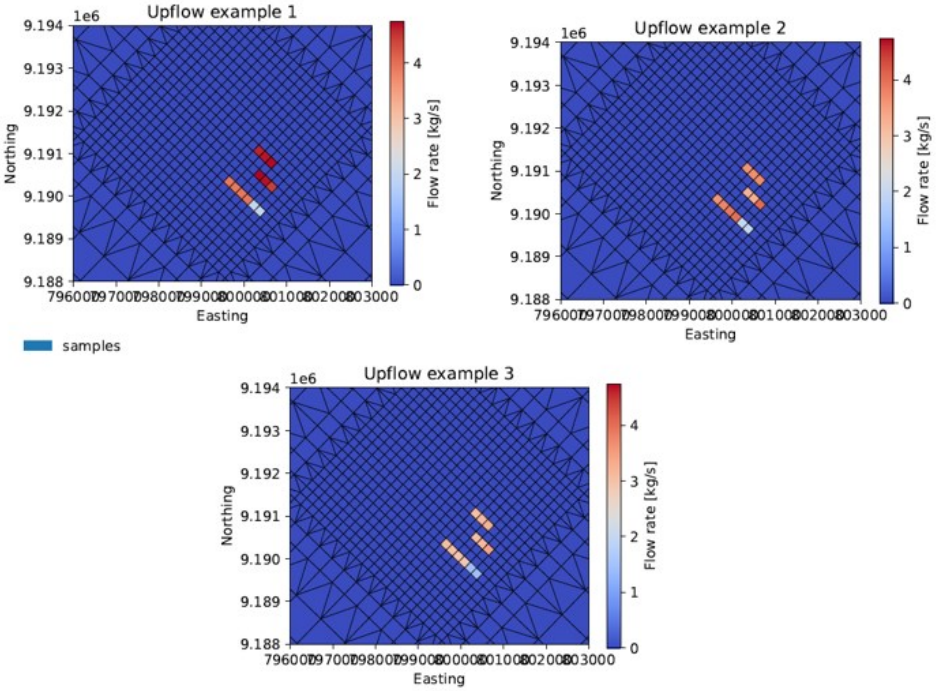

Figure 16: Three examples of up flow distribution at deep up flow sources located at bottom of the sample models' layer 49 (-1750 masL).

Depending on the location of the rock types, e.g., near the surface, deeper, or close to the clay cap, the prior mean rock permeabilities vary. The permeability of the rocks is determined by a combination of the formation permeabilities (base rocks) and modifiers due to structural setting. The modifier is a multiplier factor for calculating the permeability of fault rocks and is based on geological rules. Fault rock permeability should be multiplied by at least 1 along the fault strike and vertical direction. The purpose is to prevent the permeability from decreasing compared to its base rock in those directions. A higher permeability is also expected in the vertical direction of the intersection fault rock. Alternatively, the multiplier for fault rock permeability across the strike of the fault should be maintained to or lower 1 (Beer, et al., 2023). The same principle applies to clay cap permeability, which should have a lower permeability than the corresponding base rock, so the multiplier should be set at 1 or less. Figure 17 depicts examples of permeability in basement rocks (BH001) and how the permeability modifier is assigned to the fault (BH001) that cuts through the basement rocks. The permeability along the fault is k1, the permeability across the fault is k2, and the permeability vertically is k3. The k2 multiplier is lower than 1, and hence the fault rock permeability across the fault is decreasing. Conversely, k1 and k3 modifiers are greater than 1, increasing rock permeability in the k1 and k3 direction.

9.2 Alteration Model Conditioning

By applying Approximate Bayesian Computation (ABC), the steady-state models are filtered based on the temperature and location of the clay cap) (Beamont, 2019). The ABC method is implemented using the *ccandu* (corresponding to conditional composition and uncertainty quantification) Python package developed by the University of Auckland (Croucher A. , et al., 2020). A filtered model with its block distribution can be seen in Figure 18.

The selected block locations are mainly concentrated underneath clay cap dome in the filtered model. Those blocks represent more likely to reach temperatures around 190°C. Clay cap outer blocks away from the dome are not considered because of the uncertainty of the MT inversion at depth and clay cap edge. There are 100 samples that have been filtered down using this clay cap condition.

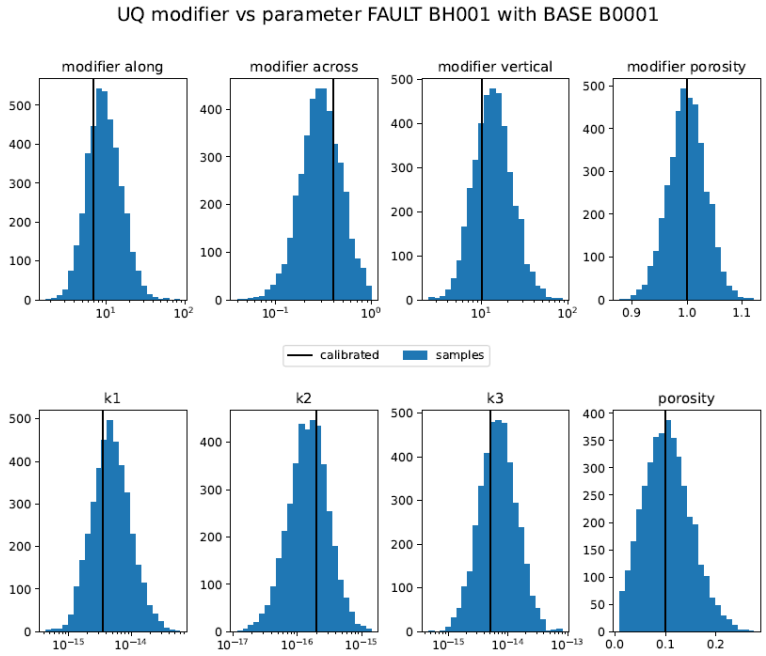

Figure 17: Permeability and Modifier Distribution of Fault BH001.

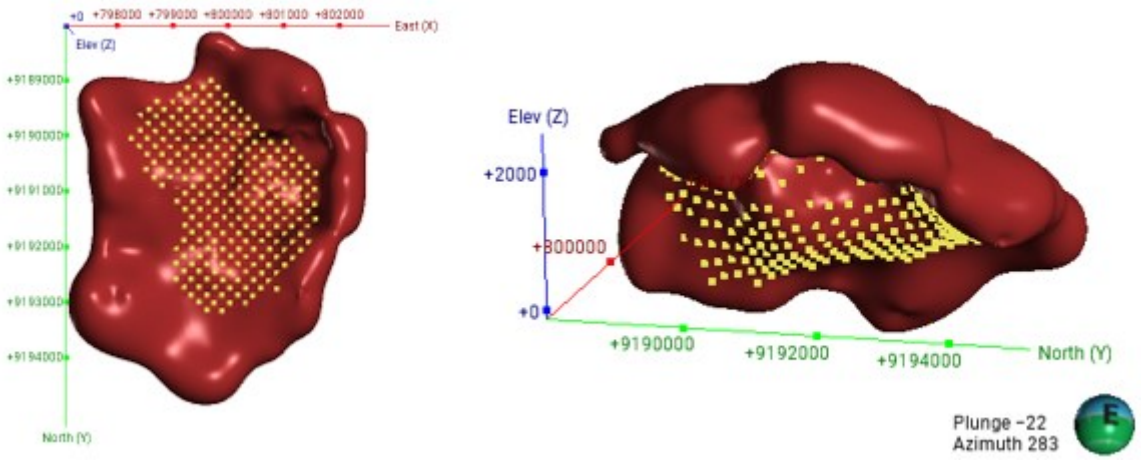

Figure 18: Block samples distribution used for conditioning the models. Down view (left) and angle up view (right).

Comparison between the unfiltered and filtered temperature distributions obtained directly beneath the clay cap is demonstrated in Figure 19. The bright red line is the calibrated model meanwhile the black dashed line indicated filtered model. Blocks under the clay cap are filtered using the ABC method based on 190°C temperature.

9.3 Power Output

In total, 1000 sample models were generated. A total of 100% of the sample models converged to a natural state (NS) when simulated using NeSI (the New Zealand eScience Infrastructure) high-performance computing facility. An average of 2-3 minutes was required to run the model on a single node (40 CPUs). Based on the clay cap temperature distribution, converged samples were conditioned to produce 100 acceptable models for the future scenario (FS). One future scenario sample took about 12 minutes to run using NeSI. The running process is fully parallelizable, and by using 100 nodes with 40 CPUs each, we can accelerate the process. The time run 1000 natural state samples and 100 future scenario samples, excluding setup and postprocessing, can be done within 1 hour, depending on the resources available.

The future scenario was based on a binary power plant using 15% thermal to electrical power efficiency. The net power output in MWe comes from the following equation.

$$Net\ Power\ Output = \left(Enthalphy_{Prod} - Enthalphy_{Inj}\right) x\ \ production\ mass\ flow\ rate\ x\ 15\%\ thermal\ efficiency$$

Figure 20 displays the consolidated results from the selected 100 samples over 25 years of production, detailing power output, gross thermal output, mass flow rate, injection mass flow rate, and enthalpy. According to the resource assessment result, Papandayan's geothermal potential is at least 12.3 MWe (P90) over this period. This means that 90% of the sample models achieve at least this power output. Moreover, the assessment indicates a potential of approximately 18.5 MWe (P50) and 28.4 MWe (P10), representing the reservoir's probable and possible power potentials, respectively.

With this condition steam production is at least 90 kg/s, the production enthalpy is stable at least 1050 KJ/kg for the full simulation, and injection enthalpy is constant at 335 KJ/kg (equal to 80°C liquid water). In addition, a reinjection mass flow rate of over 100 kg/s with at least 70 % Injection mass fraction is assumed to be necessary to achieve this production level.

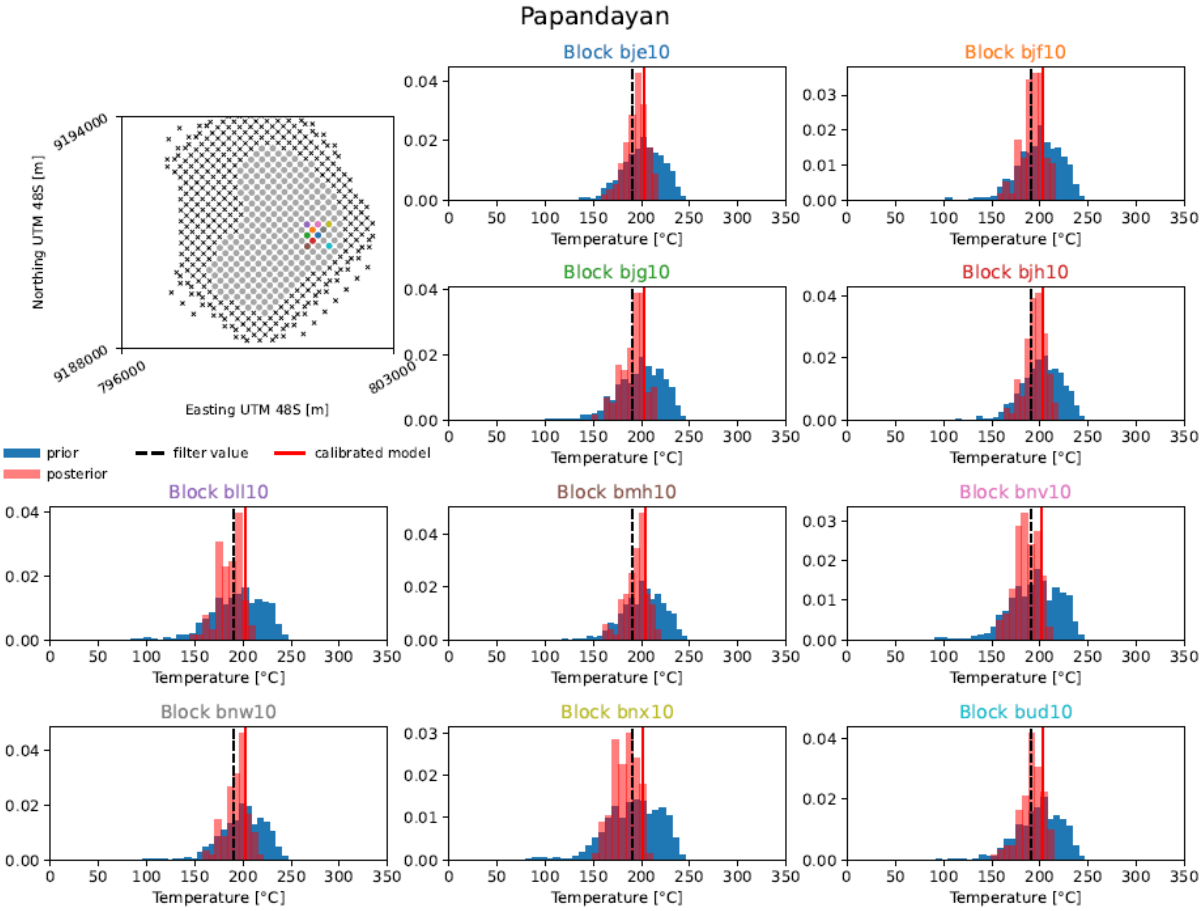

Figure 19: Temperature distributions of 10 selected blocks located directly below the clay cap, unfiltered (blue) and filtered (red).

10. CONCLUSION

Papandayan geothermal field in West Java, Indonesia, has been assessed for its resource potential. Results were obtained by considering the new, 3D natural state model produced using limited public sources and data from The Directorate-General of New Renewable Energy and Energy Conservation in Indonesia (EBTKE). Using an ensemble of acceptable sample models, the resource assessment enhances understanding the potential heat source and the permeability distribution. The approach is expected to give an accurate resource estimate by using the available data.

The natural state model was calibrated to 44 kg/s of up-flow mass rate coupled with an enthalpy of 1400 KJ/kg. The deep up-flow blocks are located across NW-SE faults, and the hot fluid originating from these blocks is capped by an alteration zone. A Magnetotellurics survey cross-section maps were integrated with 3D point data to estimate the alteration zone. Utilizing a high-performance computing facility, 1000 alternative models were generated and simulated, then filtered based on the temperature beneath the clay cap. After filtering, the top 100 most probable sample models were obtained using Approximate Bayesian Computation (ABC). These models

were used to estimate power output for 25 years of simulated production that gives a P10/P50/P90 uncertainty estimates.

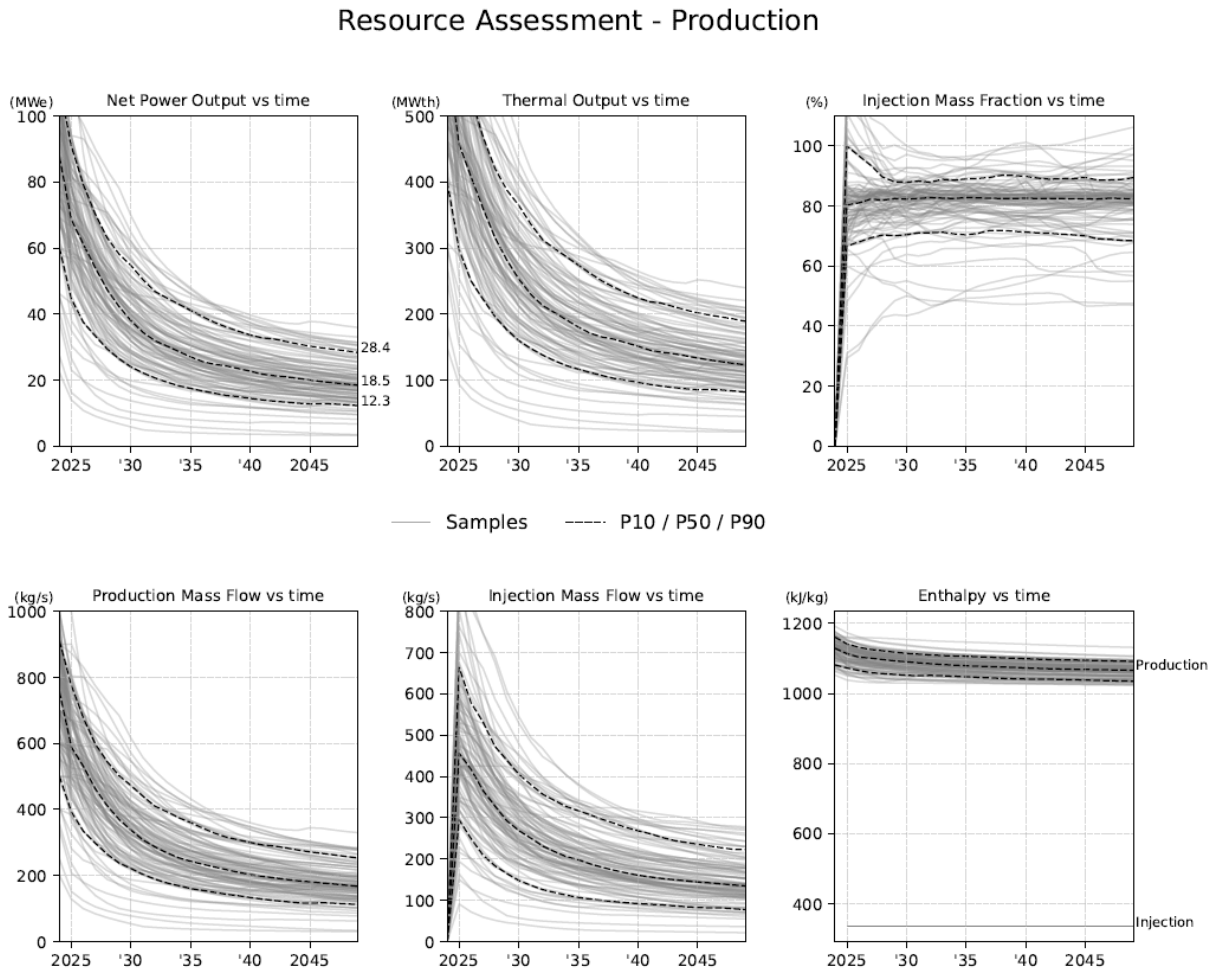

Figure 20: Papandayan Geothermal Field's total resource potential. Graphs from left to right, top to bottom, show estimated thermal power output, steam flow rate, mass flow of production, injection mass flow, and enthalpy for 25 years of production.

The results of the uncertainty quantification of Papandayan resource potential of at least 12.3 Mwe (P90). This potential is close to the estimate of the Indonesia Geology Institution made using the stored heat calculation method, in which the P90 is 16 MWe. By incorporating reservoir physics and realistic energy extraction, we have performed a resource assessment using more detailed parameters and a more realistic representation of the uncertainties.

To increase the confidence of the research study, it is recommended that a more robust geoscience study should be conducted to have an enhanced understanding of the lithology, surface manifestations, and coverage of the alteration zone. Downhole measurements are also valuable in calibrating the model and will reduce uncertainty. A resource assessment based on this study's methodology is very beneficial since it provides a realistic estimate of the resource based on available data, and it can easily be updated based on new field measurements or existing well data. Through seamless operation between the modelling tools, it is possible to modify existing models to be compatible with updated data in a straightforward and intuitive manner. Additionally, stakeholders are more likely to have confidence in the economic viability when more accurate assessments are conducted due to more realistic assumptions.

ACKNOWLEDGEMENT

We acknowledge the support of Indonesia EBTKE (The Directorate-General of New Renewable Energy and Energy Conservation) for providing support of the data and Seequent though the generous license provided for LEAPFROG Energy. In addition, Author would like to say grateful message for LPDP (Indonesia Endowment Fund for Education Agency) for granting the scholarship and supporting the first author financially during master study period.

ABSTRACT

This paper is the continuation of our previous paper, namely, Review of Lithium Extraction Suitable for Indonesia Geothermal Brine. In the competitive and growing lithium extraction from geothermal brine, efficiency plays a crucial role. Activities and its associate resources must be efficiently scheduled in order to maintain satisfactory production, reducing operational costs. However, this is still a critical and difficult task. This paper presents a decision support system including three scenarios such as direct lithium extraction only, direct silica extraction only, and hybrid extraction of both lithium and silica. The decision support system will determine the most robust among those three scenarios. A successful application of this decision support system will be executed by lithium and or silica extraction system over 10 years or more of time horizon. With direct lithium and or silica extraction sizing and scheduling results that will be implemented in the company, this case study deals with investments in the order of hundred millions of dollars.

1. INTRODUCTION

Lithium is the cornerstone of energy transition because of the following two reasons, the first reason is that it has the key ingredient in batteries for electric cars and renewable power storage, making it a critical commodity for the energy transition to reduce emissions of greenhouse gases. And the second reason is that Lithium is a big enabler of the energy transition from a battery perspective as we move to electric vehicles and add energy storage to electricity grids, allowing for greater penetration of renewables. As a result, lithium is increasingly being seen as a critical mineral by governments, where they want to secure supplies for that transition, and that has made it an increasingly important commodity. In line with this cornerstone of energy transition, Indonesia is committed to achieve Net Zero Emissions by 2060 or earlier and is beginning to put in place the policies and frameworks that can help reach this target while moving towards advanced economy status.

Lithium is an alkali metal that typically occurs in brine as LiCl. This LiCl solution is concentrated and purified through various processes and is then converted to high-purity Lithium Carbonate Li_2CO_3 and/or Lithium Hydroxide Monohydrate $LiOHH_2O$ commercial products. In the produced geothermal brines, consisted of the following chemical components such as Li, Fe, Si, Ca, Mg, Na and may include additional components such as K, B, Al, Sr, Mn, Cu, Ba, Zn, Ni, Cr.

Silica is one of the most common components of geothermal fluids and it is an important material for development of renewable energy, namely it is the main component for silicon solar cell. Silica is also used in applications in rubber, plastics, paint, paper, ceramics, pharmaceuticals, pesticides, chemical and odor absorbents, and adhesive industries.

Due to its importance and high investments for manufacturing both for instance high-purity Lithium Carbonate (Li_2CO_3) and or silica (SiO_2) crystalline nano-powder, these industries present an enormous potential of growth. To fully sized and optimized the development of these potentials are critical and simulated using a decision support system such as capital budgeting and investment for a decision making process.

The next sections in this paper present the desk study of decision support system with inputs such as Capital Expenditure (CAPEX), Operational Expenditures (OPEX), and Working Capital. A specification of Financial Model (Excel) is developed as a basis for calculating Net Present Value Finally, a conclusion is made with based on Financial Model for Capital Budgeting and Investment.

2. DESK STUDY OF DECISION SUPPORT SYSTEM

Direct Lithium Extraction (DLE) Adsorption is a commercial technology possibly could be adapted and suitable to Indonesia Geothermal Fields for the following reasons it has a fifty-year development and implementation

history, practiced commercially in South America for 26 years and recently in China, higher lithium recovery, lower water and chemicals consumption, shorter lead time to production, minimal footprint, potential for no carbon emissions, and an additional revenue stream from unused brine resources for geothermal power producers.

Adsorption is the most developed DLE technology globally, using adsorbents to adhere to the lithium for selective removal. Some sorbents developed can recover >90% of the lithium present, including recently tested lithium aluminium layered double hydroxide chloride sorbent, or LDH (Lithium-Aluminium Double Hydroxide Chloride). During more recent testing, the LDH sorbent was made by intercalating (inserting) aluminium hydroxide with lithium chloride, which made several $[LiAl_2(OH)_6]^+$ layers in the sorbent. These layers were separated by water molecules and hydroxide ions that created spacing requirements to allow lithium chloride to enter more readily than other ions, such as sodium and potassium. After the sorbent was loaded with the lithium chloride, it was washed with a diluted lithium chloride stream to remove unwanted ions, then washed a second time to unload the lithium chloride.

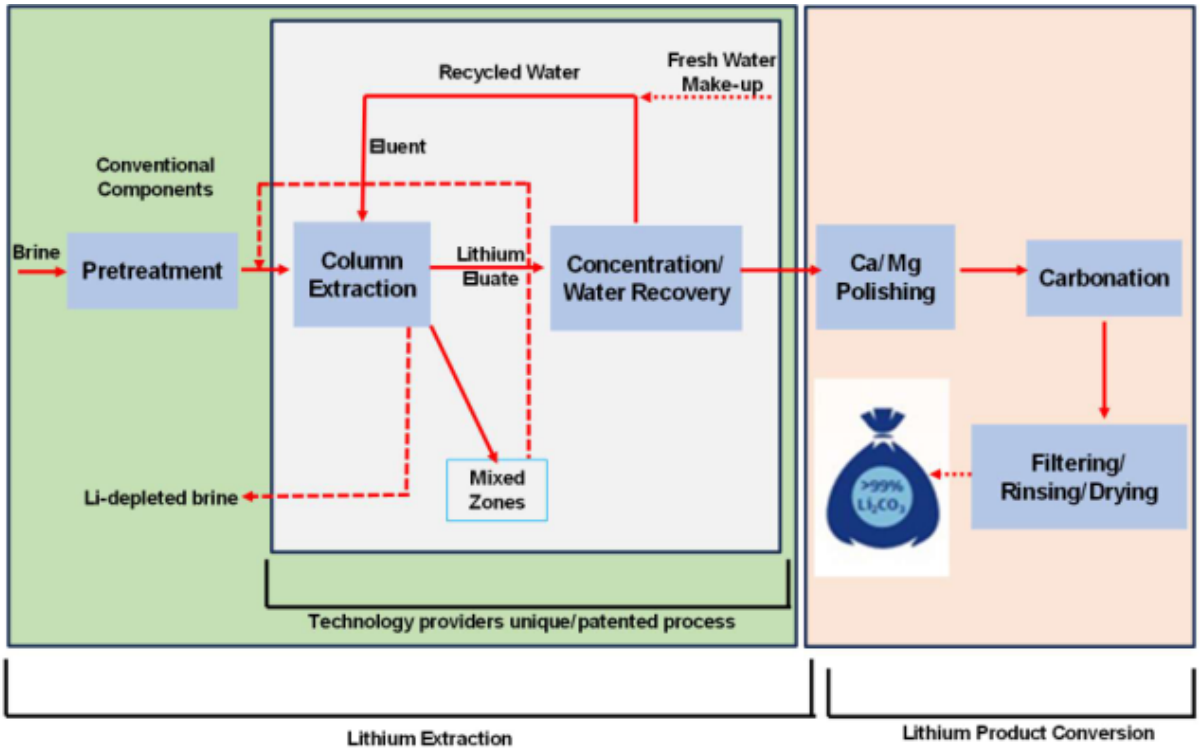

Figure 1: DLE Flow Chart (Goldman Sachss, 2023).

Pre-Feasibility Study and/or Pilot Scale in the Technical Feasibility Study of Direct Lithium Extraction (DLE), with reasonable assumptions, can provide guidance for estimating costs of lithium extraction from geothermal brines. The following table summarizes report in National Renewable Energy Laboratory (NREL) US Department of Energy in May 2021 (Warren, 2021) on DLE Project Economics. Capital Expenditures (CAPEX) are a company's major, long-term expenses while operating expenses are a company's day-to-day expenses. Examples of CAPEX include physical assets, such as buildings, equipment, machinery, and vehicles. Operating Expenses (OPEX), refer to the costs that a business incurs through its normal day-to-day operations. Examples of OPEX include employee salaries, rent, utilities, and property taxes. Working Capital is a financial metric that indicates the difference between a company's current assets and current liabilities. It is the day-to-day cash that a company needs to run business operations. Working capital helps plan for future needs and ensure the company has enough cash and cash equivalents to meet short-term obligations, such as unpaid taxes and short-term debt.

The main focus of this present study was limited to understanding techniques and costs made publicly available by companies with projects advanced to stages of development and investment that require formal reporting to pertinent institutions. These projects were focused on geothermal, salar (brine from salt-flat or lakebed), oilfield, and evaporite brines, all of which were informative for estimating costs of lithium extraction from geothermal brines. Eventually, a specific geothermal fluid will require a best-lithium extraction processes, or combination of processes, based on fluid composition and physical and chemical requirements related to power generation and reservoir management. The authors have researched that far for CAPEX, OPEX, and Working Capital of adsorption DLE from geothermal brines in the public domain. And there have not been any case studies from companies that have researched it to date. It is all still under research. And as such that is an issue that needs to

be added to this paper for further research. But for financial modeling with the specification in Figure 2, let us assume for adsorption DLE from geothermal brine for lithium factory at 2,000 ton/year CAPEX $ 60 million, OPEX $ 6,000/ton, and Working Capital $ 4 million.

By using decision support system like excel financial model, sizing and optimizing geothermal brines for Lithium Factory can be done with sensitivity analysis.

The technology for silica extraction from geothermal brine (Nursanto et l., 2023) is presented in Figure 3 Block Flow Diagram of Silica Plant.

Silica Factory from geothermal brine (Assume $ 1 = Rp 15,000) for 5,000 ton/year CAPEX $ 80 million, OPEX $ 5,450/ton, and Working Capital $ 13 million.

By using decision support system like excel financial model, sizing and optimizing geothermal brines for Silica Factory can be done with sensitivity analysis.

3. CONCLUSION

By using decision support system like excel financial model, sizing and optimizing geothermal brines for Silica Factory can be done with sensitivity analysis. The financial model also can describe whether the lithium and silica factory are feasible to be built in Indonesia. The authors have researched that far for hybrid both Lithium and Silica extraction and manufacturing together are not yet successful to date. And as such the lithium factory and silica factory will be done each by different company.

ABSTRACT

In a mature geothermal field with a dense well population, robust well targeting is essential to understand possible interference between make-up well targets with existing production wells during drilling. In a field with fewer production wells and ample steam buffer, production wells near the drilling area are often shut in temporarily to prevent adverse effects from drilling fluid. However, in a field with limited steam buffer, completely shutting in certain production wells is not always feasible due to the need to maintain steam supply for optimal power generation, therefore a specific well throttling scenario is required throughout the drilling of the reservoir section.

In Darajat Geothermal Field, a well throttling scenario is developed based on feed zone distance between new and existing well retrieved from 3D model. Monitoring of the nearby production well is conducted using real-time production data such as WHP and flowrate, meanwhile, daily geochemistry sampling is conducted to monitor other parameters like non-condensable gas (NCG) levels, superheat, pH, and total dissolved solids (TDS) in steam. Aside from the drilling impact on production wells, to avoids generation loss due to high NCG at power plant, geochemist also perform NCG monitoring at interface. Prior to drilling execution, the Geochemist also makes an estimation of the NCG content at power plant based on historical NCG increase trend, and the entry distance of the new well with existing production wells. These proactive approaches have been successfully implemented in multiple drilling campaigns at Darajat to prevent negative impacts on production wells and minimize disruption in power generation.

1. INTRODUCTION

Darajat geothermal fields are located within a mountain range of inactive andesitic volcanoes. They lie along the main trend of Sunda Volcanic Arc which extends from Sumatra to Flores (Hamilton, 1979; Hutchinson, 1989) (Figure 1). The field is located in the Kendang volcanic complex, which is a part of a Quaternary volcanic range in West Java that includes the active Gunung Papandayan (last eruption in 2002) and Gunung Guntur (last eruption in 1840) (Hadi et al., 2005; Rejeki et al., 2010). The Darajat geothermal field in West Java, about 230 km southeast of Jakarta (Figure 1), is the largest steam-dominated geothermal resource in Indonesia with an installed capacity of 271 MWe. Commercial production at Darajat commenced in 1994 with the commissioning of the 55 MWe Unit I. This was followed by Unit II (95 MWe) in 2000 and Unit III (110 MWe) in 2007. In 2009, the successful drilling campaign in 2007-2008 developed enough steam to allow Unit III to generate at 121 MWe; thus, increasing the installed capacity to the current 271 MWe. Under Joint Operation Contract ("JOC") with PT Pertamina Geothermal Energy ("PGE"), a subsidiary of PT Pertamina (Persero) (a state-owned oil and gas company), Star Energy Geothermal Darajat II, Limited ("SEGD") supplies steam to Unit I, owned by PT PLN (Persero) and operated by its subsidiary, PT Indonesia Power, and produces electricity from Unit II and III (Intani et al. 2021).

Continuous mass extraction from this field consequently promotes decline in well production due to pressure drawdown. Make-up well drillings are conducted periodically to maintain steam supply to the Darajat power plants. During well drilling, especially in the reservoir section, injection of drilling fluid to reservoir could foster adverse impact to nearby production well.

In a steam-dominated field like Darajat, an undesirable effect related to drilling fluid can be observed such as condensation due to low-temperature drilling fluid, scaling in nearby production well, and NCG increase related to air drilling. Permeability damage in a nearby well once observed during drilling with mud in the reservoir section. It occurred a long time ago, and now drilling of the reservoir section in Darajat only utilizes water / condensate.

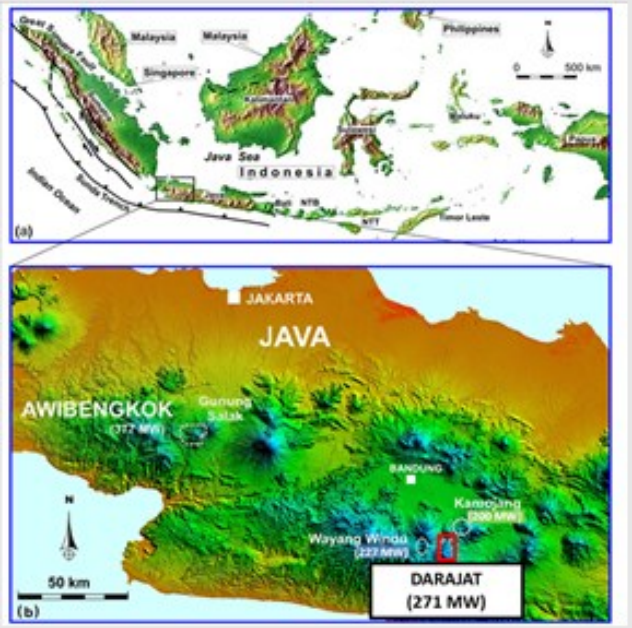

Figure 1: Location map shows Darajat contract area (red polygons).

To avoid the said effect above, most production wells near the new well trajectory are often shut in. However, shut in production wells could only proceed if sufficient steam buffer is available to support full generation. In cases of optimizing the steam buffer, sometimes completely shutting in certain production wells is not always feasible due to the need to maintain steam supply for optimal power generation.

This paper emphasizes more on the method to maintain existing well production, including minimize generation loss from increased non-condensable gas (NCG) and steam shortages due to wells shut in. The practice includes a detailed examination of a specific well throttling scenario, along with geochemical sampling and continuous production data monitoring.

2. METHODOLOGY

Monitoring activities during drilling can be divided into two distinct phases. The initial phase, termed preparation, or pre-drilling activity involves essential tasks completed prior to drilling commencement. This phase includes defining the well throttling strategy and planning the geochemistry sampling program. In contrast, the subsequent phase occurs during reservoir section drilling, primarily focusing on executing the monitoring program and setting up tactical strategies in response to any observed anomalies (see Figure 2).

To establish a dependable well throttling strategy and geochemistry monitoring program during drilling operations, it is crucial to have a robust well targeting framework as a foundational reference. In Darajat, the well targeting approach utilizes natural fracture modeling method for well placement, this method using fracture drivers to map the location of producing fractures (Intani et al., 2022) by using the natural fracture modelling method, which relies on specific criteria to identify optimal drilling locations and feed zone estimations within the well. This methodology ensures a clear trajectory and accurate estimation of the feed zone's location, essential for assessing proximity to existing wells.

In Darajat, a guideline based on historical data has been developed to determine the minimum separation distance between a new well target and the feed zones of existing offset wells. According to this guideline, the well throttling program is structured as follows:

200 - 250 m : Throttle offset production well to 25%
150 - 200 m : Throttle offset production well to 50%
< 150 m : Shut-in offset production well(s)

This throttling program were developed based on monitoring experience during drilling and have been calibrated through multiple drilling campaigns in Darajat to establish the most effective structure. However, these rules may vary by field depending on factors such as reservoir condition and fracture types.

For the geochemistry monitoring program, wells located within a 250-meter radius from the lateral distribution midpoint of the new target well are selected for sampling activities. Baseline geochemistry sampling is conducted

on these wells before reservoir section drilling begins, providing a reference for subsequent analyses. During reservoir section drilling, geochemical sampling focuses on several key parameters: NCG (Non-Condensable Gas), TDS (Total Dissolved Solids), pH, and Superheat. Monitoring NCG is particularly crucial because it often exhibits an increasing trend during drilling, attributed to air drilling or condensation in nearby wells. NCG, being a natural component of geothermal fluids, can have a significant impact on the operational efficiency of geothermal power plants (Özcan and Gökçen, 2010). Meanwhile, superheat value can indicate the arrival of drilling fluid in nearby production wells. At Darajat, additional parameters such as TDS and pH are also monitored. Since drilling fluid has higher TDS and pH compared to the steam condensate, these parameters provide further insight into the impact of drilling fluid on nearby production wells.

In estimating the increase in NCG in the well and power plant, historical data during normal production indicates that wells located closer to the midpoint production of the new target well (within 250 m) tend to exhibit a higher trend of NCG increase compared to those further away or with different trajectories. NCG levels typically show a gradual increase during drilling operations, peaking before stabilizing and potentially declining once the drilling concludes. Based on historical trends, NCG increases in wells with lateral distances less than 250 m can exceed five times the baseline data, highlighting the variability and importance of monitoring and strategic management during drilling operations

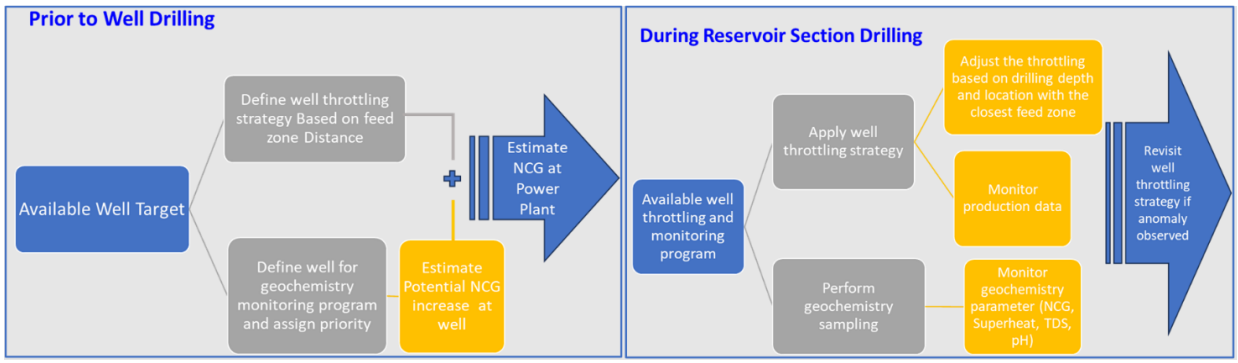

Figure 2: Flowchart of geochemistry monitoring program activity prior to well drilling and during reservoir section drilling.

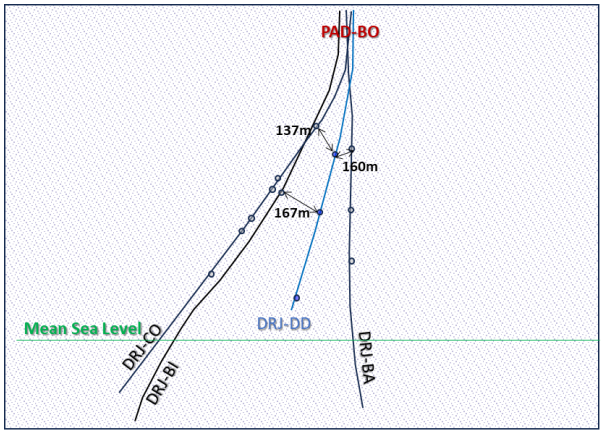
Geochemists should create an NCG mass balance calculator to estimate the impact of NCG increase at production wells on each power plant. The NCG Mass balance is a simple spreadsheet which includes the mass flow rate and NCG from production wells supplying each unit. This NCG mass balance spreadsheet should include the adjusted mass flowrate resulted from the throttling program to calculate a better NCG estimation at the power plant. Accurate NCG estimation at power plants are needed to make sure NCG handling capacity at the power plant is sufficient to overcome the NCG increase, or else the unit might be degraded, and some adjustments should be made to the well throttling program or NCG removal system. During reservoir section drilling, geochemistry monitoring is conducted on the selected nearby well. Initially, wells with close distance (<250 m) should be monitored daily, meanwhile the wells with further distance (250 – 500 m) can be monitored every two days. Aside from geochemistry data, online production data of neighboring wells is also being monitored to see if any data anomalies appear. The frequency of geochemistry sampling can be adjusted according to the monitoring result. The well throttling strategy could also be adjusted if any anomaly occurs in the monitored well, which gives a bad sign to the production.

3. RESULT AND DISCUSSIONS

In the last couple of drilling campaign in Darajat, the well throttling strategy and well monitoring program during drilling have been carried out. This practice is essential to ensure optimum power generation and maintain well productivity during drilling.

3.1 Well Monitoring Result

An illustrative example of a well throttling program can be observed during the drilling of DRJ-DD in 2019, where nearby wells with feed zones less than 250 meters away were subject to specific operational adjustments. According to table in Figure 3, two such wells were throttled, while one located within less than 150 meters had to be shut in. To mitigate steam loss resulting from throttling, a dynamic strategy was implemented, adjusting throttling in response to the drilling progress. As the drilling depth moved away from the targeted zone, the throttling rates were modified to optimize flow from the affected wells.



Offset Well	Min. Distance	Closest Target	Mitigation
DRJ-CO	137 m	Target 1	Shut in
DRJ-BA	160 m	Target 1	Throttling 50%
DRJ-BI	166 m	Target 2	Throttling 50%

Figure 3: 3D visualization depicting the distances between the new well target and identified feed zones in offset wells, alongside details of the implemented throttling strategy as shown in the accompanying table.

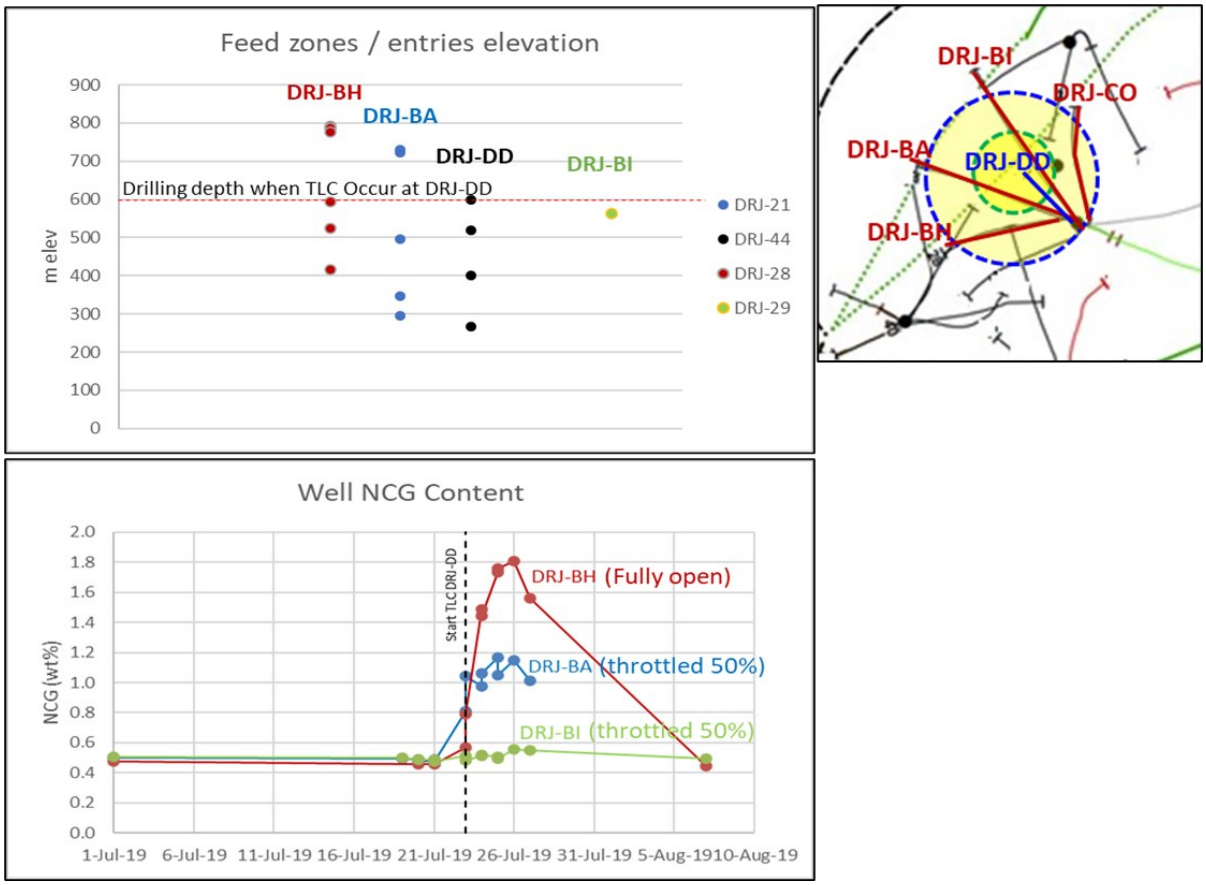


Figure 4: Graphic represents the correlation between well feed zones, TLC depths, and NCG increases observed in surrounding wells during DRJ-DD drilling.

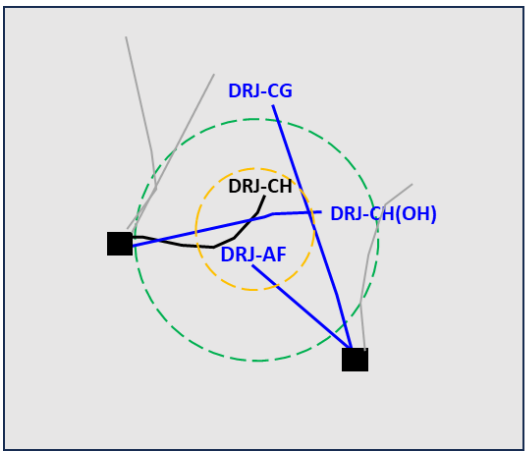
During the DRJ-DD drilling, geochemistry monitoring revealed an increase in Non-Condensable Gas (NCG) coinciding with Total Loss Circulation (TLC) events. Significant NCG elevation was observed at offset wells located within a 250-meter radius from the midpoint production of DRJ-DD (see Figure 4), including DRJ-BI and DRJ-BA, which were among the throttled wells. Particularly, DRJ-BH, situated within a 500-meter radius from DRJ-DD, exhibited a significant NCG increase, peaking at 3.6 times the baseline value. This increase surpassed that of DRJ-BA and DRJ-BI, potentially influenced by factors such as similar entry elevations and higher mass extraction towards DRJ-BH compared to the closer wells.

Conversely, no significant changes in TDS (Total Dissolved Solids) or superheat were detected in these affected wells, suggesting that the NCG rise was likely associated with air drilling rather than condensation due to the

introduction of drilling fluid injection. Moreover, no production anomalies were reported from these wells during the NCG increase phase.



Offset Well	Min. Distance	Closest Target	Mitigation
DRJ-CH (OH)	55 m	Target 1	plugged
DRJ-AF	161 m	Target	Throttling 50%
DRJ-CG	225 m	Target 2	Throttling 25%

Figure 5: Lateral view depicting the distances between the new well target and identified feed zones in offset wells, complemented by details of the implemented throttling strategy as outlined in the accompanying table.

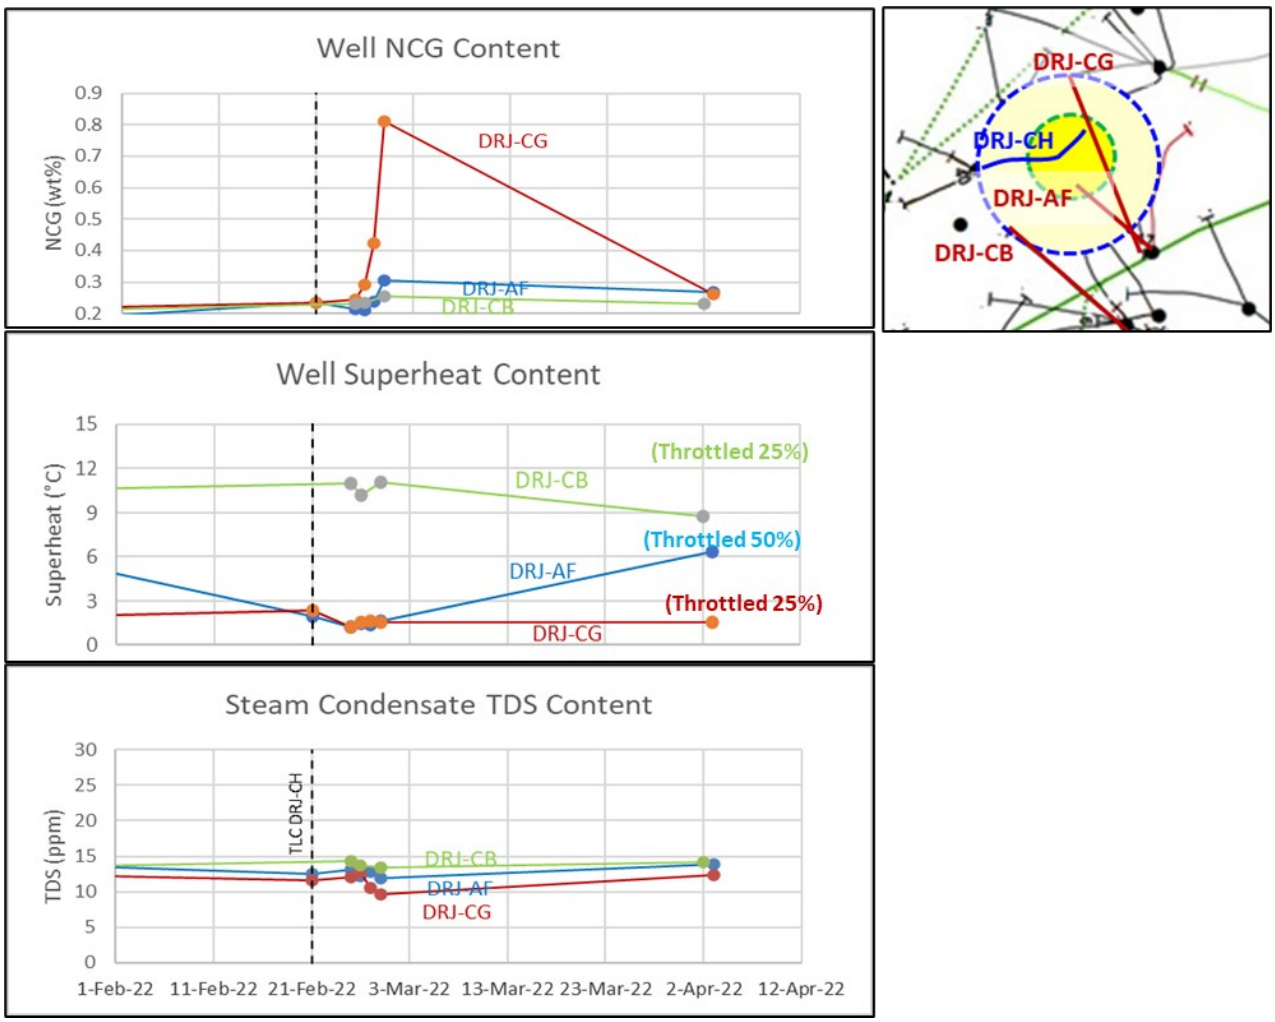


Figure 6: Graphic showing NCG increase and other observed geochemistry parameter in surrounding wells during DRJ-CH drilling.

Another example of effective throttling was applied during the DRJ-CH reservoir section drilling in 2022. Throughout this period, the DRJ-AF and DRJ-CG wells were operated at throttling rates of 50% and 25%, respectively. Significant increases in NCG were noted at the neighboring wells, DRJ-AF, and DRJ-AG, which are situated within a 250-meter radius of the midpoint production zone. Particularly noteworthy was the NCG increase at well DRJ-CG, where levels spiked up to four times higher than the baseline measurements, highlighting the complexities and impacts of operational adjustments during the drilling process. This finding again highlight correlation between higher mass extraction and flow streamline which affect NCG increase in the nearby well.

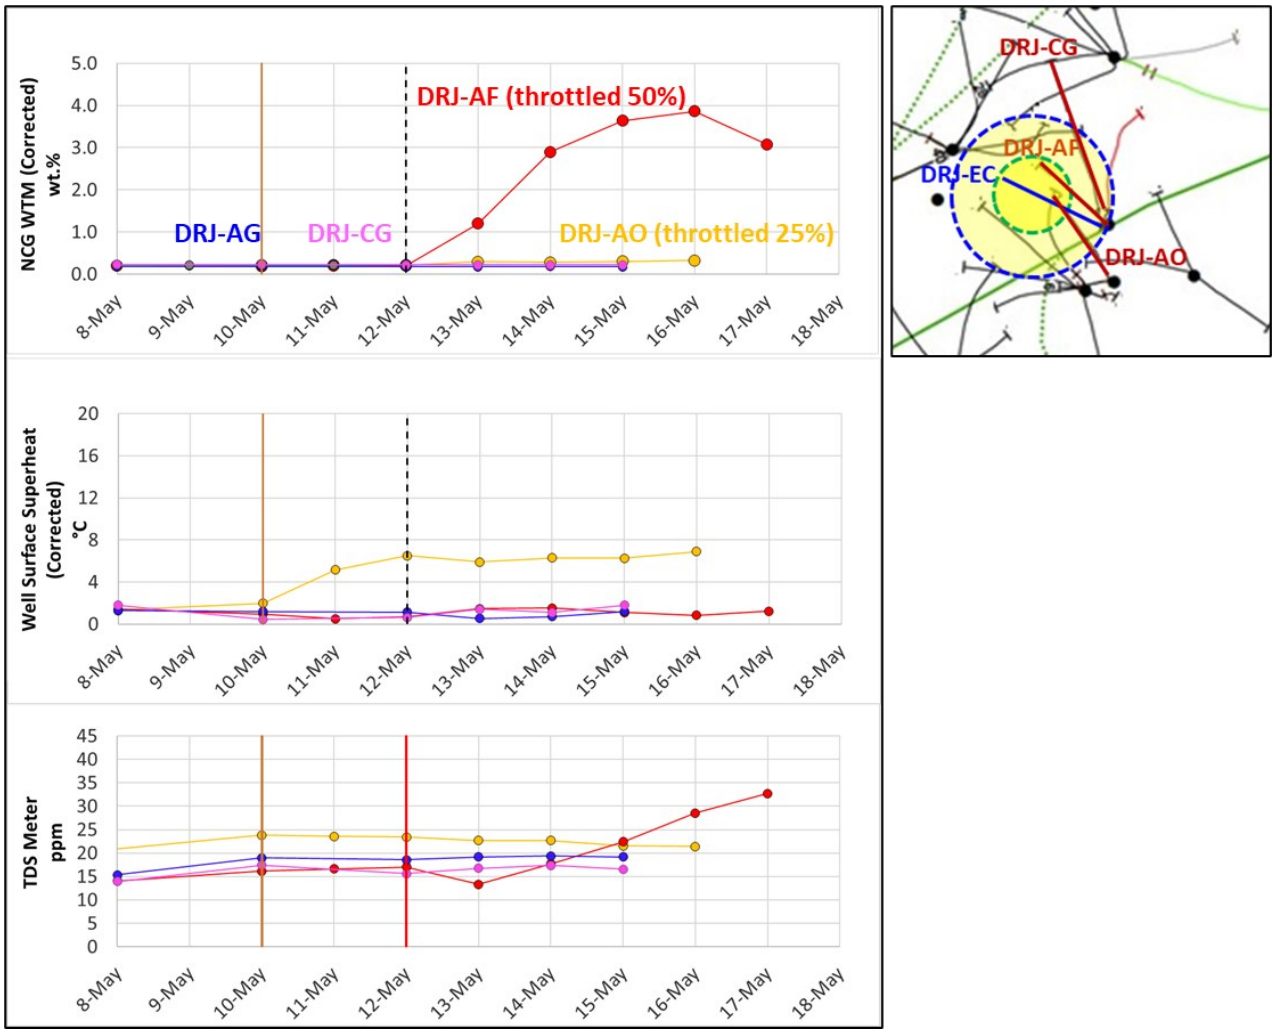

Figure 7: Graphic showing NCG increase at DRJ-AF and which was followed by TDS increase, suggesting drilling fluid effect in produced steam.

However, no pH and superheat change observed from these affected wells, suggesting the NCG increase was more related to air drilling instead of the condensation due to arrival of drilling fluid injection. The same condition as observed in nearby well during DRJ-BH drilling in 2019.

In the most recent drilling campaign, ongoing at present, a distinct trend in NCG increase has been noted compared to previous years. During DRJ-EC drilling, several nearby wells were temporarily offline due to unit shutdowns. Amid reservoir section drilling, DRJ-AF and DRJ-AO were throttled at rates of 50% and 25%, respectively. However, following TLC events at DRJ-EC, DRJ-AF experienced a significant NCG increase, rising up to 19 times the baseline value, exceeding recorded historical trends in Darajat. Conversely, DRJ-AO exhibited only a 1.3-fold NCG increase from baseline. The anomaly in DRJ-AF's NCG increase is attributed to surrounding wells' shut-in conditions, causing accumulated NCG from air drilling to be extracted at the nearest well, DRJ-AF. Despite the NCG increase, no production declines were observed from DRJ-AF (see Figure 8). However, the observed change in TDS and pH trends in DRJ-AF suggests the potential presence of drilling fluid reaching this well, in addition to air drilling components.

Geochemical monitoring is conducted not only at production wells but also at the power plant interface during reservoir section drilling. The primary objective of this monitoring at the power plant interface is to track the NCG

(non-condensable gas) content and ensure it remains within the handling capacity of the power plant. In recent drilling campaigns at Darajat, the implementation of a well throttling system has successfully kept the increase in NCG levels at the power plant below the capacity threshold of the Unit GRS system. Figure 9 below exhibits NCG increase at Darajat power plants during drilling in 2022. NCG increased significantly at Unit-B, but still below the NCG handling capacity of Unit-B at 1.5 wt.%.

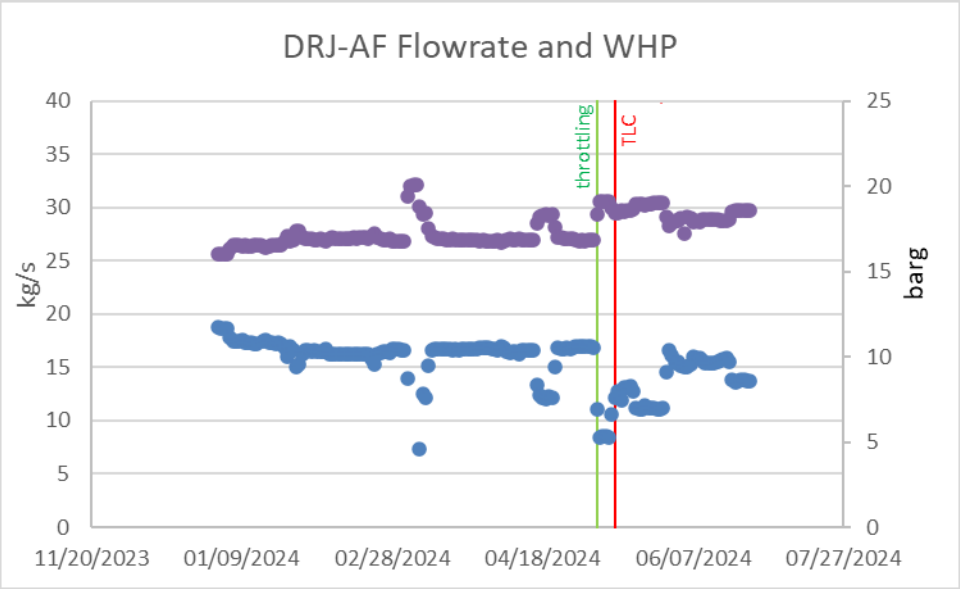

Figure 8: Production profile of DRJ-AF during drilling no indication of production anomaly observed during the high NCG increase in this well.

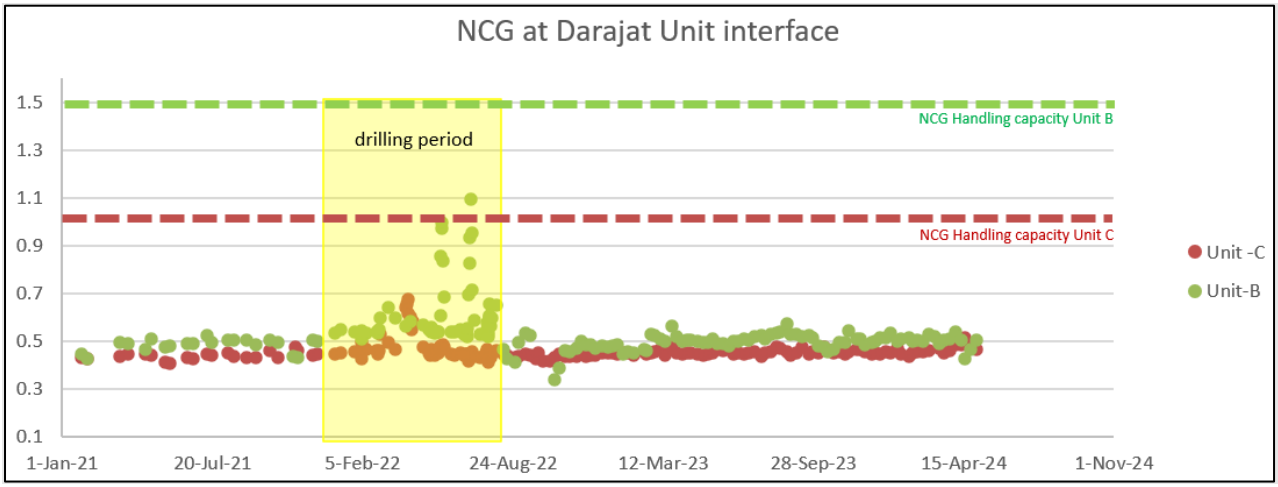

Figure 9: The NCG profile at the DRJ Unit-B interface during drilling in 2022 showed an increase up to 1.1 wt%. However, this remains below the handling capacity of Unit-B for NCG

3.2 Discussion

Observing the pattern of NCG increase in nearby production wells during drilling activities in Darajat reveals that beyond factors like feed zone distance, structure trend and well azimuth, mass extraction dynamics significantly influence the direction of NCG accumulation due to air drilling. Given the lower density of gas from air drilling compared to steam, it tends to accumulate in the shallower parts of the reservoir and migrates towards areas of lower pressure or higher mass production during specific operational phases, potentially shifting as operational conditions adjust. Interestingly, in Darajat, there appears to be no clear correlation between productivity of the drilled well and NCG increase in adjacent wells, suggesting that NCG elevation does not necessarily indicate a proportional impact on production.

Nevertheless, conducting thorough geochemistry monitoring provides substantial benefits on the production front, enabling preventive measures to mitigate any adverse effects on existing wells by promptly analyzing geochemistry data alongside production metrics. This proactive approach allows for timely mitigation strategies to be implemented upon identifying any indicators from the monitored data. Furthermore, having prior knowledge

of potential NCG increases in production wells and power plants facilitates readiness to manage higher NCG levels if they exceed operational thresholds, ensuring continuous and efficient power generation.

On top of that, the expense of deploying this monitoring program is considerably less than the potential hazards arising from inadequate well throttling strategies and monitoring. By integrating this program, the likelihood of production decline due to condensation or scaling in production wells during drilling is minimized, thereby safeguarding against revenue loss from reduced generation output.

ACKNOWLEDGEMENT

We thank Star Energy Geothermal Darajat II, Limited (SEGD) and for supporting this project and Pertamina Geothermal Energy (PGE) granting permission to publish this paper.

ABSTRACT

The Dieng Plateau in the Central Java Province of Indonesia is known for its significant geothermal potential, particularly within the Dieng Geothermal Field. This paper presents a comprehensive analysis of the geothermal resources and heat demand in the area, focusing on the potential benefits of recovering separated brine as a heat source. The study includes an assessment of the local community's heat demand for bathing, with a survey indicating that 82.7% of respondents use hot water for bathing, primarily utilizing gas (LPG) for heating. Furthermore, the paper discusses the operational details of geothermal power plants in Dieng and highlights the significant amount of unused energy in the form of separated brine. The energy analysis demonstrates the potential for utilizing brine as a heat source, presenting advantages for the company, local communities, and the government. Based on the heat demand survey, every household's total energy consumption in one month was about 703 Gcal or 35,334 GJ/year. This amount of energy is equivalent to 18% of the annual energy consumed by each individual in Indonesia. Currently, PT Geo Dipa Energi uses a single flash system in which the separated brine is not utilized yet. It is potentially to recover the heat of 68.8 MW from this separated brine. The proposed recovery method involves using a counter-current heat exchanger made of stainless steel to prevent corrosion, with the separated brine flowing through the tube side and the groundwater flowing through the shell side. The calculated recovery energy is 28,190 kW, representing 40% of the total energy in the separated brine. Implementing separated brine heat recovery could bring various benefits, including creating a new revenue stream for the company, adopting a techno-social approach, ensuring a sustainable hot water supply, reducing carbon emissions, promoting education and tourism, and affecting the geothermal development. Moreover, there is potential for a reduction in government subsidies for providing natural gas, which could amount to Rp2,876,841,485 annually or lead to a decrease in gas consumption for providing heat in Dieng amounting to Rp4,018,581,255.

1. INTRODUCTION

Located in the regions of Wonosobo, Banjanegara, and Batang in the Central Java Province of Indonesia, the Dieng Plateau is an area of great geothermal interest. It is part of the Dieng Volcanic Complex (DVC) and is known for its diverse geothermal features, including fumaroles and hot springs. This region, referred to as the Dieng Geothermal Field, encompasses a high-temperature liquid-dominated reservoir spanning over 9.5 square kilometers. Studies have indicated that the Dieng geothermal field has the capacity to produce approximately 355 MW of power, primarily from the Sileri, Sikidang, and Pakuwaja sectors (Boedihardi et al., 1991 in Harijoko et al., 2016). Currently, geothermal energy is mainly utilized indirectly, with electricity generation sources being the primary form of utilization. PT Geo Dipa Energi (Persero) is a Special Mission Vehicle under the Indonesia Ministry of Finance, which is tasked to develop and operate a geothermal power plant in the Dieng Geothermal Field. Currently, two power plants produce geothermal energy in Dieng Geothermal Field: Dieng Unit-1 60 MW and Small-Scale Geothermal Power Plant (DSSGPP) 10 MW. The other utilization is direct utilization in the form of tourist attractions such as fumaroles and hot spring pools. Local communities mostly manage the hot spring pool, while the government owns the geothermal manifestation, such as fumaroles.

The Dieng plateau is situated 2000 meters above sea level, resulting in a temperature of around 16°C (see Figure 1). Compared to Jakarta, there is a 13°C temperature difference, making Dieng an attractive tourism destination for those who enjoy cooler weather. Based on weather measurements taken in 2023, the temperature is relatively high at the beginning and end of the year, while it reaches the lowest point around August. Sometimes in August-September, the temperature drops below 0°C, leading to "embun upas", a crystallized fog, formed in the surrounding area of Dieng (see Figure 2). This condition has led the local community to adapt by using hot water for household needs such as bathing. The research on energy demand focused on conducting an initial survey to

understand people's behavior regarding energy use for heating purposes. It is important to note that the research was limited to capturing the energy demand specifically for bathing. According to the survey, 82.7% of respondents use hot water for bathing, while the rest opt for other alternatives. Additionally, 95.3% of respondents utilize gas for heating water, while 4.7% use electricity for the same purpose.

In another perspective, PT Geo Dipa Energi operates a single flash steam geothermal power plant with a significant amount of unused energy in form of separated brine. Based on the first and second laws of the thermodynamics approach, Pambudi (2014) estimated exergy in the production well is at 59,518 kW and electrical generation at 21.71 MW with second law efficiency of around 36.48%. The separated brine value was 13.52 MW. Rudiyanto in 2021, another study showed that the exergy available in the production well was 106,515 kW, and electrical generation was at 40.68 MW with a second-law efficiency of 38.19%. This study showed that the amount of separated brine in the separator was 23.48 MW. A recent study, Hendra in 2023, the thermoeconomics in the Dieng geothermal field was studied using the same approach, and the result showed that the exergy available in the production well was 167,075 kW and electrical generation at 51.57 MW with second law efficiency of around 30.8%. The separated brine value was 51.7 MW. The summarized result of the previous study is presented in Table 1.

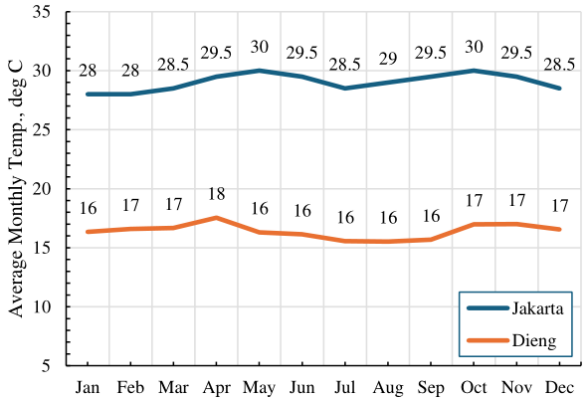

Figure 1: Average trend temperature comparison between Dieng and Jakarta over 2023 (Data: internal data measurement for Dieng, www.timeanddate.com for Jakarta).

Figure 2: "Embun upas" phenomenon in Dieng (Photo: travel.okezone.com).

Table 1: The summarized previous study related with thermodynamics in Dieng Geothermal Field.

Years	Available Exergy at Production Well (kW)	Electrical Generation (kW)	Exergy at Separated Brine in Separator (kW)	Overall Exergetic Efficiency (%)
2014[1]	59,518	21,710	13,523	36.5
2021[2]	106,515	40,680	23,481	38.2
2023[3]	167,075	51,570	51,771	30.8

Note: [1](Pambudi et al., 2014), [2](Bayu et al., 2021), and [3](Kurniawan et al., 2023)

The primary objective of this study is to comprehensively illustrate the potential benefits of harnessing brine as a heat source in the Dieng Plateau area. Utilizing brine as a heat source is one alternative that brings numerous advantages for the company, local communities, and government.

2. HEAT DEMAND

An initial survey has been conducted to understand the local community's behavior in using energy to provide hot water for daily activities within the Dieng Plateau. The survey's limitation is that it only captures the demand for heat for bathing. The survey was conducted by broadcasting a survey form through social media and an instant messaging app. The target of respondents is individuals who live in the Dieng Plateau area. 52 respondents filled out the survey. Although the number of respondents is small compared to the whole population, this number of respondents is sufficient for a pilot study (VanVoorhis, 2007). Figure 3 describes the number of respondents who use hot water for bathing, 82.7% of whom use hot water for bathing, while the rest opt for other alternatives. The next question is about how the respondents get the hot water. This question describes the type of energy that was used to generate heat to provide hot water. Based on the author's perspectives, there are three common energy sources to provide heat: solar water heaters, electrical water heaters, and natural gas water heaters. The survey

results show that respondents only use two energy resources, electrical and natural gas, with 4.7% and 95.3% for electrical and natural gas, respectively (see Figure 4).

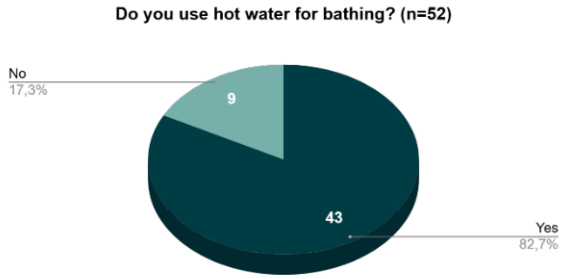

Figure 3: Respondents who use hot water for bathing.

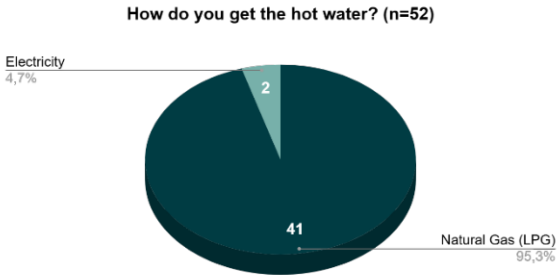

Figure 4: The energy source for providing heat for bathing.

The number of natural gas users is quite significant compared to gas. The author's hypothesis behind this phenomenon is that natural gas water heaters are more cost-competitive in operational cost and instant use compared to gas water heaters. The type of natural gas plays an essential role in operating the natural gas water heater since the price of natural gas is quite different. Natural gas in Indonesia is generally divided into subsidies and non-subsidies natural gas. The price of subsidies for natural gas is Rp4,250/kg (finance.detik.com), while for non-subsidies is Rp15,500/kg (bisnis.tempo.co). The survey result in Figure 5 also describes the type of gas used by respondents; the result shows that 90.2% of respondents use LPG 3 kg, which is a subsidized natural gas, while the rest of the ops use LPG 5.5 kg and 12 kg, which are non-subsidies.

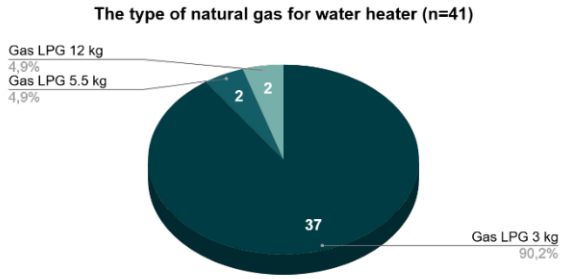

Figure 5: Natural gas types used by respondents who use gas water heater.

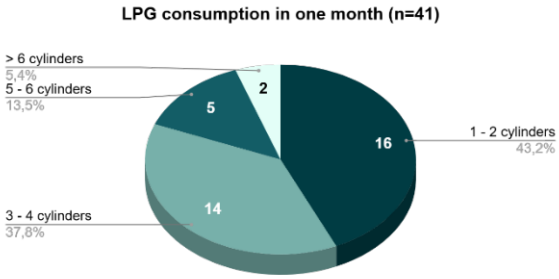

Figure 6: Respondents LPG consumption in one month for providing heat.

Figure 6 illustrates the monthly natural gas consumption in households, measured in cylinder units. The data reveals that 43.2% of households consume 1-2 cylinders, 37.6% consume 3-4 cylinders, 13.5% consume 5-6 cylinders, and 5.4% consume more than six cylinders. The size and the number of household members influence the quantity of cylinders used. Specifically, smaller cylinders lead to higher consumption, and households with more members have higher gas consumption. The relationship between Figure 5 and 6 is summarized in Table 2.

Table 2: Total natural gas (LPG) consumption in one month in Dieng Plateau area.

LPG Type (kg)	LPG Consumption in One Month (cylinders)	Respondents (1 respondents = 1 household)	Natural Gas Consumption (kg/month)
3	2	16	96
3	4	14	168
3	6	5	90
3	8	2	48
5.5	2	2	22
12	2	2	48
Natural Gas Consumption			**472**
Average LPG/Respondents (kg/month-household)			**11.5**

The average LPG consumption for one household is 11.5 kg per month. In terms of energy, 1 kg of LPG produces approximately 11,254 kilocalories (Kcal) of energy (www.esdm.go.id). The total energy required to provide heat for bathing is calculated to be 129,558 Kcal. This number is used as initial data to obtain the heat demand in the

Dieng Plateau area. The total number of households in the Dieng Plateau area is 6,889, distributed in two regencies and seven subdistricts.

Table 3: The number of households in the Dieng Plateau area (kemendagri.go.id).

Regency	Subdistrict	No. of households
Banjarnegara	Banjarnegara – Karangtengah	1,303
Banjarnegara	Batur – Dieng Kulon	1,056
Banjarnegara	Batur – Karangtengah	1,374
Banjarnegara	Batur – Kepakisan	1,044
Banjarnegara	Wanayasa – Karangtengah	600
Wonosobo	Kejajar – Dieng	783
Wonosobo	Kejajar – Sikunang	729
	Total	**6,889**

Based on the survey data and combined with the information from Table 3, the total energy consumption in one month was about 703 Gcal or 35,334 GJ/year. This amount of energy is equivalent to 18% of the annual energy consumed by each individual in Indonesia (Wong et al., 2024). Related to the subsidies given by the Government, the proportion of households who use subsidies and non-subsidies based on the survey is 90.2% and 9.8%, respectively. This proportion equals Rp239,736,790 and Rp95,144,981 for subsidies and non-subsidies in one month.

3. RESOURCE ASSESSMENT

The resource assessment begins with understanding the characteristics of the reservoir and production wells. As previously mentioned, Dieng has a geothermal potential of 355 MW from the Sileri, Sikidang, and Pakuwaja sectors. The fluid originates from a magmatic source and has a relatively high H2S/CO2 ratio in the central zone, with a low total gas content, which is uncommon for high-temperature geothermal systems. The reservoir temperature is around 300°C, and the geothermal fluid's enthalpy ranges from 1,163-1,860 kilojoules per kilogram (kJ/kg). It has a chloride content between 12,000 – 15,000 parts per million (ppm), gas content of 0.3-2.3 weight % of produced steam, steam fraction ranging from 30 – 50% (Layman et al., 2002), and silica content between 1,145-1,400 ppm in the discharge conditions (Pambudi et al., 2015).

Currently, PT Geo Dipa Energi generates electricity from Dieng Unit 1, which has a capacity of 60 MW, and a Small-Scale 10 MW unit with a total output of around 58.5 MW gross. The steam was collected from nine production wells located in the Sileri prospect area. Some of the well characteristics have already changed compared to the initial condition. Figure 7 shows that most production wells have characteristics closer to saturation liquid, with only two wells showing characteristics closer to saturation vapor. Wells closer to saturation liquid will produce more liquid than vapor. From an electrical production perspective, producing from wells with high steam fraction is more uncomplicated and relatively cost-economic than wells with low steam fraction. However, from a brine extraction viewpoint, producing from wells with a low steam fraction is more beneficial, as more energy from brine can be extracted.

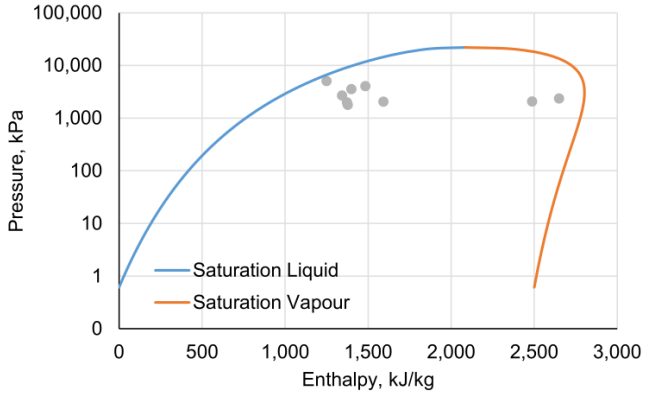

Figure 7: Production well in Dieng Geothermal Field characterized by pressure and enthalpy.

The total electrical generation is approximately 58.5 MW, resulting in a total brine production of around 314.2 tons per hour from all wellpads. The separator pressure at the wellpads ranges from 11 to 13 bar gauge. In this study, it is assumed to be 12 bar gauge for all wellpads. At this operating pressure, the brine temperature is 180°C,

with an enthalpy of approximately 787 kJ/kg. Therefore, the total energy available in the brine is approximately 68.8 MW.

4. DISTRICT HEATING BENCHMARKS

District heating powered by geothermal is not a new technology, especially for a four-season country with geothermal potential. China, Iceland, Turkey, France, and Germany are the leaders in district heating based on capacity and annual energy use. The total installed capacity is now 12,768 MWt, and the annual energy use amounts to 162,979 TJ/year (Lund et al., 2021). Geothermal energy as a source of district heating brings enormous benefits to the environment, economy, and lifestyle. The use of geothermal energy saved 100 million tons of CO2 emissions compared to emissions from using fossil fuels (Gunnlaugsson et al., 2015). In Indonesia, no report describes the direct use of geothermal energy for district heating. The only update about direct use is from WGC2015, where there was direct utilization for aquaculture in Lampung, palm sugar processing using brine in Lahendong, and mushroom cultivation in Pangalengan (Darma et al., 2021).

The author chose Iceland as a benchmark in this section since the same approach will be implemented in this paper. Geothermal district heating started in 1930 utilizing artesian flow from the shallow well in Iceland. Significant development started in 1950, as the demand for heat increased. Nowadays, two sources of district heating in Reykjavik are from low temperature geothermal and heated groundwater In low-temperature geothermal sources, hot water from geothermal wells flows to the surface and then to a deaerator to release the gas content in the fluids. Hot water production mainly uses submersible or vertical pumps to lift the water to the surface. The hot water flows to a tank before being distributed into the city. In another area of Iceland, low-temperature geothermal energy comes from springs, such as Deildartunga in the Reykholt geothermal field. Deildartunga Spring is the largest low-temperature hot spring in the world, producing 180 liters per second of boiling water. Deildartunga provides hot water for the district heating service of Akranes-Borgarnes in Western Iceland to approximately 10,000

residents of Akranes and Borgarnes. It distributes hot water across West Iceland via a 63-kilometer pipeline network from the Deildartunga hot spring (Gunnlaugsson et al., 2015).

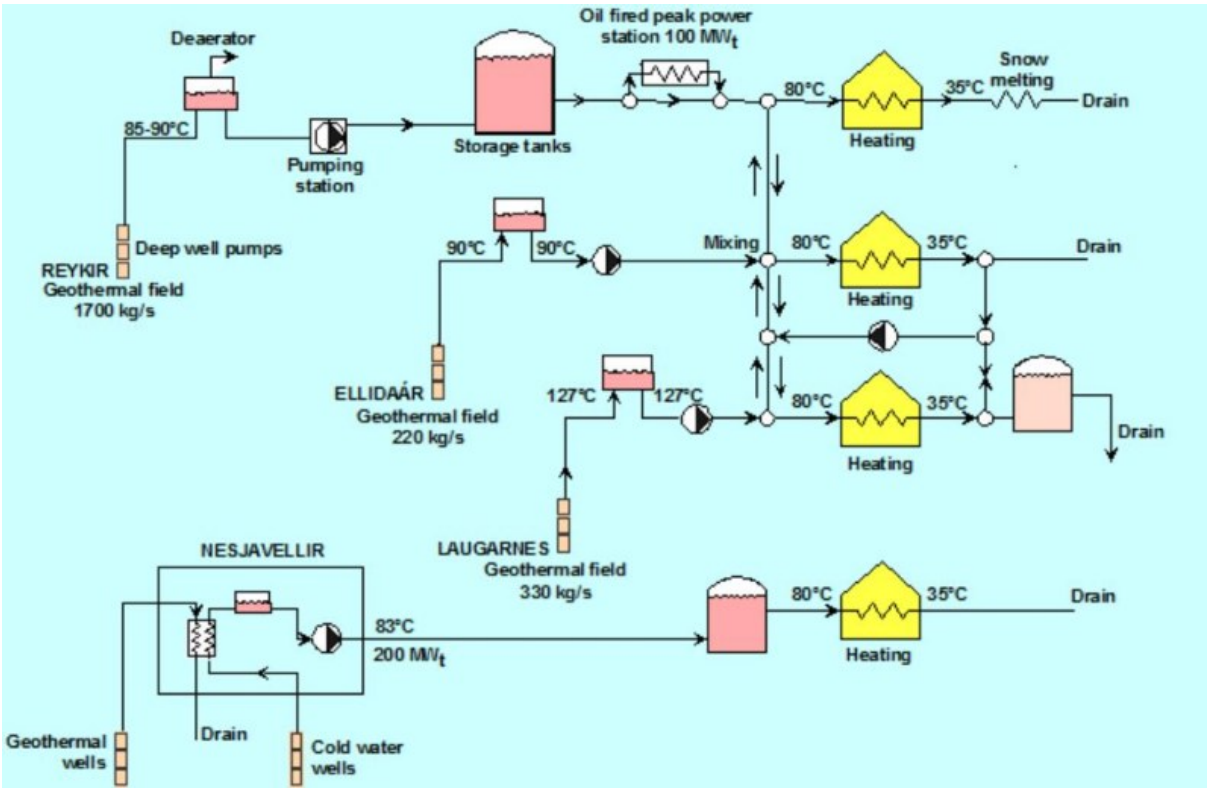

Figure 8: Simplify the district heating system in Reykjavik (Gunnlaugsson et al., 2015).

MW of hot water for district heating for Reykjavik and the surrounding area. Nesjavellir uses a heated groundwater system to produce hot water since the chemical composition in the geothermal water then the fluids cannot be used directly. The groundwater mainly acts as cooling waterfor condensing in the condenser (see Figure 9). The initial groundwater temperature is around 5 – 7°C with a flow rate of 1200 kg/s entering the condenser, and after

the condensing process, the groundwater temperature increases to about 55°C. In order to reach a sufficient temperature for district heating, the groundwater flows through a heat exchanger to increase the temperature to 87°C using separated brine from the separator at 192°C temperature (Gíslason, 2000). Then, the process continues to the deaerator to remove gas content, especially oxygen. The heated groundwater is injected with some geothermal steam, both to remove the last traces of dissolved oxygen by reacting with the hydrogen sulfide (H2S) in the steam and to adjust the water pH to 8.5 (Ballzus et al. 2000 in Gíslason, 2000).

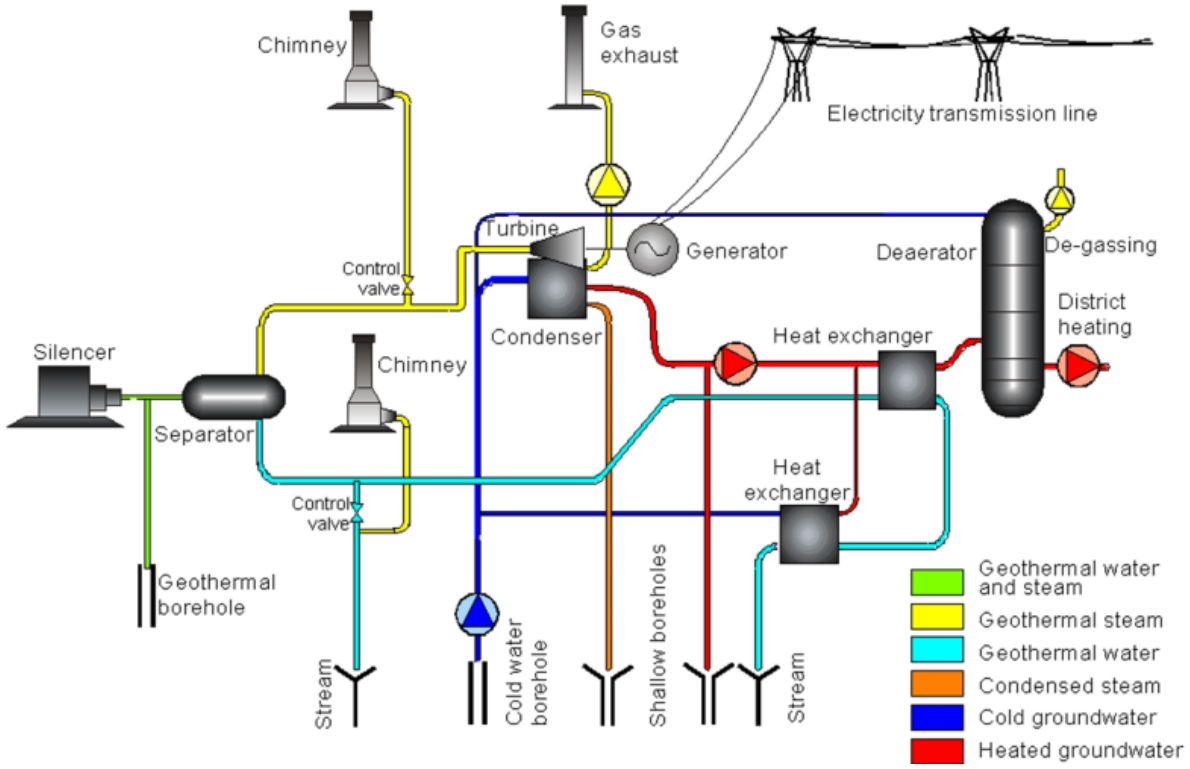

Figure 9: Schematic diagram of Nesjavellir Geothermal Power Plant (Gíslason, 2000).

Nesjavellir is one of the cogeneration power plants in Iceland, which produces 120 MW of electricity and 300

The shell and tube heat exchanger were used in Nesjavellir with brine in the tube and fresh water in the shell side. The heat exchanger has a counter flow of fluids direction and is made of stainless steel (Ballzus et al., 2000). This concept of heated groundwater in Nesjavellir is being tried to be adapted in the Dieng Geothermal Field with several adjustments due to the different fluid characteristics and flow process.

5. HEAT RECOVERY METHOD

In the typical process of geothermal production, the geothermal fluids flow from the reservoir to the surface under isenthalpic conditions and then to the separator for the separation process. The separation between steam and brine depends on the initial enthalpy from the well and the separation pressure, leading to variations in the steam fraction and thermodynamic conditions at different wells or wellpads. Figure 10 describes the process flow diagram in the steam field. The throttle valve controls the wellhead pressure and flow rate through adjustments to the valve opening. As the fluids are flushed, this leads to a decrease in pressure and temperature, eventually reaching a saturated state (1). The fluids are separated at the separator into steam and brine. The water level in the separator, regulated by the control valve (CV), influences the separation process. The separated steam (2) is directed to the power plant, while the separated brine (3) flows to the silencer to reduce noise when releasing the brine into the atmosphere. The pressure difference between the control valve and the silencer causes the brine to flash (4). Subsequently, the separated steam and brine are separated in the silencer. The steam is released into the atmosphere, and the brine is cooled in the open canal and cooling pond and then pumped to the injection well (5).

In this section, this study will outline the proposed considerations for recovering heat energy from separated brine. While similar heat recovery processes have been successfully implemented in Iceland, it is essential to note that adjustments are still necessary due to the uniqueness characteristics of each geothermal field. For example, at the Dieng power plants (Dieng Unit 1 60 MW and Small-Scale 10 MW), the condensing process relies on a circulating water system to condense the steam, thereby limiting groundwater consumption. As part of the proposed process, we plan to heat groundwater directly with separated brine from the separator at approximately 180°C.

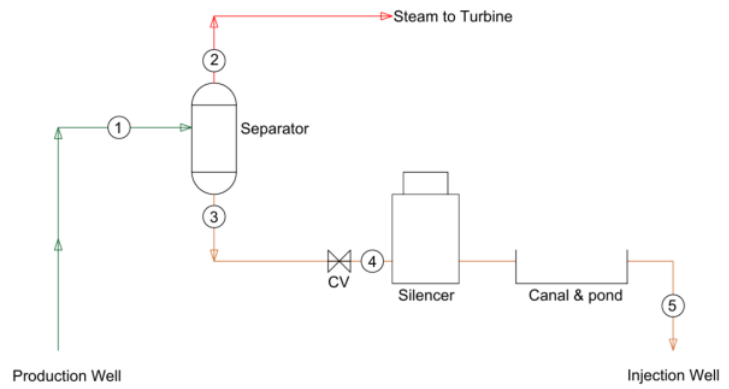

Figure 10: The process flow diagram in the wellpad of Dieng Geothermal Field.

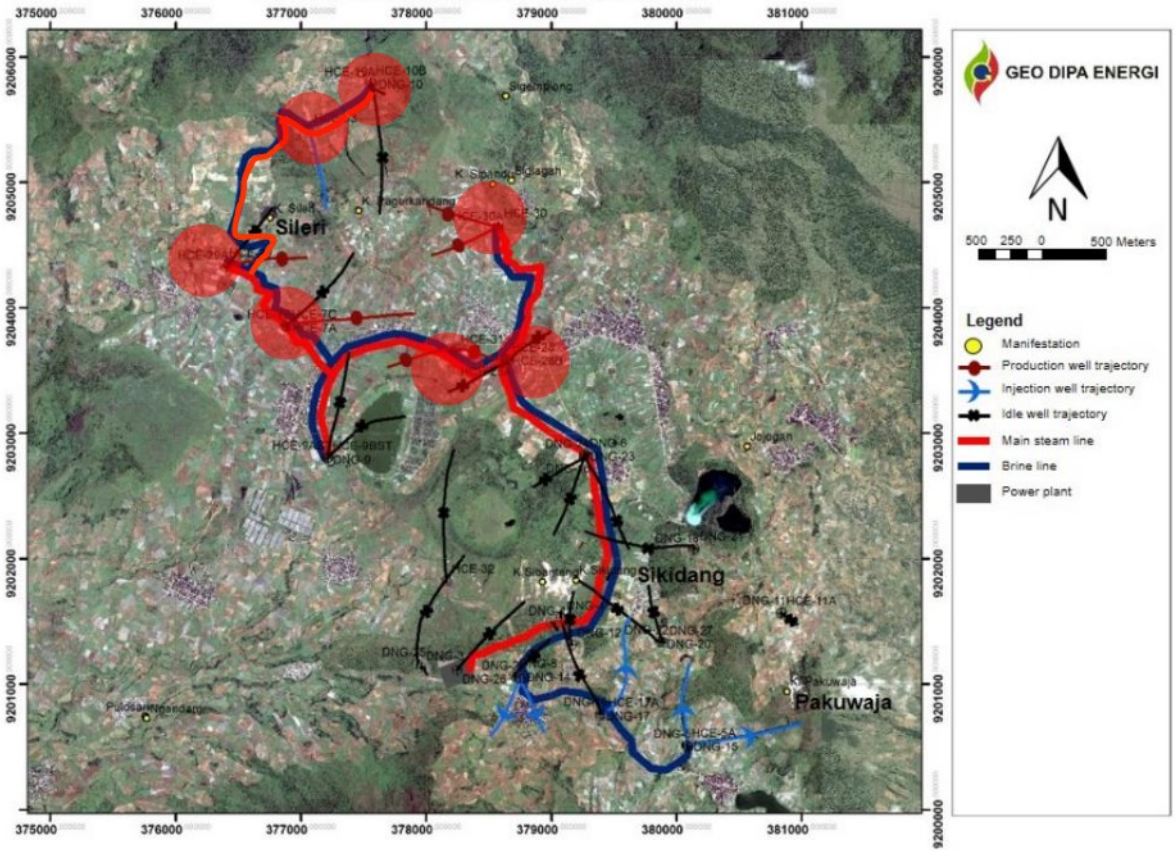

Figure 11: The map of the Dieng geothermal field (Modified from PT Geo Dipa Energi, 2018 in Sondakh, 2018).

5.1 Resource Management

The wellpad area in Dieng Geothermal Field is located separately and distributed in different locations. The red circle in Figure 11 figures out the location of the wellpad. The separation system is not centralized hence the separated brine is not collected in one area. In this particular scenario, it is essential to consider how resources can be effectively managed. This can be done by addressing various scenarios as below:

1. Separated brine is not collected into one area

Based on technical calculations, it is possible to collect brine from all wellpads in one area. However, this scenario is not a reliable solution due to the silica content in brine, which can cause silica deposition along distribution lines. Furthermore, this scenario needs high investment and maintenance costs.

2. Heat exchangers are installed on each wellpad

Installing heat exchangers on each wellpad provides a more reliable solution, even though the initial investment is high. This scenario offers a higher capacity factor, allowing for varying maintenance schedules for each wellpad.

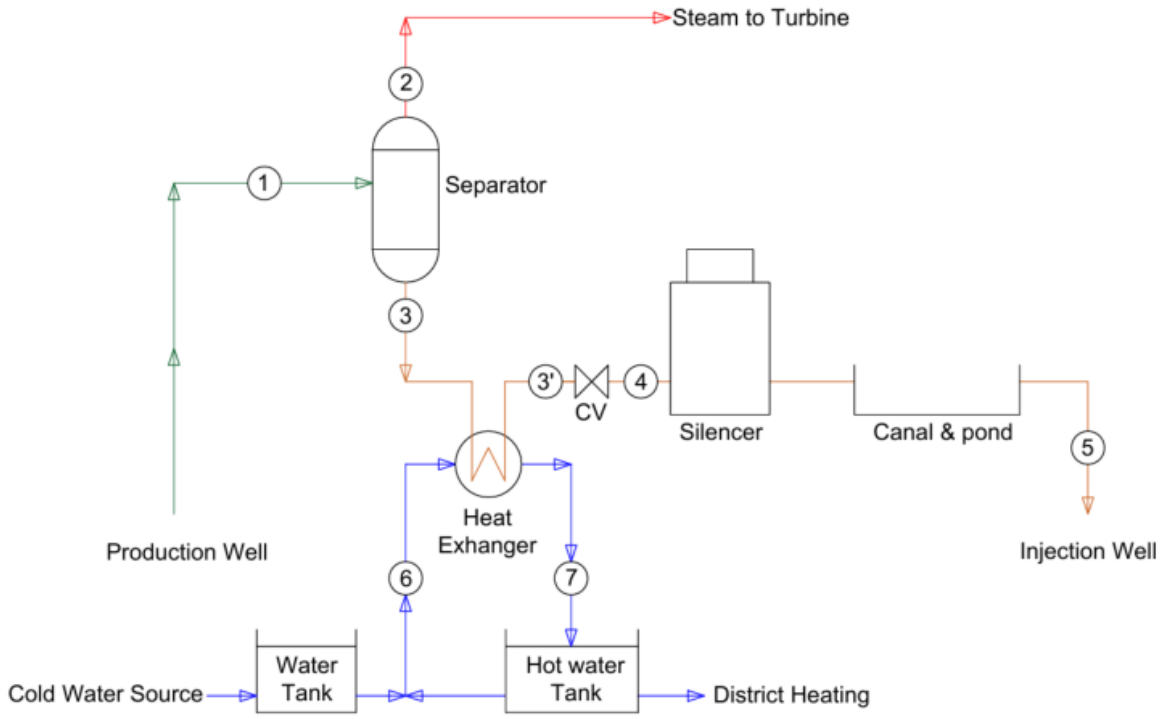

Figure 12: Proposed schematic of separated brine heat recovery.

5.2 Heat Exchanger

The heat exchanger plays a crucial role in energy extraction as a heat extractor of separated brine. In the proposed system, the type of heat exchanger is shell-and-tube, with separated brine on the tube side and groundwater on the shell side. The technical limitations considered in this study regarding heat exchanger selection are flow direction, surface area required, and material selection.

1. Flow direction

There are three common types of heat exchangers based on the flow direction: co-current, counter-current, and mixed (Learman, 2009). The proposed approach in this research is counter-current instead of parallel flow because running a parallel regime carries the potential for a temperature cross. This occurs when the temperatures of the streams are equal, whereas the objective of heat recovery is to ensure that the outlet temperature of the cold stream is higher than that of the hot stream (Welty et al., 2008 in Velasquez, 2020).

2. Surface area required

The selection of flow direction affects the surface area required. It is important to note that when designing the heat exchanger, the minimum required heat transfer surface area is often used to keep the cost down (Velasquez, 2020). The author compared the three types of heat exchangers, and the result shows that at the same heat exchanger duty (Q) required, counter-current heat exchangers have higher LMTD than other types with a lower heat transfer surface area required (see Table 12).

3. Material selection

The separated brine in the current condition is treated with 98% sulfuric acid to prevent scaling in the control valve (see Figure 10). This treatment lowers the pH of the separated brine to around 3 – 4. The proposed material will be stainless steel for both shell and tube.

5.3 Heat Recovery Process

As shown in Figure 10, the heat exchanger is intended to be positioned between the separator and the control valve. This arrangement prevents a significant pressure drop that could cause steam formation. If the heat exchanger is installed after the control valve, steam could be formed due to the pressure drop from the operating system to atmospheric pressure. In Figure 12, the heat recovery process begins with groundwater being transferred from any source to fill the cold-water tank and then piped to the heat exchanger (stream 6). The groundwater temperature increases due to heat transfer from the separated brine, while the temperature of the separated brine decreases due to heat transfer to the groundwater. A circulating line is proposed from the hot water tank to the

heat exchanger to accommodate demand fluctuations. When the demand is low, the groundwater will be circulated to the heat exchanger to maintain the temperature at the desired level. The detailed heat mass balance in this heat recovery process is detailed in Table 4.

According to thermodynamic calculations, the heat recovery from the brine at this circumstances is approximately 28,190 kW, which can produce 345 tons of hot water per hour. An interesting change in the system is the steam fraction formed in the silencer after heat recovery. In a previous study (Kurniawan et al., 2023), the steam fraction in the silencer was approximately 18%, whereas in this simulation, it dropped to 1%.

Table 4: The thermodynamic value of each stream in Figure 12.

Stream	Mass Flow (ton/hour)	Enthalpy (kJ/kg)	Steam Frac. (%)	Temp. (°C)	Pressure (bar a)
3	314.2	794	0	187	11.7
3	314.2	461	0	110	9.73
4	314.2	461	1	92	
6	345.2	84	0	20	
7	345.2	377	0	90	

6. THE BENEFITS OF DISTRICT HEATING

The implementation of district heating, a highly efficient system, benefits the company and the local community around the geothermal area. According to a previously mentioned study, the local community currently relies on the supply of natural gas (LPG), which involves a long distribution supply chain. The specific benefits of district heating are described below.

1. Stream revenue for the company

Currently, with the use of a single flash geothermal system, all separated brine is flashed to the atmosphere and then cooled down in the pond and open canal. However, by recovering the heat from this process, the company can add additional value to its current operation condition. This presents an opportunity to sell hot water, as there is a demand available for it. Therefore, the implementation of district heating allows the company to maximize the efficiency of its geothermal system and create a new revenue stream through the sale of hot water, thereby increasing its overall profitability.

2. Techno-social approach

The techno-social approach of district heating refers to the combination of technological and social factors in the implementation and operation of the heating system. This approach emphasizes the use of technological solutions for efficient energy production and distribution, while also considering the social impact and benefits for the local community. According to the survey results, 84.6% of the respondents want to use geothermal energy as a heat source for providing heat. By directly meeting the needs of the local community, the engagement between the company and the local community will increase, thereby reducing social problems or rejection. This, in turn, will increase the acceptance of geothermal development within the local community.

3. Sustainable supply of hot water

Using geothermal energy for district heating offers numerous benefits compared to traditional LPG heating. Geothermal energy provides a sustainable hot water supply using heat from the separated brine. It is an essentially unlimited resource. This means there is no concern about supply shortages or price fluctuations due to limited stock, as is often the case with LPG.

4. Carbon reducing

Moving from LPG to geothermal energy for district heating offers significant carbon reduction benefits. Geothermal energy produces much lower carbon emissions than traditional LPG heating. Utilizing geothermal energy for district heating can contribute to environmental sustainability and reduce our carbon footprint. This transition aligns with promoting sustainable and environmentally friendly practices, making it a positive step towards addressing climate change.

5. Education and tourism

Implementing geothermal district heating will bring significant educational and tourism benefits as it will be the first of its kind in the country. This pioneering initiative can serve as an educational model for students, researchers, and professionals interested in sustainable energy solutions. It can provide valuable insights into the practical application of geothermal technology, showcasing the environmental and economic advantages of

district heating systems. Furthermore, the unique nature of this proposed project can attract attention from domestic and international tourists. Visitors interested in sustainable energy and environmental initiatives may be drawn to witness the innovative geothermal district heating system. This can create opportunities for educational tours and workshops, fostering greater awareness and understanding of geothermal energy and its potential impact on addressing climate change.

6. Reducing the subsidies

The survey findings indicate that a significant proportion of respondents currently utilize natural gas, a predominantly subsidized resource. Making the switch to geothermal energy has the potential to significantly reduce the reliance on government subsidies for energy production and consumption.

7. CONCLUSION

According to the survey findings, a significant 82.7% of respondents depend on hot water for bathing, with 95.3% of them using natural gas (LPG) as the primary heat source. This reliance on natural gas amounts to 6.51 GJ/year, which equals 18% of the annual energy consumed per person in Indonesia. Additionally, in the Dieng area, PT Geo Dipa Energi is currently generating geothermal electricity using a single flash system, but the separated brine from this process is not being utilized. Calculations indicate a potential heat recovery of 68.8 MW from this separated brine. The proposed recovery method involves using a counter-current heat exchanger made of stainless steel to prevent corrosion, with the separated brine flowing through the tube side and the groundwater flowing through the shell side. The calculated recovery energy is 28,190 kW, representing 40% of the total energy in the separated brine. Implementing separated brine heat recovery could bring various benefits, including creating a new revenue stream for the company, adopting a techno-social approach, ensuring a sustainable hot water supply, reducing carbon emissions, and promoting education and tourism. Another important advantage of geothermal district heating is the potential reduction in government subsidies for providing natural gas. This reduction could amount to Rp2,876,841,485 annually or decrease total gas consumption (subsidies and non-subsidies) for heating in Dieng, amounting to Rp4,018,581,255 annually.

Keywords: fracture model, critically stressed fractures, geomechanics, enhanced geothermal

ABSTRACT

Stochastic techniques, when implemented with sufficient data, calibration, and quality control, enable us to build robust 3D geomodels. In this paper we present a multidomain geoscience approach integrating geology, geophysics, geomechanics, and fracture mechanics. The workflows include fracture characterization, fracture modeling, and geomechanics to comprehend overall geothermal reservoir conditions. Multiple data sources were deployed to reduce uncertainty and optimize lateral landing and field development in geothermal fields. Although natural fractures occupy a small volume of the subsurface formation, they often dominate fluid flow and solute transport in a geothermal system. One of the critical factors that dictate the ability of fractures to conduct fluid flow is their mechanical properties, which are dependent on their state of stress. We present a novel workflow that integrates a natural fracture permeability model that has been analyzed using critical stress prediction with other geological information to improve the delineation of favorable geothermal conditions or a "sweet spot" map as reference for well targeting at the Utah Frontier Observatory for Research in Geothermal Energy (FORGE) project site, Utah, USA. The reference field is classified as hot dry rock or an enhanced geothermal system (EGS); however, the workflow proposed in this study is applicable to other geothermal systems. The workflow starts with analyzing the open-source dataset of the Utah FORGE site to generate high-resolution 3D geological models, containing information such as lithology, geological structures, and temperature models. Openhole evaluation logs from six wells were consumed, including the injector and producer wells 16A-32 and 16B-32. Subsequently, the model is populated with a discrete fracture network (DFN) using a natural fracture prediction algorithm, which is a geomechanical inversion approach to model fracture networks (type, orientation, and spatial distribution) by calculating the stress distribution and rock failure criteria at the time of fracturing using available reservoir structure data, including faults, measured stress conditions, and tectonic settings. Once the fracture model is created, a critical stress analysis using a 3D mechanical earth model is performed on the fracture model to identify critically stressed/open fractures that contribute to fluid flow in the geothermal reservoir. Finally, the identified fracture planes that contribute to fluid flow are upscaled into a 3D fracture permeability model using the Oda method. The full 3D fracture permeability model is calibrated and tuned by using the laboratory core experiments elastic properties measurements, stress evaluation from fracture injection tests and fracturing treatments, microseismic and other downhole optic fiber measurements. The average map of the geomechanically analyzed fracture permeability model is statistically combined with temperatures maps to obtain the probability distribution or chance maps of favorable geothermal conditions with a high probability value, indicating a higher chance to have a geothermal area with excellent production potential. This strategy can be used in enhanced geothermal systems to enhance connection through fractures while mitigating thermal breakthroughs. The approach can also be used in field development of mature and green hydrothermal fields to maximize the power plant outputs.

1. INTRODUCTION

Geothermal systems aim at extracting heat from the Earth and transporting it to surface plants for power generation. Developing geothermal energy provides an alternate source of energy from oil and gas and is critical in diversifying the global energy mix today. A functional geothermal system, among other things, requires in-situ heat, carrier fluid (typically water), and system permeability (flow capacity). Based on these requirements, the energy developments within geothermal are broadly classified into three parts: (a) conventional hydrothermal systems (CHS) that have all three required elements. The source rock has permeability, either in the matrix or through large preexisting fractures; (b) EGSs that target the reservoirs where system permeability is not sufficient for flow. Hence large fracture networks are created through surface pumping of high-pressure fluid to hydraulically fracture the rock. These developments require an injector-producer doublet to be functional. The cold fluid is injected and circulated through the rock and benefits from the heat transfer from hot rock during its

transient travel from the injector to the producer; and (c) advanced geothermal systems (AGS) also target the same reservoirs as in EGS but here the network is created by the drilled wells instead of fractured rock. The heat transfer happens in the transient time of the circulating fluid through the network. Because these systems do not require the fluid to interact with the reservoir rock matrix, these are also known as closed-loop systems.

In this paper we try to address critical applications in the second development type above; i.e., EGS, using the detailed dataset of the US Department of Energy (DoE) -funded FORGE project. The success of an EGS project depends on a few things, such as (a) integrated life-cycle modeling of the geology, stratigraphy, natural fractures, hydraulic fracture propagation, geomechanical and geochemical dynamics during fracturing and circulation phases. A detailed review on this from the subsurface perspective is given by Kresse et al. (2024); (b) relative lateral placement of the doublet wells—this is critical because the cost efficiency of the project will depend on achieving a fine balance in well placement. The balance is required between close spacing between wells, which enables achieving a successful connection, at the same time with enough distance between them that enables sufficient transient time to achieve the required heat transfer; (c) thermal breakthroughs through highly conductive channels—these features can carry large amounts of circulation fluid compared to other parts of the network, limiting the capacity of EGS as a heat exchanger; (d) overall system conformance—similar to shale developments where maximizing cluster efficiency is critical, EGS also requires uniform fracture network generation. Cluster efficiency is defined as the ratio of effectively stimulated clusters and total clusters. This parameter dictates the production performance of shale completions. In EGS, similar nonuniformity in stimulating across the full lateral can lead to ineffective heat sweep efficiency.

Building a reliable 3D geomodel with accurate structural stratigraphy, geologic features, and geometry is a precursor to successful life-cycle modeling for EGS. The formation stratigraphy dictates the volumetrics and therefore the amount of energy that can be commercially produced from it (Wallis et al. 2017). In designing the EGS, we aim to artificially define this ultimate reservoir geometry, shape, and extent, and hence the preexisting geological structure and the stratigraphy is critical for consideration.

Also, constructing a reliable, realistic model of the existing discrete fracture adds to the previous step, serving the same purpose of assisting in an effective engineered design of the EGS. Fluid circulation depends on the density, orientation, and capacity of these fractures to interact with induced fractures to either reopen temporarily or for extended periods of time, thus adding to the system conductivity. For this reason, fracture characterization is equally critical in the overall design scheme.

In this paper, we attempt to construct a reliable geomodel with fractures based on multiple data sources such as image logs, injection-falloff test analysis, triaxial core test results, microearthquake data during phase1 stimulation of FORGE in 2022, openhole acoustic data, and calibrate elastic properties calculation from the doublet wells 16A(78)-32 and 16B(78)-32. In addition to the data, multiple stochastic property modeling techniques were used to come up with a model that addresses the four key challenges of EGS highlighted earlier in this section.

Even though the target for this study (from the perspective of the FORGE dataset) is EGS, the application spectrum can be implemented in CHS developments as well. Since reinjection of fluid through injection wells for pressure management is a critical element of CHS, structural modeling, and well placement patterns for production and injection wells are a high value task for geothermal operators. The work described here can efficiently be extended for applications history-matching processes and well placement to enhance field-development strategy.

2. REFERENCE FIELD

This research uses data originating from Utah FORGE in Utah, USA. This site is located around 322 km south of Salt Lake City and around 16 km north of Milford. The FORGE site is unpopulated and covers an area of about 5 km2. The site is situated within Utah's Renewable Energy Corridor, close to a wind farm, solar field, geothermal plant, and a biogas facility (Figure 1). The FORGE site is a field laboratory managed by the U.S. DoE, which provides a unique opportunity to develop and assess new technologies for characterizing, creating, and sustaining an EGS in a controlled environment. The main objective of the FORGE project is to demonstrate to the public, stakeholders, and the energy industry that EGS technologies have the potential to contribute significantly to future power generation (Moore et al., 2020).

The investigations for geothermal around the FORGE site have been ongoing since the late 1970s. Based on several science investigations, the geological condition of this field has been well defined. The lithology of this site consists of Tertiary plutonic rocks (granitoid), Paleozoic and Mesozoic sedimentary sequences, and Quaternary rhyolite lava flows. The geological structures in this field consist of four faults and fault systems, including the basin-bounding fault unconformity, Opal Mound fault, Negro Mag fault, and Mineral Mountain West fault system (Bartley, 2019; Kirby, 2019; Knudsen et al., 2019; Simmons et al., 2019). The basin-bounding fault unconformity marks the contact between the basin fills and the basement rocks, fault dips around 30°. Opal

Mound fault is a steep east-dipping fault, it is the hydrological barrier that prevents the westward hydrothermal flow of the Roosevelt Hydrothermal System (Allis and Larsen, 2012; Allis et al., 2016; Simmons et al., 2019). Black fault is a steeply dipping fault that strike in the E-W direction, it offsets old alluvial fan deposits in the Negro Mag wash area, and geomorphic evidence shows that most of the Pleistocene rhyolite bodies are located south of the fault. Mineral Mountains West fault system consists of parallel N-S trending and forming normal fault segments, these faults are rooted in the basin-bounding fault unconformity, with observable offsets exposed at the alluvium deposit's surface (Bartley, 2019).

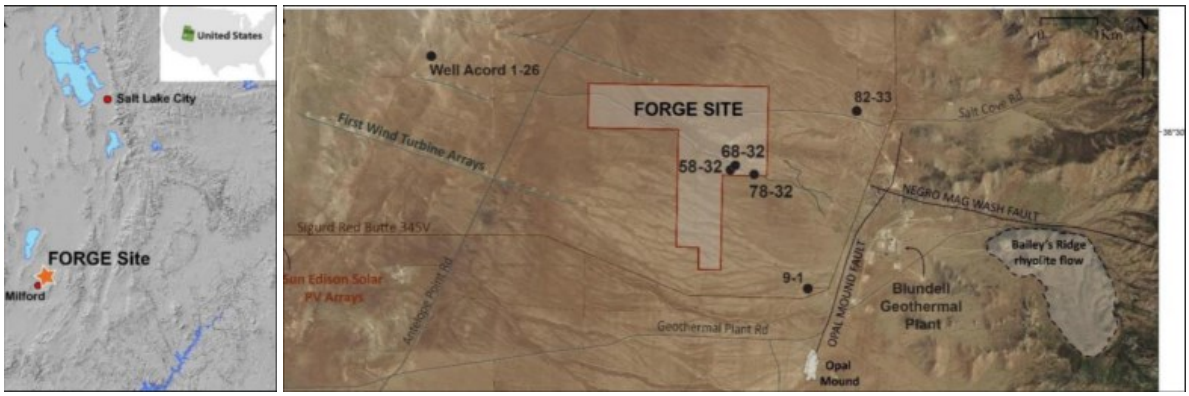

Figure 1: Location maps of the Utah FORGE site (left) and expanded view of the area surrounding the Utah FORGE site (right) (after Moore et al., 2020).

The Utah FORGE site is located within the Roosevelt Hot Springs geothermal area. The reservoir temperature of Roosevelt Geothermal Area that exceeds 250°C has a shallow cooling magma as the heat source (Moore et al., 2020). Suitable temperature range for EGS in the Utah FORGE site is found in the granitoid basement rock at a depth of at least 2,000 m with characteristically low permeability and consistent mechanical properties (Moore et al., 2020). In this field, the Opal Mound fault forms a hydraulic barrier separating the convective, permeable Roosevelt Hot Springs geothermal system from the low-permeability thermal regime to the west, beneath the FORGE site (Knudsen et al., 2019).

The FORGE site is located within a normal faulting regime, with a moderate contrast between the maximum and minimum horizontal stresses (McLennan, 2018). Induced fractures showed trend NNE-SSW as the direction of σHmax, while the stress gradient for σhmin, based on the results of the 2019 stimulations, range from 16.7 to 17.6 kPa/m. A gradient of 25.6 kPa/m (1.13 psi/ft) was calculated for σV. Three stimulations were conducted in 2019. The first stimulation was performed in the openhole section of the well, resulting slightly lower than the 2017 tests, suggesting the fracture system had developed some degree of permanence. Multiple stress signatures suggest closure of tensile fractures and dilated natural fractures (Moore et al., 2020).

3. DATA

Compared with earlier study, the only data that is different in this new study is the addition of data from new wells (16A-32 & 16B-32). The data from this well was then combined with the existing 3D model from the previous study. The structural, lithology, temperature, fracture, and geomechanics models are available within the same project modeling software. The novel value from this new study is added data from new wells. All the data and information usen in the study were obtained from the published website at the Energy and Geoscience Institute at the University of Utah (Energy and Geoscience Institute, 2021).

3.1 Existing Models

The existing models used to update the fracture and geomechanics models are the structural (faults) model, lithology model, temperature and fracture model. The faults model is a key input for the inversion process using a natural fracture prediction (NFP) fracture driver. This fracture driver is a geomechanical inversion approach to model fracture networks (type, orientation, and spatial distribution) by calculating the stress distribution and rock failure criteria at the time of fracturing based on the available reservoir fault model, measured stress conditions, and tectonic settings. The lithology model was used to filter the granitoid zone as the main lithology for the fracture modeling process. Moreover, the existing temperature model was used for the probability map. This model was built from the temperature log and temperature contour points, which distributed into the 3D model by using the kriging algorithm (Mulyani and Juandi, 2019). Previous research has been done to build a fracture model based on critical stress analysis to identify the effective fractures that contribute to fracture permeability (Mulyani et al., 2023). Four producer wells (Wells 58-32, 9-1, 52-21, and 14-2) were used to build this fracture model, with only one well (Well 58-32) that has the fracture point. With this limitation on the data availability, the uncertainty

level of the sweet spot generated based on fracture permeability is still high. The distribution of critically stressed fractures from the existing model can be seen in Figure 2.

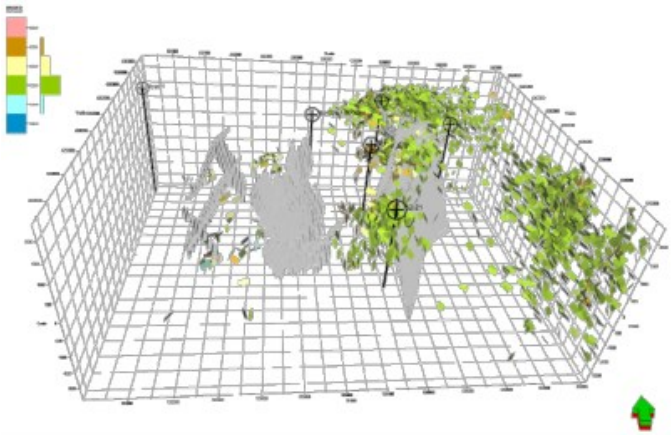

Figure 2: The distribution of critically stressed fractures based on the existing fracture model in the study area.

3.2 New Well Data

Two additional wells have been added to the previous study: Wells 16A-32 and 16B-32. These wells are an injector with borehole image data and a producer with modulus, elastic, and rock strength logs. Well 16A-32 has a maximum depth of 8,565 ft TVD located west of Well 58-32. Well 16B-32 is highly deviated like 16A-32, with a maximum depth of 8,352 ft TVD, as shown in Figure 3.

Figure 3: Satellite maps of the Utah FORGE site with location of existing Well 58-32 and new Wells 16A-32 and 16B-32 (left), and the cross section that parallels the trajectory of Well 16A-32 (right) (after Finnila and Jones, 2024).

Core data from Well 58-32 has also been obtained, to add the mechanical properties for the calibration of the previous study. A total of six wells (58-32, 9-1, 52-21, 14-2, 16A-32, and 16B-32) were used in this study to generate a more comprehensive fracture model.

The main input for the fracture model is well point fracture data, using all attributes such as dip angle, dip azimuth, and fracture classification. The fracture point data used for fracture modeling are the fracture data that are being defined as conductive-continuous fracture, conductive-noncontinuous fractures, conductive-partial resistive fractures, fault, and microfault. The original number for fracture data are 3.414 fractures; then after being filtered for fracture type, resulted in 2.966 fractures. These fracture data are located along the well trajectories at (-944 m) to 942 m depth. The main inputs for geomechanics analysis are well log data such as gamma ray, density, and sonic from Well 16A-32.

4. WORKFLOW

As a followup study to previous research, this research has a similar workflow including data preparation, fracture modeling process, critical stress analysis, fracture permeability upscaling, and creating the probability map. The next section gives the detailed explanation for each step of the process.

4.1 Data Preparation

During data preparation, added data from Well 16A-32 and 16B-32 were loaded into modeling software. All added data available in digital format can be imported directly without additional digitization process. The quality control was done by assessing the correct location of well data and the right content of well log information. The example of new data that have been loaded into modeling software are well path of 16A-32 and 16B-32, fracture point data along Well 16A-32, and microseismic data at the bottom of Well 16A-32 and 16B-32, as shown in Figure 4.

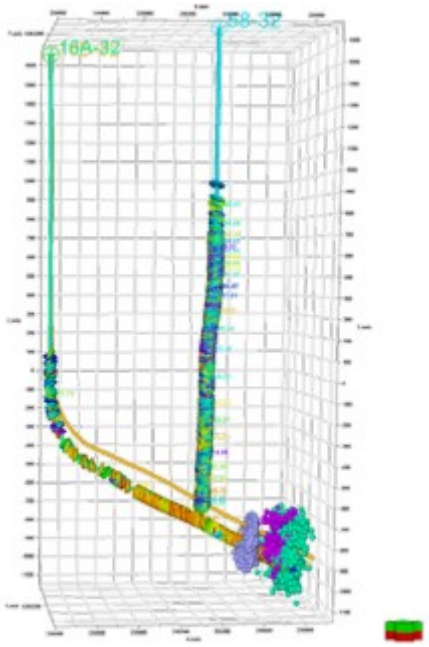

Figure 4: The additional data loaded into modeling software consist of well trajectories, fracture point, and microseismic.

4.2 Fracture Modeling Process

The purpose of modeling fractures is to create simulation properties with the power to predict the reservoir behavior. By modeling the fractures explicitly, one can honor the spatial relationships between properties in adjacent cells. Fracture modeling is a multistep process that involves the preparation of fracture well data, fault, and 3D grid model, followed by fracture driver generation and finally running the fracture model. Following the existing study done in 2022, in this study NFP was used as single fracture driver to create the DFN (Mulyani et al., 2022). NFP is a geomechanically based solution uses a geomechanics approach for computing maps of both natural fracture orientation and density trends, from observed major faults and observed fracture data along wells. To run the NFP process, fracture data with fracture characteristics information such as dip azimuth and dip angle should be classified into several fracture types. In this study the fracture classification is done using a cutoff dip angle of 70o to separate between fault (dip <= 70°) and joint (dip > 70°). The fracture data used as input were obtained from Wells 58-32 and 16A-32, with a total of 2,966 fracture data. The main process for NFP is creating the tectonic model. It was created by running multiple geomechanical simulations to acquire the best-fit stress parameters based on the present-day fault and fracture data. To improve accuracy, the tectonic model was subdivided into four tectonic events based on the prevailing major faults in the study area, from oldest to youngest: Fault Unconformity, Opal Mound fault, Negro Mag fault, and Mineral Mountain West fault system (Figure 5). The fracture data were used concurrently to model each tectonic event. For every running process, selected fracture data will be correlated to each tectonic event with the lowest fit cutoff of 0.7.

The result of all tectonic event modeling is consistent with the observed normal faulting regime with a different angle of principal stress and stress ratio. The unconformity fault used for tectonic event 1 has a stress ratio of 0.28 and angle 42°. The Opal Mound fault for tectonic event 2 has a stress ratio of 0.04 with angle 14°. The Negro Mag fault as tectonic event 3 has a stress ratio of 0.92 and angle 161°, and tectonic event 4, Mineral Mountain fault, has a stress ratio of 0 and angle 90°. The maximum fit of tectonic events 1 to 4 are as follows: 59.1%, 66%, 59%, and 66%. The maximum fit is a parameter showing how the match is the original well fracture data with calculated fracture data as the result of geomechanical inversion process. A higher maximum fit value will give a higher confidence for the geological accuracy of the tectonic model. This result is slightly higher than the existing study.

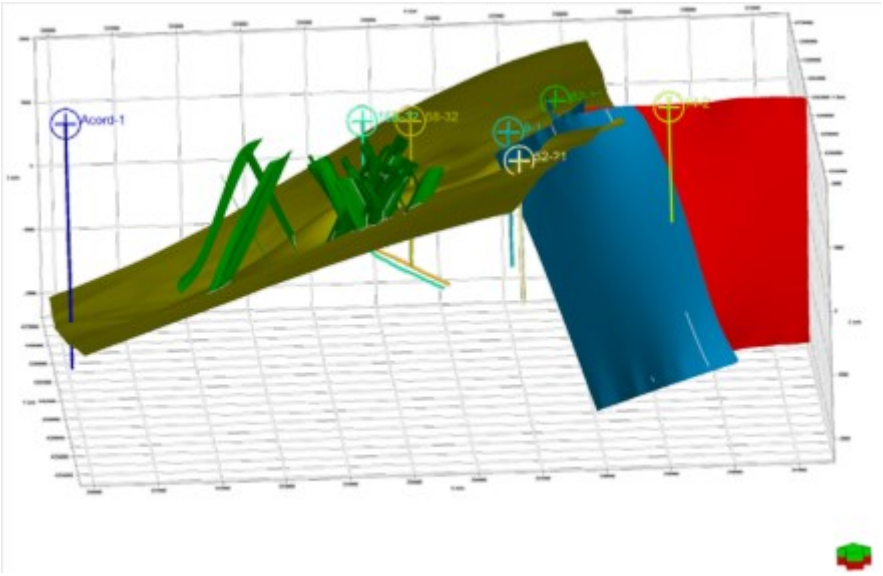

Figure 5: Fault model at the study area consisting of Fault Unconformity (yellow), Opal Mound fault (blue), Negro Mag fault (red), and Mineral Mountain West fault system (green).

Figure 6: The fracture model at microseismic location shown by fracture plane (blue) with fracture length around 460 m used for geometry input for DFN modeling.

The tectonic model process will create new attributes of fracture point well data, including fracture orientation of calculated fractures based on the geomechanics inversion for each tectonic event that was generated. The process will automatically compare the fracture orientation between observed data and calculated fracture data in the same position. In this case, if fracture data have a good match with tectonic model 1, then it will be classified as explained fracture by tectonic event 1. Meanwhile, the rest will be used for the next tectonic model and the fractures that could not be explained by any tectonic model will be classified as residual or unknown fractures. The sequences of tectonic events run for this study resulted in 317 fractures from original 2,966 fractures or around 11%. The total fractures that can be explained by those four tectonic events is around 89% higher than the previous study, which is around 82% of fractures that could be explained by NFP.

The next process is generating the fracture driver. This process used the final tectonic model and working 3D cellular grid as inputs. The results of this process are fracture properties driver set such as dip angle, dip azimuth, and intensity for each fracture type. The results are six fracture drivers set generated by all tectonic events for the fracture modeling process. In this study, the fracture model set that can be generated are tectonic model 1 (fault), tectonic model 1 (joint), tectonic model 2 (fault), tectonic model 2 (joint), tectonic model 3 (joint), and tectonic model 4 (joint). These new results are more comprehensive than the existing study because this one corresponds with all faults in study area, so each fault has representative fractures related to that fault.

The simulation method used in the fracture modeling process is stochastic and used granitoid for the zone in 3D grid, which was interpreted as a zone of interest in this reference study. For each fracture set, the parameter for fracture distribution, geometry, orientation, and aperture that will be modeled should be defined correctly. The fracture distribution and orientation used fracture intensity, dip angle, and dip azimuth from fracture driver

properties and the constant concentration value 10 to get more variation of fracture orientation. The parameter of fracture length for the fracture model following exponential algorithm which requires a mean value and a maximum value to be defined. The mean value of fracture length that is being used as input in the model is 25 m and maximum length of implicit fractures or the shortest discrete fracture is 250 m. To avoid the creation of large fractures, the maximum length of modeled fractures was defined as 460 m. The value of maximum length of fracture model was identified based on the available microseismic data. In this case, all microseismic data were used to create a deterministic fracture model resulting in three fracture planes with length around 460 m (Figure 6). For the fracture aperture model, log-normal was used as the method with an aperture mean of 0.000075 m and standard deviation of 0.0000015 m (Mulyani et al., 2022).

4.3 Critical Stress Analysis

The comprehensive geomechanics workflow for 3D critically stressed fracture analysis is implemented in this study by incorporating multidomain data from geology and geophysics (static model, magnetotelluric model, and fracture model) and new technology as a method during 3D mechanical property distribution (machine learning), as shown in Figure 7. The process begins with establishing a robust 1D geomechanics or 1D mechanical earth model (1D MEM) before conducting 3D geomechanics analysis. Initially, a 1D analysis was performed on the five offset wells available in the Utah FORGE area, adding one new offset well compared to the previous study in 2023. The 1D MEM was constructed and validated with rock mechanics testing data from another study from McLennan (2018). In the subsequent steps, the 1D MEM is scaled up to a 3D geomechanics grid and distributed across the entire 3D geomechanics model. Finally, the 3D geomechanics model undergoes simulation using a geomechanical simulator (finite element) to predict the stresses in the field. The simulated stresses output was used as one of the inputs for discontinuity stability analysis (critically stressed fracture) in the field.

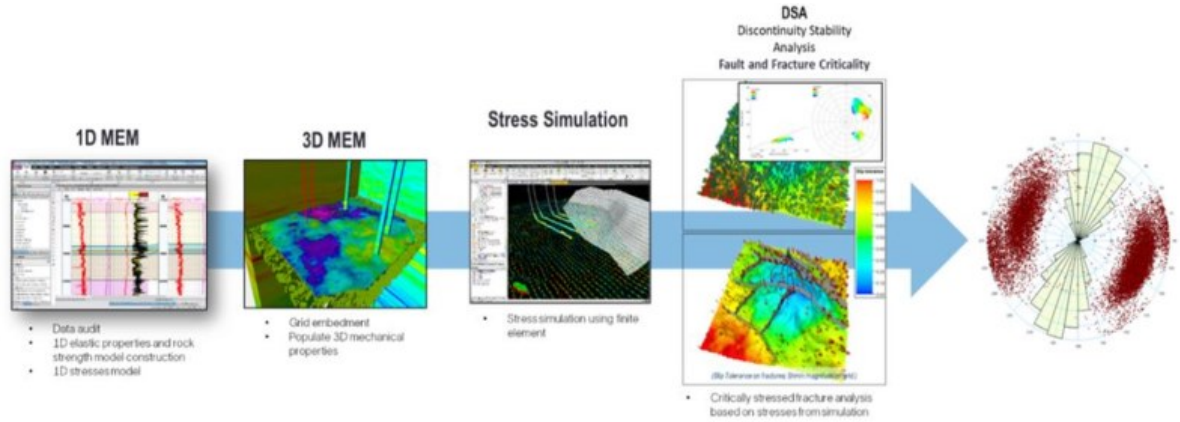

Figure 7: Workflow of 3D geomechanics for critically stressed fracture analysis.

4.4 Fracture Upscaling and Probability Map

The final stage of this study is combining the updated fracture permeability model with the available temperature model. Following the workaround from the earlier study, the updated fracture permeability model was obtained from a scale-up fracture network property from critically stressed fractures. This process converts the fracture attributes into dual-porosity or dual-permeability simulation properties. These are fracture porosity, fracture permeability, and sigma factor (the connectivity between the fractures and the matrix). In this study, the main output from the scale-up fracture network is the fracture permeability. The algorithm to calculate this property called the Oda method. It is a statistical calculation estimating permeability, based on the total area of fractures in each cell and their various parameters. This algorithm does not take the connectivity of fractures into account and can underestimate fracture permeability when the intensity is low (SLB, 2024).

The probability map is obtained through harmonic averaging of the fracture permeability for all directions; this way areas that feature poorly on at least one of the maps penalize the combined map (Figure 8). The harmonic mean works well with log-normal distributions and is commonly used for permeability because it is sensitive to lower values. After the permeability maps were calculated, the temperature model is then combined by using arithmetic averaging. This method can minimize the risks linked with uncertain data and geological interpretation. The resulting probability map is a combination of high potential zones based on identified permeability and temperature yields a synthetic view of the most favorable drilling locations (Mulyani et al., 2023).

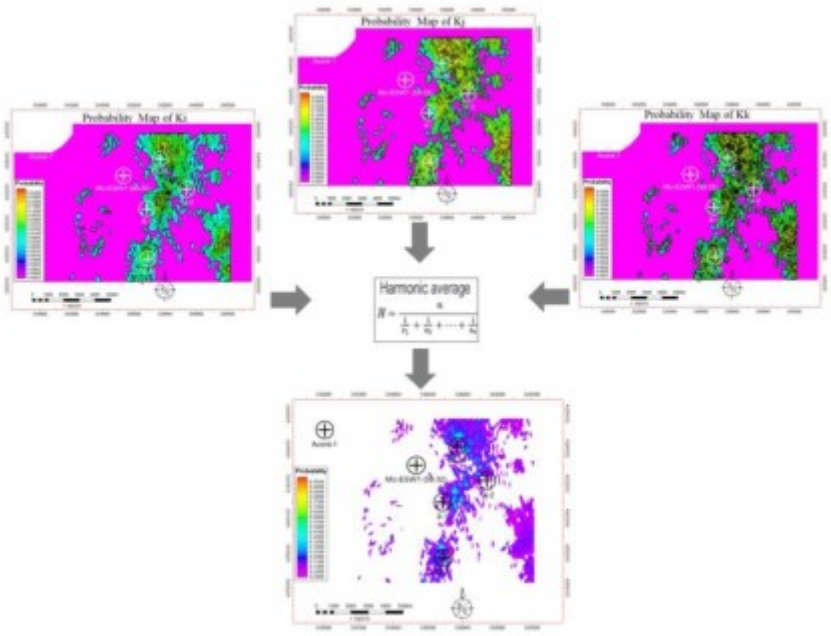

Figure 8: Harmonic averaging method to combine the parameters of fracture permeability ki, kj, and kk.

5. RESULTS AND DISCUSSION

In this study all results from the existing study were updated with new well data. The new results from this study consisting of updated fracture model, updated geomechanics model, updated critically stressed fractures, and updated probability map. The following is the detailed explanation for each result.

5.1 Updated Fracture Model

The existing fracture model was created by using the NFP fracture driver and fracture point data from a single well (58-32). Based on the tectonic model created by using the available faults data, four fracture driver sets were obtained: Tectonic model 1, related with Unconformity faults, resulting joint and fault type of fractures with high intensity in the southern part. Tectonic model 2 related with Opal Mound Faults resulting fault type of fractures with high intensity in the eastern part. Tectonic model 3 related with Negro Mag Fault and has a very small number of explained fractures data, therefore no intensity of fracture that can be calculated, while tectonic model 4 related with Mineral Mountains Faults resulting joint type and has highest intensity in the southwestern part. The total fracture model as a visible patch in this DFN is 104,438. Fracture orientations of all fractures in the model has two general orientations, including NW-SE and E-W (Figure 9). The NE-trending fractures are muted in the resulting model. The dip azimuth was dominated with fractures with a direction around N 300o E and the dip angle shows a normal trend (Mulyani and Aulia, 2022).

Figure 9: Fracture model from one fracture set at existing fracture model (left), dip angle and azimuth of fracture model (right). Observed general orientations including NW-SE and E-W (after Mulyani and Aulia, 2022).

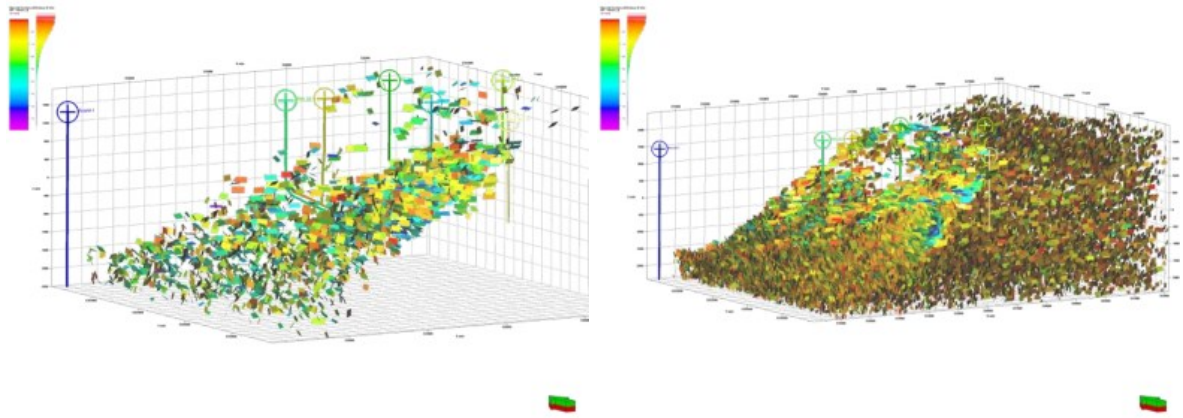

Figure 10: Fracture model generated from NFP of Unconformity Fault consist of fracture set 1 (fault) in the left and fracture set 2 (joint) in the right. The color of patches shows the dip angle of the fracture plane.

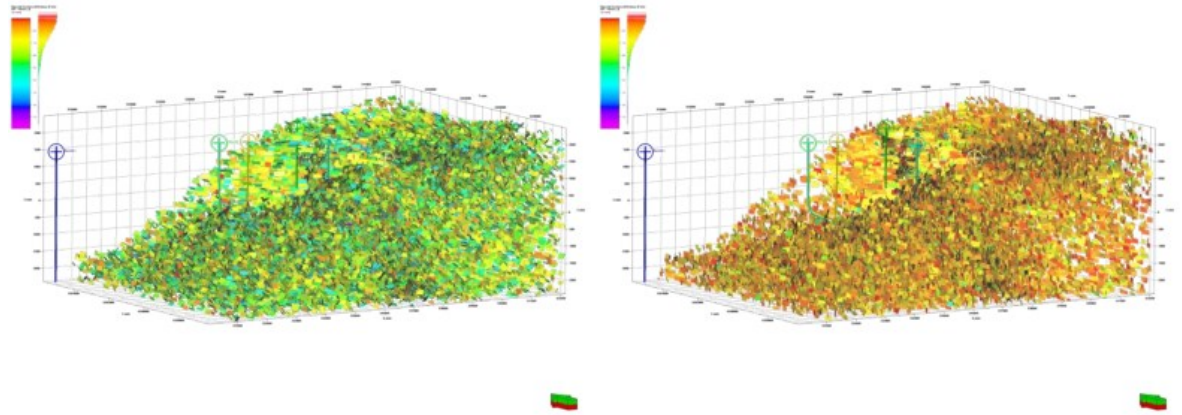

Figure 11: Fracture model generated from NFP of Opal Mound Fault consist of fracture set 3 (fault) in the left and fracture set 4 (joint) in the right. The color of patches shows the dip of fracture where fracture set 4 (joint) has igher value.

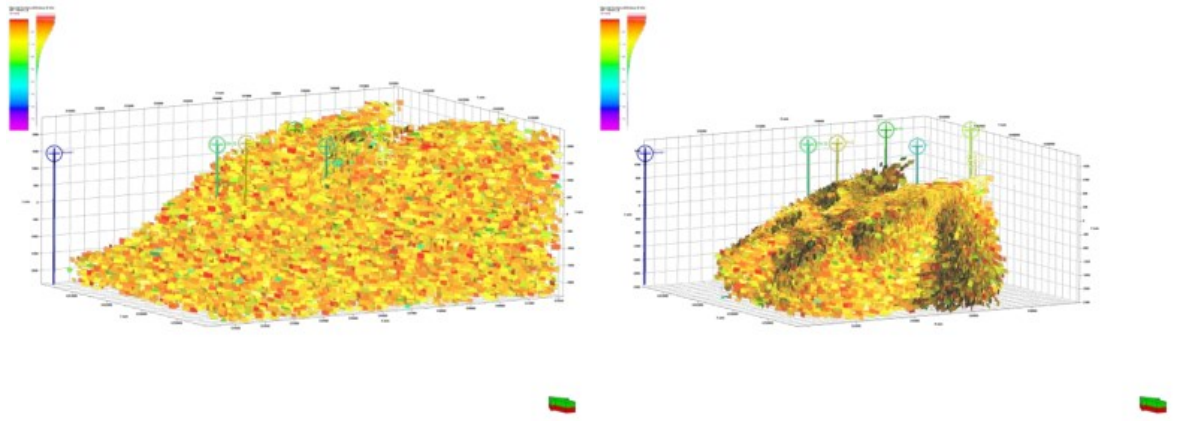

Figure 12: Fracture model generated from NFP of Negro Mag Fault consist of fracture set 5 (joints) on the left and fracture model generated from NFP of Mineral Mountain Fault System consist of fracture set 6 (joints) on the right.

The updated fracture model was created by using the same faults model to run NFP, with fracture point data from Well 58-32 and Well 16A-32. The DFN generated from fracture modeling consisting of six fracture sets based on NFP fracture drivers. There are two fracture sets corresponding to Unconformity Fault. The first fracture set defined as fractures related to faults shown in Figure 10 (left). This fracture model was distributed along the unconformity fault with more intensity on the lower part of the fault. The second fracture set defined as fracture

related to joints shown in Figure 10 (right). This fracture model has higher intensity compared with the fracture model related to fault and distributed in a whole granitoid zone.

There are two fracture sets corresponding to Opal Mound Fault. The first fracture set is defined as fracture related to faults, shown in Figure 11 (left). The second fracture set is defined as fracture related to joints, shown in Figure 11 (right). Both fracture sets have relatively high intensity with the fracture model distributed in a whole granitoid zone.

The fracture set corresponding to Negro Mag Fault consists of one fracture set related to joints. The fracture set distributed in a whole granitoid zone with relatively high fracture intensity in the eastern part as shown in Figure 12 (left), while the fracture set corresponding to Mineral Mountain Fault system consist of one fracture set related to joints. The fracture set concentrated in the central part is shown in Figure 12 (right). This fracture set is located under the Mineral Mountain Fault system, which is rooted to the Unconformity fault.

Each fracture patch from those fracture models has information about dip angle, dip azimuth, surface area, and fracture length. Therefore, we can see the fracture orientations for the entire model and the selected fractures crossed by the wells. The dip angle and dip azimuth of all fractures in the model can be seen in Figure 13. The orientation of the fault model is dominated with a N-S trend with dip angle ranging from 30° to 90°.

To validate the fracture model, fracture planes nearest the wellbore with a radius of 250 m were extracted to get their fracture orientations (Figure 14). The radius value was obtained based on the minimum length of fracture that will be generated as a discrete fracture in the model (Mulyani and Aulia, 2022).

The comparison between original fracture data from wells and fracture model's orientations are shown in Figure 15. Based on the trend of dip angle and dip azimuth in the histogram, the orientation of the fracture model has a good match with the fracture from well data. The orientation of the fracture model in the stereonet is relatively different than the one from well data; however, the results of the fault model have the same orientation with fracture data from Well 16A-32, which is relatively NE-SW. Overall, the fracture model was validated to be used for the next process in this study.

5.2 Updated Geomechanics Model

1D MEMs were developed to model pore pressure, rock mechanics properties, and in-situ stresses along the well trajectory. For this analysis, five wells were chosen as reference points to construct the 1D MEM within the Utah FORGE field: NU-ESW1 (58-32), 9-1, 52-21, 14-2, and 16B-32 (as additional offset well). Among these wells, 14-2 was specifically designated for blind testing during the 3D modeling phase. Rock mechanics properties, including Young's modulus, Poisson's ratio, unconfined compressive strength (UCS), and friction angle (FANG) were derived using density, compressional sonic, and shear sonic logs. These properties were calibrated against rock mechanics tests conducted by McLennan (2018), as illustrated in Figure 16.

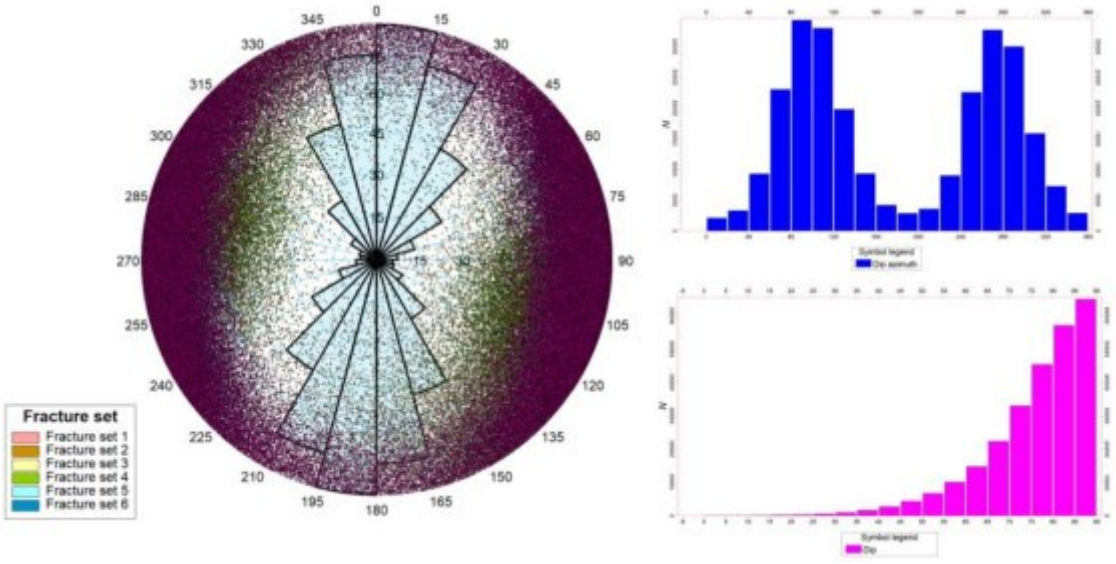

Figure 13: Dip angle and dip azimuth of updated fracture model with orientations relatively N-S.

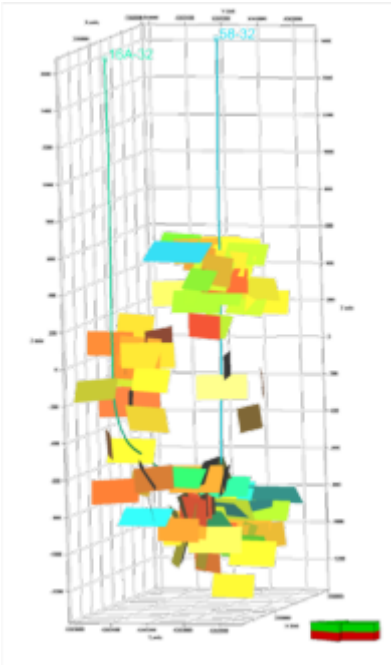

Figure 14: Selected fracture plane from fracture model near Wells 58-32 and 16A-32.

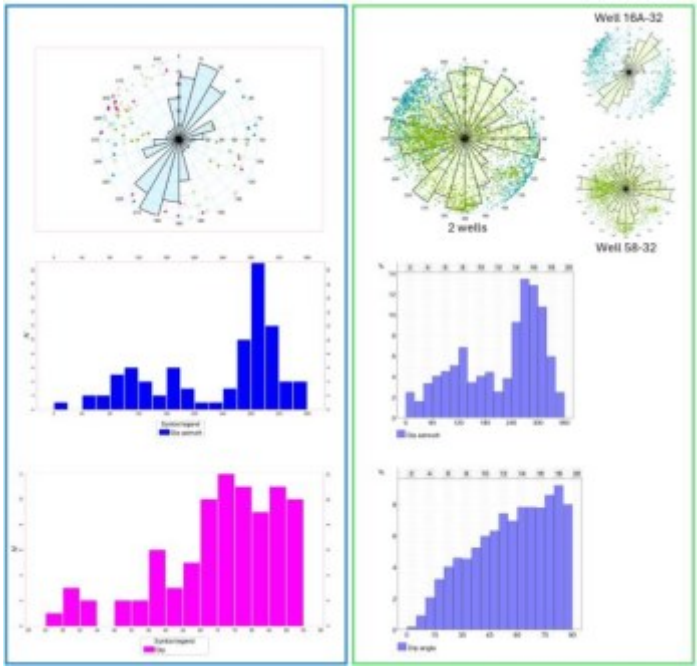

Figure 15: Comparison of fracture orientation from fracture model near well bore (left) and fracture orientation of fracture point data from well 58-32 and 16A-32 (right). The trend of dip angle and azimuth are match, while the orientation shown by stereonet has more similarity to well 16A-32 with trend Northeast-Southwest.

The temperature effect on mechanical properties must be considered as well (Blanton and Olson, 1999). Temperature measurements from Well MU-ESW1 (58-32) indicated a maximum of 266°F or 130°C. Li et al. (2021) conducted experimental tests on granite rock, indicating that mechanical properties (Young's modulus, UCS, tensile strength) do not notably change until temperatures reach 300°C, as depicted in Figure 17. Thus, given the maximum temperature recorded in Well MU-ESW1 (58-32) is 130°C, the study concluded that temperature effects on mechanical properties are negligible for this analysis.

Horizontal in-situ stresses were modeled based on the poroelastic method while honoring the overburden (vertical aspect) and tectonic process (horizontal). In this study, minimum horizontal stress was updated and calibrated with diagnostic fracture injection test (DFIT) interpretation report data from the field by Xing et al. (2020) with

the average value of 0.62 psi/ft and maximum horizontal stress average value of 0.77 psi/ft. Stress azimuth was taken from drilling-induced failure data from an image log in Well MU-ESW1 (58-32). Overall, the stress regime in this area is normal stress regime with the maximum horizontal stress direction being N30°E. The complete 1D MEM results are shown in Figure 16.

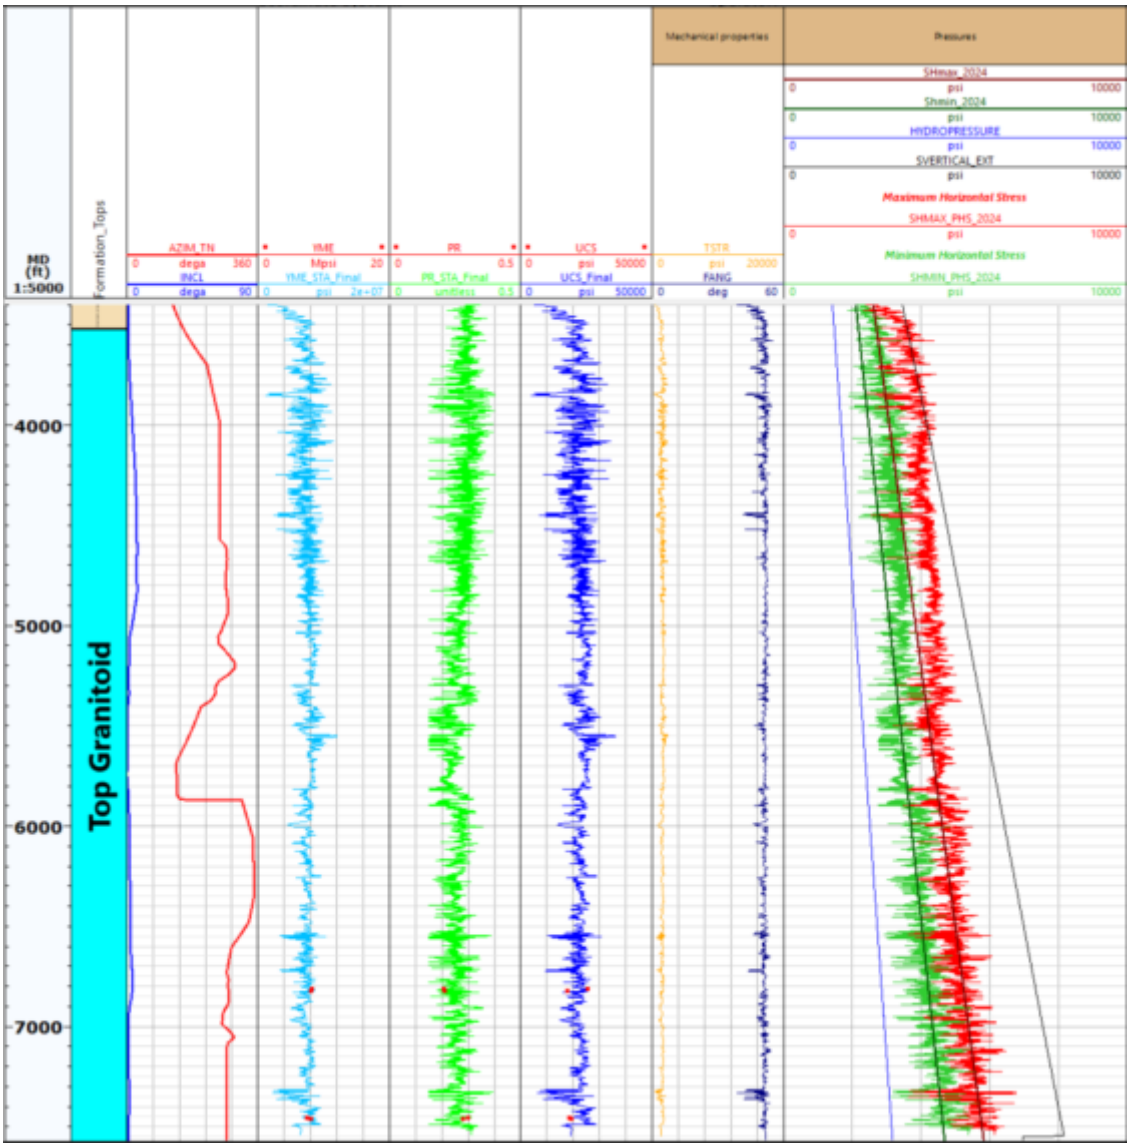

Figure 16: 1D MEM from Well MU-ESW1 (58-32). Red points in tracks 4 to 7 are rock mechanics test results from McLennan (2018). Dark green line in track 8 is average minimum horizontal stress value (0.62 psi/ft) and dark brown line in track 8 is average maximum horizontal stress value (0.77 psi/ft) from Moore et al. (2020).

The 3D static model is used as the foundation for constructing the 3D geomechanics model. However, the existing 3D static grid already encompasses the overburden area (approximately 2000 m above mean sea level). Therefore, an embedding process was undertaken to incorporate the lateral and subsurface burdens from the original 3D grid. This step was necessary to meet the requirements of the finite element method used in the geomechanical simulator, which relies on boundary stress conditions. The objective of this embedding process was to develop the 3D geomechanics model with a maximum 1:3 ratio, ensuring the effective transfer of constant stress/strain boundary loads applied on the surface to stress/strain dependent on the material properties. The original static grid consists of approximately 2.9 million cells, while the total number of cells after embedding increased to around 4.3 million (Figure 18).

The distribution of 3D mechanical properties was achieved using the machine-learning algorithm EMBER (embedded model estimator). EMBER integrates geostatistical models of spatial continuity and correlation into a decision forest-based framework for property modeling. Unlike methods that directly rely on geostatistics, EMBER embeds these models into a machine-learning approach, bridging the gap between geostatistical

techniques and other variables such as seismic data or, in this study, 3D magnetotelluric data. The results of the 3D mechanical properties are shown in Figure 19.

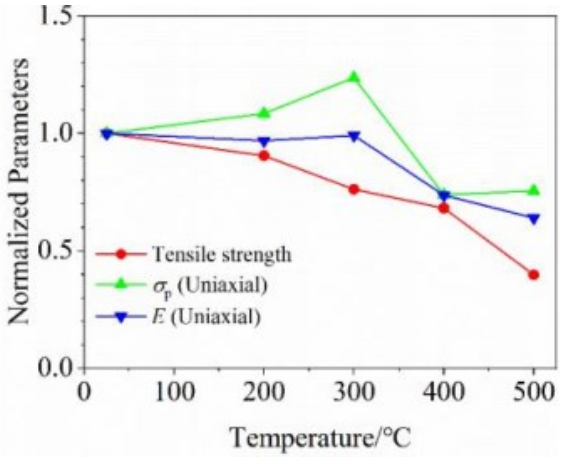

Figure 17: Temperature-dependency of granite under thermal treatment.

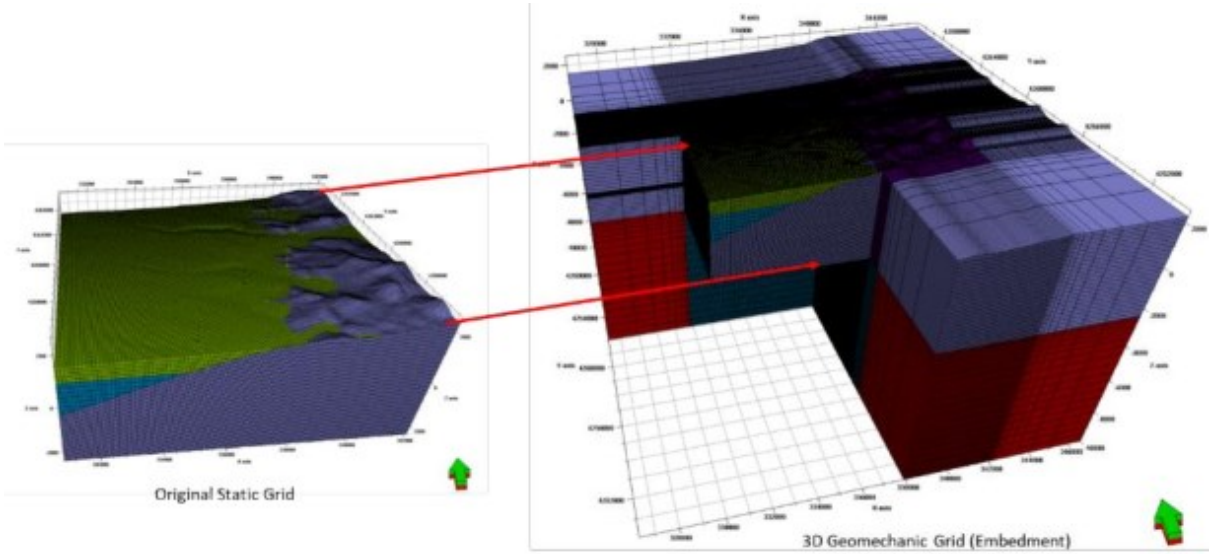

Figure 18: Grid embedment result.

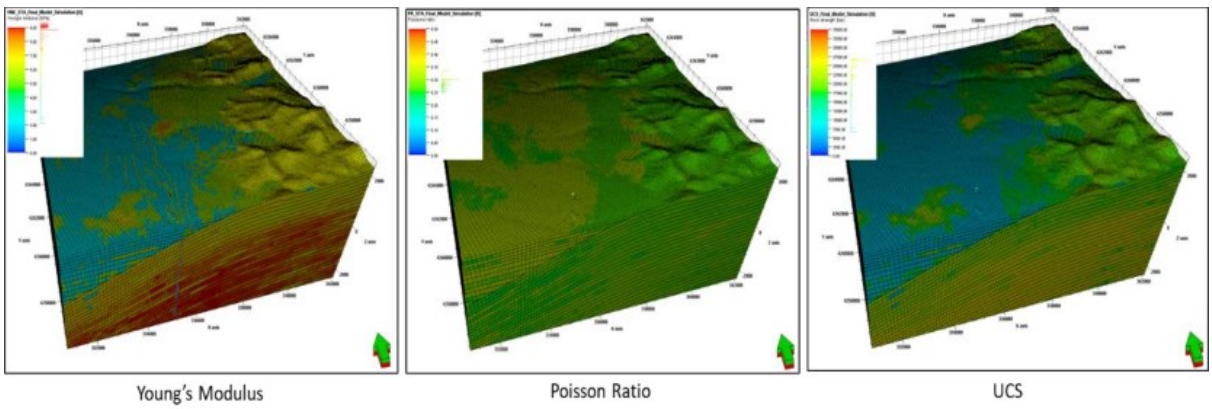

Figure 19: 3D mechanical properties.

The 3D stress simulation used strain parameters derived from previous 1D MEM analyses. Subsequently, the calculated 3D stress distribution was compared and validated against the 1D MEM stress profiles obtained from offset wells. The 3D geomechanical model was subjected to external far-field stresses along with internal vertical gravitational, pore pressure loads and distributed elastic properties of the model. An equilibrium stress condition was computed using a finite-element geomechanical simulator that incorporates plasticity. The variation of

minimum horizontal stress (Shmin) and maximum horizontal stress (SHMax) within the granitoid interval is illustrated in Figure 20.

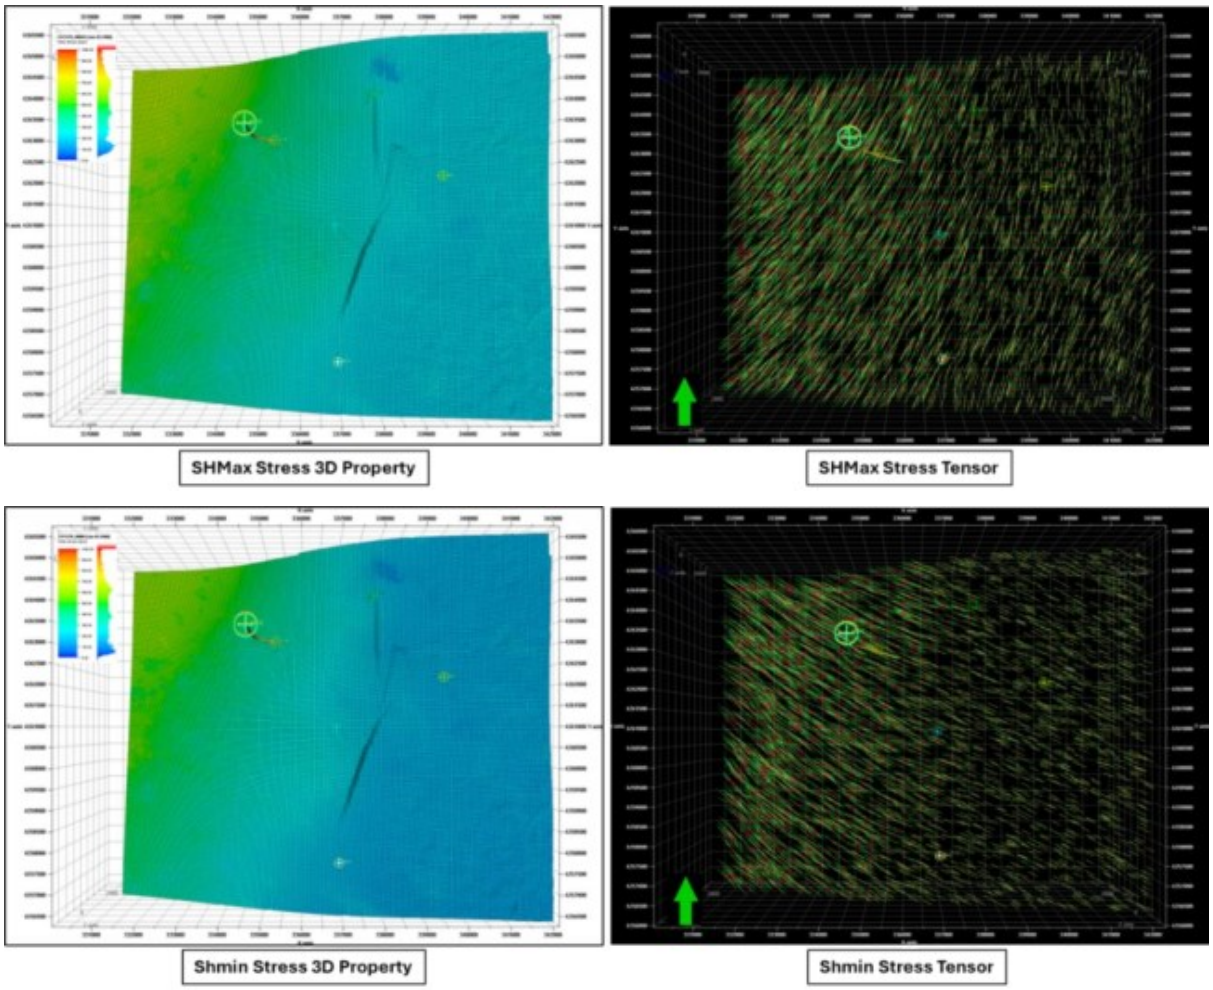

Figure 20: Variation of 3D horizontal stresses in granitoid interval.

5.3 Updated Critically Stressed Fractures

In this analysis, Discontinuity Stability analyzed the stability of fractures, specifically critically stressed fractures, using results from a geomechanical simulation conducted earlier in the study. Fracture stability was evaluated according to the Mohr-Coulomb criterion, which considers parameters such as the friction angle, cohesion of the discontinuity, dip angle, dip azimuth, and the 3D stress distribution provided by the geomechanical simulator. In this study, internal properties for the fracture were updated, and a friction angle of 22.5° (equivalent to a coefficient of friction of 0.41) was assumed for the fracture properties.

The discontinuity stability analysis for fractures shows that the fracture set 3 is more contributed in critically stressed fractures compared to the others fracture sets. The critically stressed fracture orientation predominantly with strike azimuth around North-South (175 deg and 355 deg) and with dip between 45° and 75° as shown in Figure 21. The 3D critically stress distribution in the field was shown in Figure 22.

5.4 Updated Probability Map

The fracture permeability model from updated critically stressed fractures consist of three sets in each direction (k_i, k_j, and k_k). According to the location of critically stressed fractures, the high fracture permeability was distributed intensively in the east of Opal Mound Faults as shown in Figure 23. Some regions in the west of Opal Mound Faults have relatively high fracture permeability at the lower part (from -1000 m to -1500 m) and concentrated at the intersection between the basin-bounding fault unconformity and the Mineral Mountain's fault system.

Aligned with the previous study, the average value for permeability in j and k directions (k_j and k_k) were higher than fracture permeability in i direction (k_i) (Mulyani et al., 2023). The average value of each fracture permeability

direction is k_i = 0.0044 md, k_j = 0.0106 md, and k_k = 0.0098 md. The average map of fracture permeability at three directions can be seen in Figure 24.

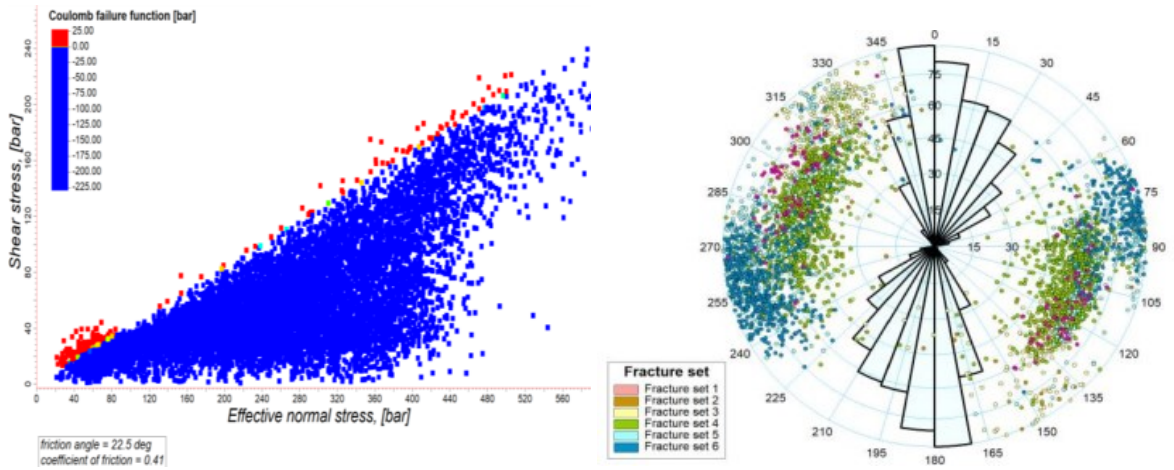

Figure 21: Critically stressed fracture orientation.

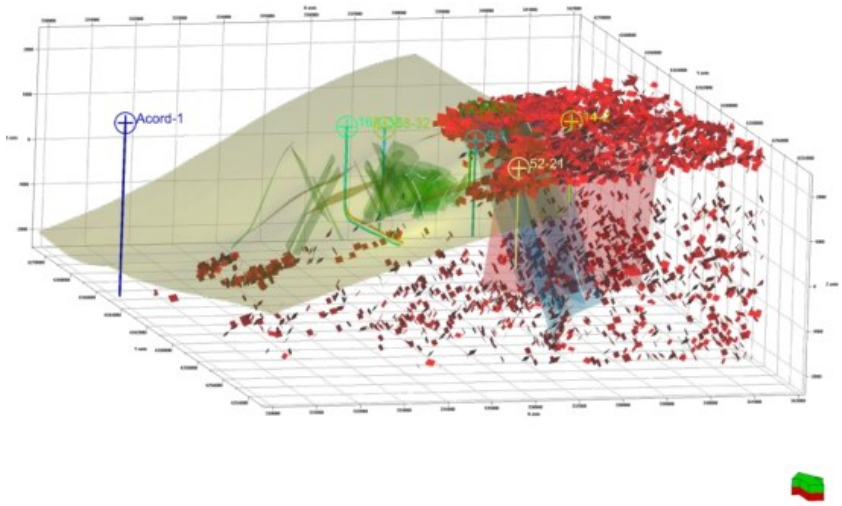

Figure 22: 3D critically stressed fracture distribution.

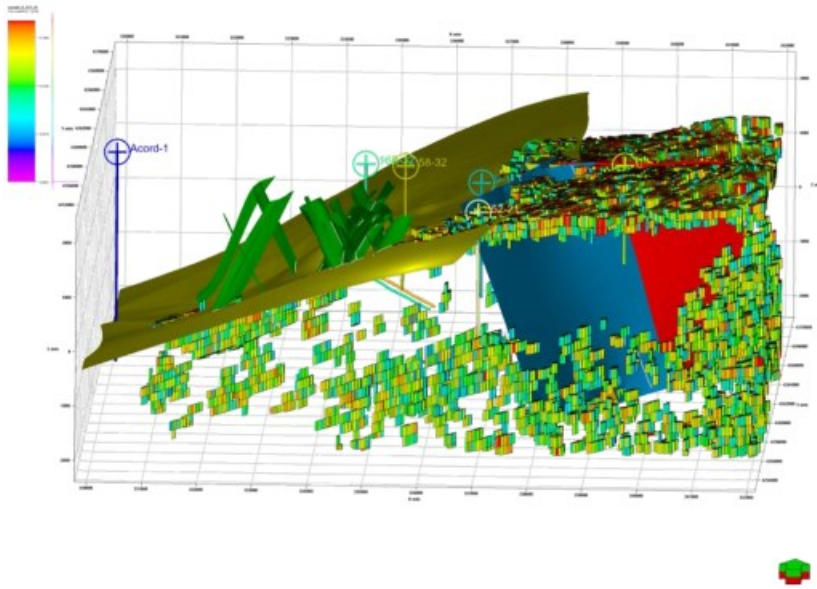

Figure 23: The distribution of high fracture permeability at *i* direction (k_i) based on updated critically stressed fractures and the faults model in the study area.

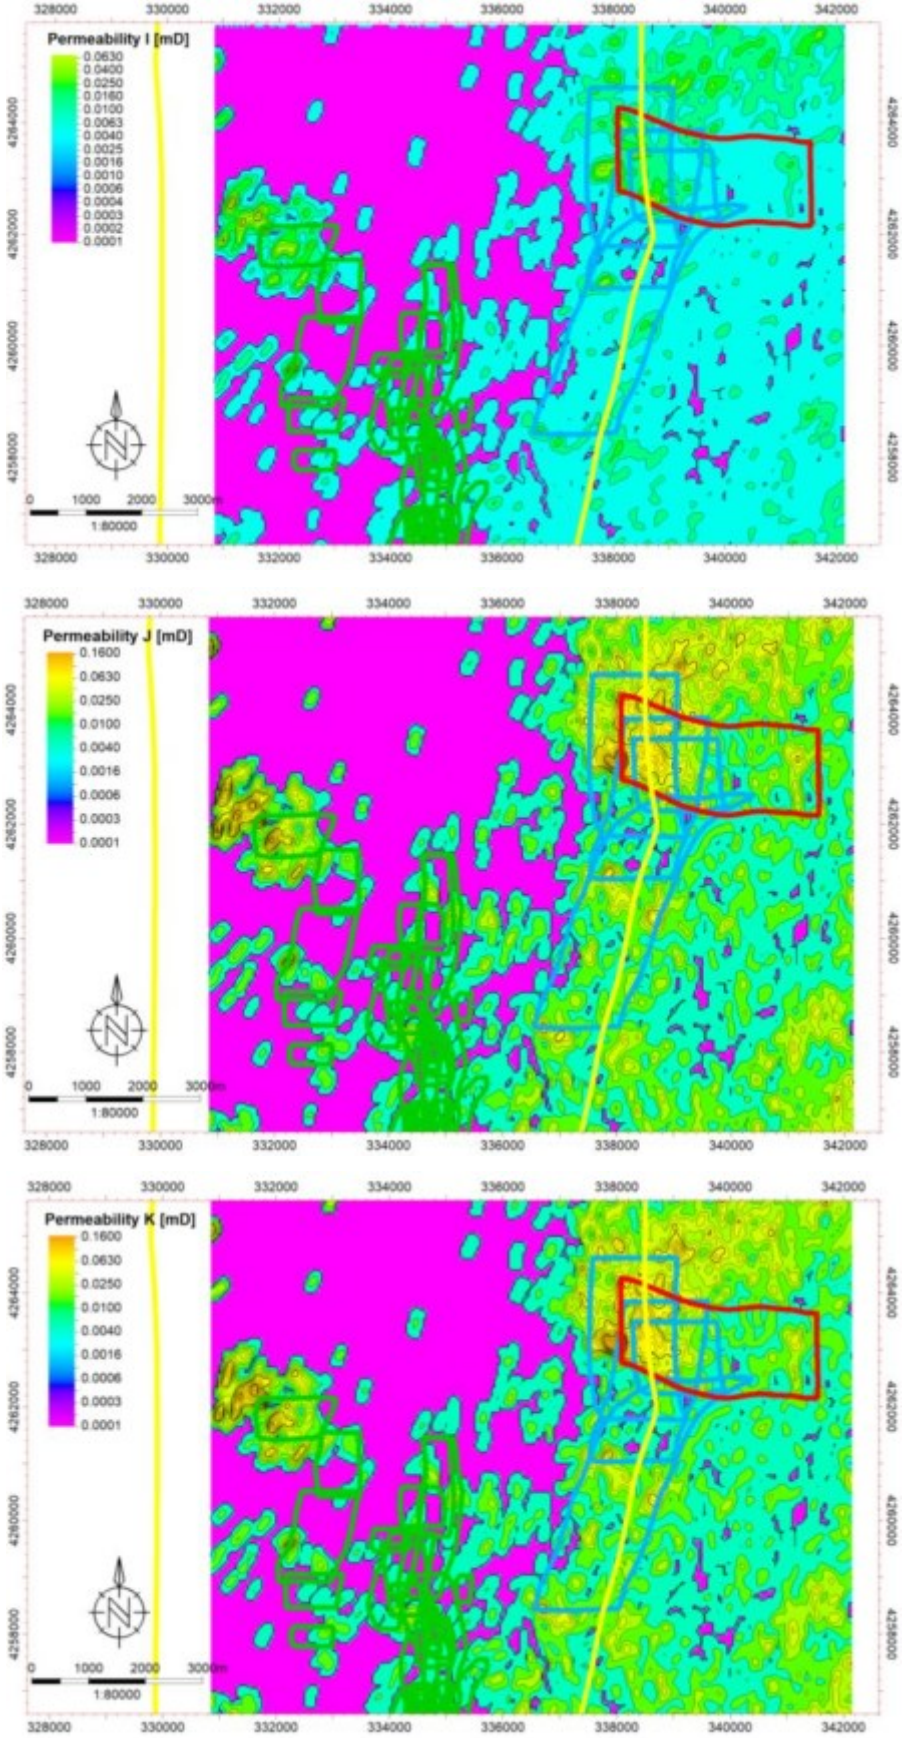

Figure 24: The average map of fracture permeability at *i* direction (k_i) (top), *j* direction (k_j) (middle) and *k* direction (k_k) (bottom) based on updated critically stressed fractures and the polygon of the faults model in the study area.

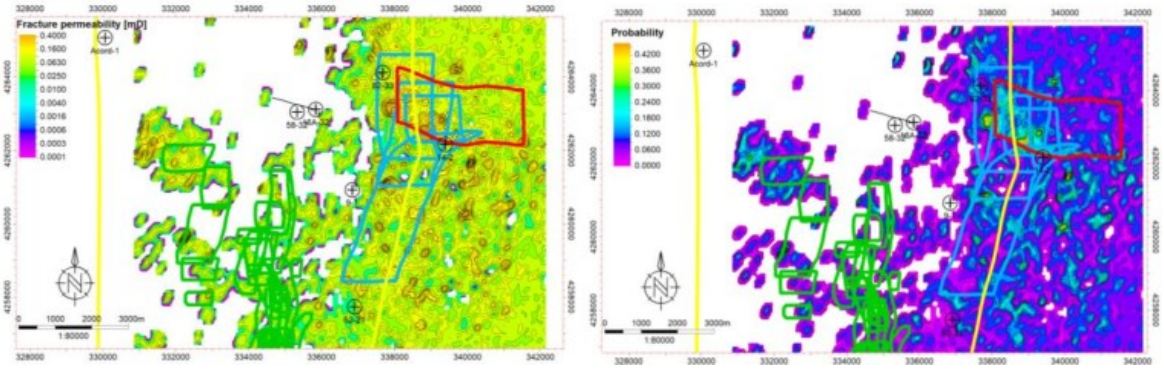

Figure 25: The result of harmonic averaging the fracture permeability k_i, k_j and k_k (left) and the probability map of fracture permeability equal to or greater than 0.95 m in the study area (right).

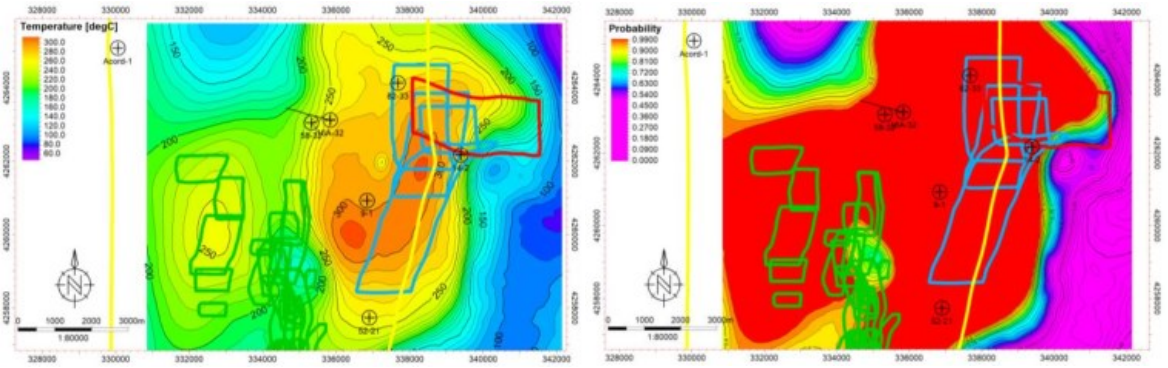

Figure 26: The average map of temperature model at the granitoid zone (left) and the probability map of the temperature equal to or greater than 200°C in the study area (right).

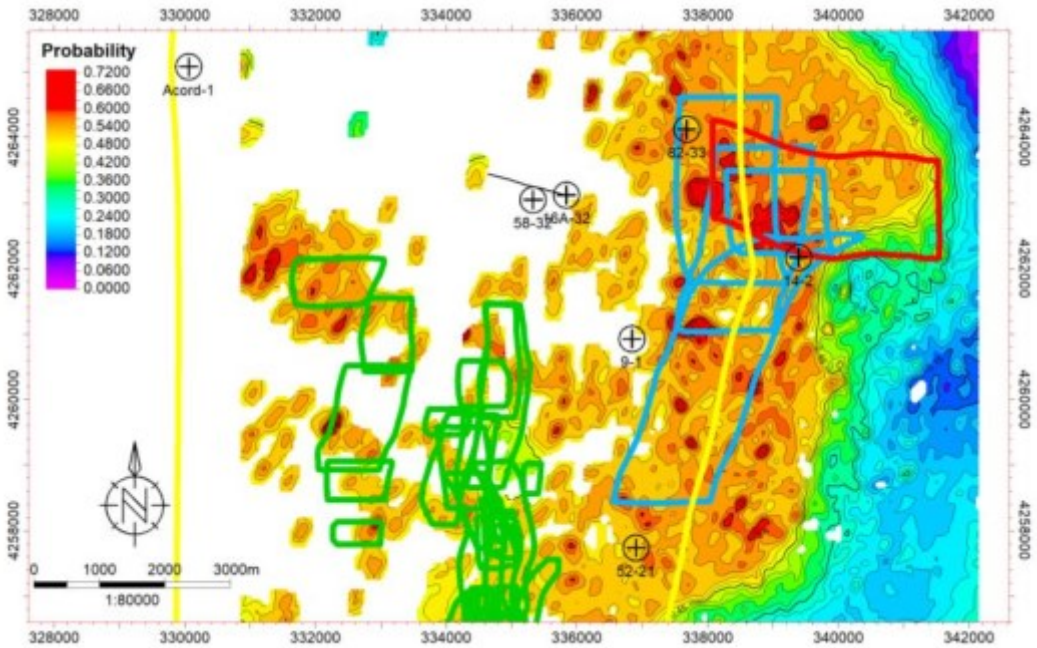

Figure 27: The final probability map of chance to get fracture permeability more than 0.95 md and temperature more than 200°C. The sweet-spot area identified with red color (high probability) is distributed close to the location of the faults model.

All those average maps extracted at the granitoid zone emphasize the region of interest. Overall, the fracture permeability has the same trend for all directions. Based on an average map of fracture permeability at k_j and k_k, the region with the highest value of fracture permeability is found at the area that overlaps with the Opal Mound Fault (blue polygon), Negro Mag fault (red polygon) and the base-bounding fault unconformity (yellow polygon).

The other region with the highest value of fracture permeability is found in the east, at the edge of the Mineral Mountain Faults system.

To obtain a probability map, the fracture permeabilities at three directions were combined by using the harmonic averaging shown in Figure 25 (left). After that, the value of fracture permeability was truncated with the threshold for the good permeability (probability=1) which is 0.95 md. The final fracture permeability then was normalized, with a range value of 0 to 1, as shown in Figure 25 (right).

The temperature map was used to generate a geothermal sweet spot probability map. In this study, the threshold for the hot temperature (probability=1) is 200°C. The temperature map that has been normalized with range value from 0 to 1 shows the probability of area with temperature greater than 200°C (Figure 26).

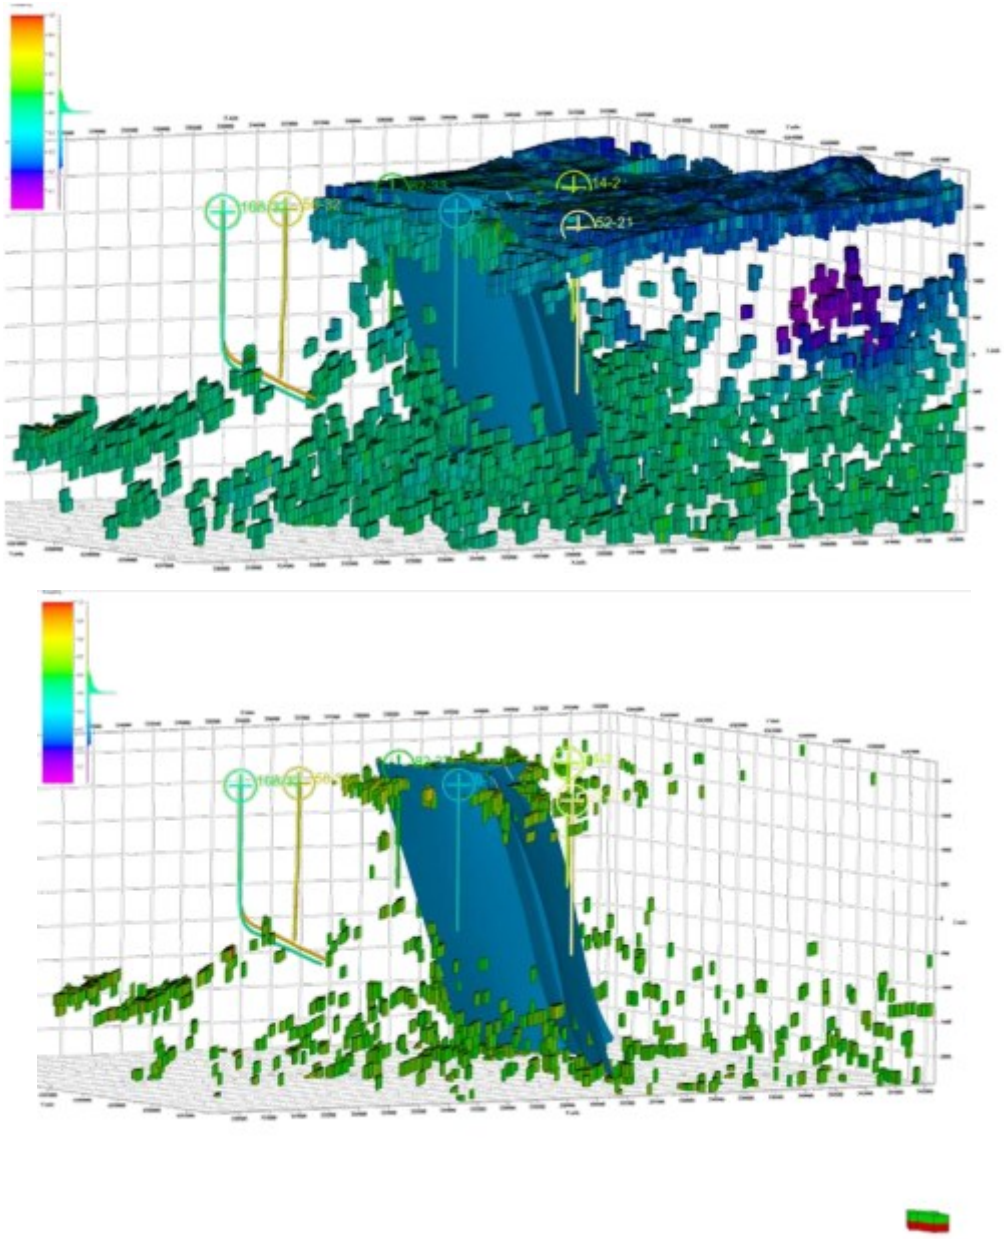

Figure 28: The 3D model of probability for the sweet-spot area (top) and the 3D model that has been filtered for the high value probability (> 0.6) (bottom). This visualization can give an overview for the next target for future development in this field.

The integration between harmonic average maps, which is the probability of effective permeability with the probability of temperature, represents the probability of the geothermal sweet-spot area. The arithmetic average of permeability and temperature probability map can be seen in Figure 27. The final probability map of the favorable area shows the higher chance of good permeability and good temperature region located between Well 82-33 and 14-2. The other location that is far from other wells can be found in the east, south of Well Acord 1.

This result is different from the earlier study, where the most favorable area was located in the central part of the study area or close to Well 9-1 (Mulyani et al., 2023).

Based on the literature study, the Opal Mound Fault is defined as the barrier between the hydrothermal system east of the faults and the low permeability west of the faults. This study aligns with those assumptions where the area with high probability for good temperatures and permeability more concentrated in the east. However, the area in the west can still be developed by having an enhanced process to increase the permeability. In this case, good fracture permeability from critically stressed fracture can be used as targets for the engineering process to get best results. Furthermore, the map of probability can give the picture of connectivity between critically stressed fractures in the western area. All the information can be extremely useful for a development plan in both the hydrothermal system region and the enhanced geothermal system part. The detailed visualization from the probability of a favorable geothermal area can be seen in a 3D view (Figure 28). In this study, a good potential reservoir exists mostly in the eastern part of the study area. However, the area with high probability (more than 60%) of good temperature and permeability occurs also in the western part, close to new Wells 16A-32 and 16B-32. Based on filtered values for high probability, some connecting regions with good reservoir potential can be identified as reference for the development target in the study area.

6. APPLICATION FROM RESULTS

The robust 3D modeling techniques demonstrated here present a spectrum of different applications to resolve existing challenges for EGS and CHS developments. Lateral landing for the producer in EGS requires a fine balance (detailed in the Introduction section). This requires optimizing the well placement along with the fracture geometry development. Having a reliable and calibrated initial model is only possible with an accurate 3D geomodel encompassing all the discrete fracture elements along with an accurate propagation model. Khan et al. (2024) demonstrates the criticality of the EGS network development, as shown in Figure 29. Even though their current work did not use this robust approach, the model presented in this paper will be integrated with a complex fracture propagation model in the near future. A sophisticated fracture model by itself will fail to accurately predict the producer lateral landing location and trajectory, if used without a robust geomodel with integrated geologic and geomechanical modeling.

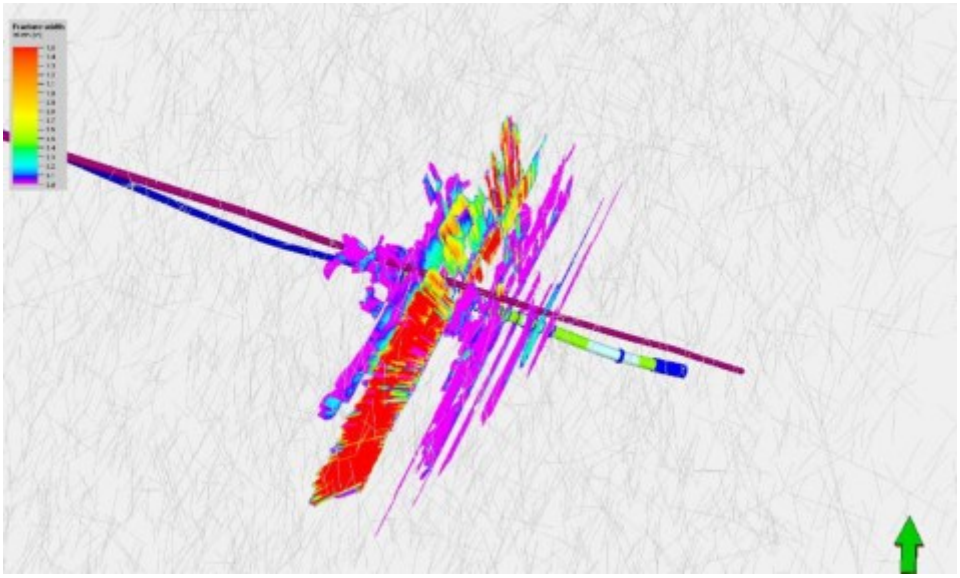

Figure 29: Stimulation fracture conductivity footprint with the DFN elements in grey plan view for fracture width showing the importance of hydraulic fracture interaction with natural fractures (after Khan et al., 2024).

In the context of EGS, understanding the locations of large faults or natural fracture elements with high aperture is critical to avoid connecting with these features and consequently mitigating thermal breakthroughs. This can be the next critical application of our approach here. Reasonable knowledge of reservoir shape, structure, and geometry, and the ability to predict (in probabilistic terms) a thermal breakthrough because of connecting the hydraulic fracture network with that feature is critical for our hydraulic fracturing design phase.

Extension of this modeling work can reap benefits for CHS projects as well. Loss of wells in terms of flow rate, enthalpy, and power generation because of a thermal breakthrough is equally critical for conventional systems as well. The consequences of these breakthroughs of unheated reinjection fluid to the production wells are a reduction

in discharge enthalpy and a reduction in total flow rate (due to the lower steam fraction and greater fluid column weight in the wellbore) (Horne, 1985). Figure 30 (from Inoue and Shimada, 1985) shows the loss of Well H-4 at Hatchobaru geothermal field in Japan due to thermal breakthrough. Despite once being one of the most immense producers in the field, the entire steam output of the well was lost over a period of about 2 1/2 years. If we implement a tight coupling between our probabilistic sweet-spot models with the dynamic reservoir models of the operators' field, such issues can be avoided.

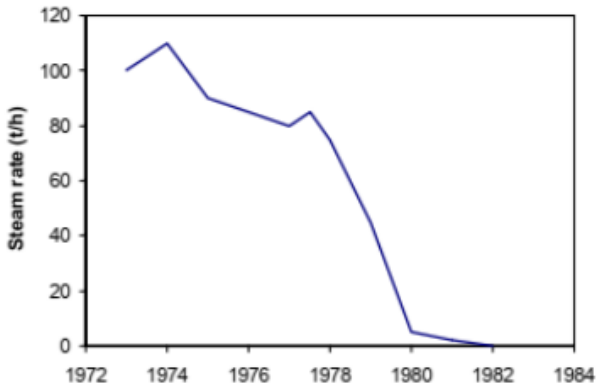

Figure 30: Thermal breakthrough occurrence in Well H-4 at the Hatchobaru geothermal field in Japan, causing complete loss of mass flow (after Inoue and Shimada, 1985).

Another possible application of this modeling work is aiding in history matching of CHS dynamic models. History matching of production data typically involves matching pressure, enthalpy, chemical ions, productivity index, etc. Typically, chemistry data aids in identifying connecting or boundary/barrier systems in the field between injectors and producers. In simple structured grid models, this exercise would not be appropriate as much as with a robust model presented here. The granular definition of geological and fracture features would enhance the experience of history matching, yielding accurate matches and changing the 3D model features in a more reliable way.

7. CONCLUSIONS

The integration workflow of critical stress prediction with other geological analyses resulted in the updated delineation of a favorable geothermal conditions map at the Utah FORGE project site. The calibration of this study was done by using added geomechanics parameters from the latest Wells 16 A and 16 B. The result showing the highest probability of sweet spot was found east of the Opal Mound Fault. The area west of Opal Mound Fault has some regions with good potential to be developed for enhancing connection through fractures while mitigating thermal breakthroughs. Detailed location of that region can be used as reference for the engineering process to develop the enhanced geothermal system at the project site. Overall, the results from this study show more comprehensive results than the earlier study due to added well information. This suggests the importance of updating the subsurface model for each new well dataset to get a better vision of the future development plan in the geothermal field.

ABSTRACT

Geothermal modelling plays a crucial role in the successful development of geothermal fields. It aids in the planning of resource utilization, as well as the assessment and management of geothermal fluid production to achieve optimal performance. A critical application of a wellbore/reservoir model is conducting future scenario simulations to make accurate forecasts using a well-calibrated reservoir model. To accurately simulate the future performance of geothermal wells, it is crucial to understand the coupling requirements and effectively integrate wellbore and reservoir simulators. T2Well is a simulator for non-isothermal and multiphase fluid flow that can model tightly coupled wellbore-reservoir flow. T2Well extends the capabilities of the numerical reservoir simulator TOUGH2 by integrating a wellbore sub-domain into the numerical grid, allowing it to compute flow in both the wellbore and the reservoir concurrently and efficiently. However, there are no published examples and no known projects where it has been applied to a full-scale 3D geothermal model.

This paper presents the construction of the 3D reservoir model following the standard practice in developing a dynamic model for a geothermal system. We utilized T2Well with Equation of State (EOS) 1 to identify the necessary model setup requirements for a convective hot geothermal reservoir system with temperature ranges from 250°C to 270°C. The initial conditions for the fully coupled wellbore-reservoir simulation are based on the results of the natural state simulation of a synthetic geothermal field. This research also provided insights from setting up the input data and model parameters within the T2Well environment.

1. INTRODUCTION

Geothermal modelling is pivotal for planning geothermal energy resources and evaluating and managing the production of geothermal fluids to ensure optimal performance. Traditionally, wellbore and reservoir models have been treated independently during simulations of future scenarios. The results from such simulations are typically derived from the reservoir conditions at the feedzones rather than from wellbore simulation results. While it is possible to manually convert the feedzone conditions to well production forecasts using a wellbore model at each reservoir simulation time step, this method is complex, time-consuming, and often results in extended simulation durations. Therefore, optimally coupled wellbore and reservoir models, along with a comprehensive understanding of the coupling requirements, are invaluable for accurately simulating the production forecasts of a geothermal field. This approach also aids in accurately simulating the future performance of geothermal wells using production history data derived from field surveys.

Several researchers have explored the integration of a geothermal reservoir simulator with a wellbore simulator. Hadgu et al. (1993) explicitly coupled TOUGH (Pruess, 1987) with the steady-state wellbore simulator WFSA (Hadgu and Freeston, 1990) using a bridging function named COUPLE, which facilitates the exchange of information between the simulators. Bhat et al. (2005) performed an explicit coupling of TOUGH2 (Pruess et al., 1999) with the HOLA simulator (Bjornsson, 1987) by integrating HOLA as a function/subroutine within TOUGH2. Gudmundsdottir (2012) utilized TOUGH2 and the steady-state wellbore simulator FloWell (Gudmundsdottir et al., 2012; Gudmundsdottir and Jonsson, 2015) to create a linked wellbore-reservoir simulator using the DELV type. However, no published examples or known projects have applied a tightly coupled wellbore reservoir simulation to a full-scale 3D geothermal model.

This paper presents a fully integrated wellbore-reservoir simulation applied to a full-scale 3D geothermal model using T2WELL (Pan and Oldenburg, 2014). The construction of the 3D reservoir model follows the modelling framework developed by the Geothermal Institute (O'Sullivan et al., 2023; Nugraha et al., 2022), which facilitates the generation of a dynamic model for a geothermal system. We employed T2Well with Equation of State (EOS)1, the same version used by Renaud et al. (2021a; 2021b; 2020; 2019a; 2019b) in their studies, to delineate the necessary model setup requirements for a convective hot geothermal reservoir system with temperature ranging

from 250°C to 260°C. Initially, we constructed the 3D numerical model with refinements in the main upflow and wellbore areas using PYTOUGH (Croucher, 2011; 2015) scripts. This research investigated the fully coupled wellbore-reservoir simulation with one vertical production well, referred to as WELL1. The initial conditions for the fully coupled wellbore-reservoir simulation are based on the results from the natural state simulation of a synthetic geothermal field. The production setup of the tightly coupled wellbore-reservoir simulation was executed using PYTOUGH scripts, and the fully coupled simulation results were visualized using TIM (Yeh et al., 2013).

2. T2WELL SIMULATOR

T2Well is a fully coupled simulator for non-isothermal and multiphase fluid flow, capable of modelling coupled wellbore-reservoir flow, and was first introduced by Pan et al. (2011). T2Well expands the functionalities of the numerical reservoir simulator TOUGH2 (Pruess et al., 1999; Finsterle et al., 2014) by incorporating a wellbore sub-domain within the numerical grid. This integration enables concurrent and efficient flow computation in the wellbore and the reservoir. The Drift Flux Model (Shi et al., 2005) is employed to seamlessly integrate the wellbore flow, applicable across a wide range of flow regimes, with the reservoir Darcy flow without resorting to any approximations such as single-phase flow, productivity index, or quasi-steady state (Pan and Oldenburg, 2014).

Initially, T2Well was deployed as a wellbore simulator for CO_2 and variable salinity water mixtures, simulating transient non-isothermal processes associated with CO_2 flow in deep wellbores. This included transitions from supercritical to gaseous phases, integrating the capabilities of the wellbore simulator T2Well and the reservoir simulator TOUGH2 (Pan et al., 2011). In this context, T2Well was utilized with the equation of state, ECO2N, to simulate CO_2 injection and leakage behavior via wellbores. Furthermore, T2Well has been applied in studies involving Enhanced Geothermal System (EGS) simulations with ECO2H (Pan et al., 2015), energy storage applications of compressed air with EOS7C (Oldenburg and Pan, 2013), and modelling the Macondo well blowout with EOIL (Oldenburg et al., 2011).

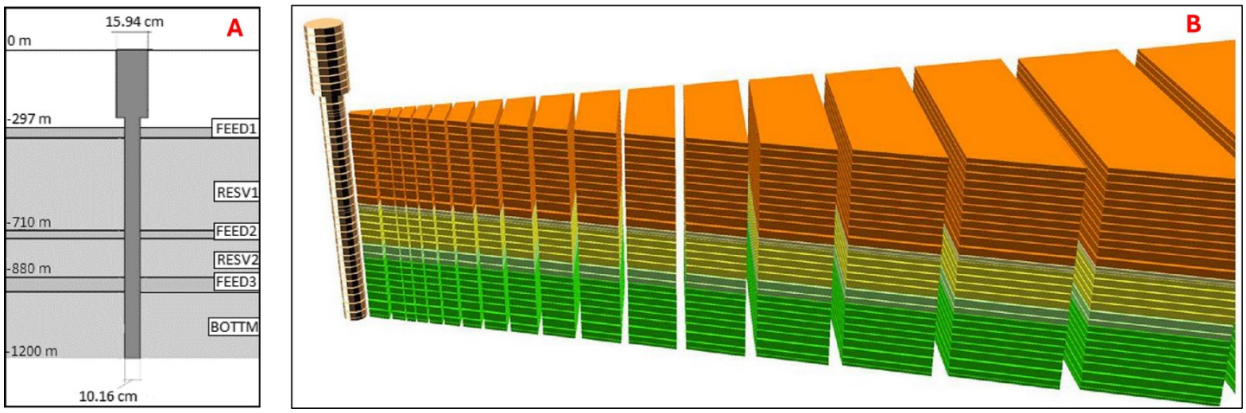

Figure 1: Conceptual model (A) and vertical cross-section of WW-01 wellbore-reservoir model (Vasini et al., 2018).

Vasini et al. (2018) employed T2Well and the EWASG Equation of State (EOS) to interpret a small production experiment in high-enthalpy geothermal reservoirs. The T2Well-EWASG was validated through a fully-coupled wellbore-reservoir simulation using their developed WW-01 wellbore-reservoir model (Figure 1). This model excluded the cap-rock's grid blocks; thus, the heat exchange between the wellbore and the cap-rock (area above 297 m depth) was simulated using T2Well's analytical function.

In subsequent work, Battistelli et al. (2020) integrated the new EOS2H module, suitable for subcritical and steam-like supercritical H2O-CO2 mixtures, into T2Well, the same version used by Vasini et al. (2018). The T2Well-EOS2H code was validated through simulations conducted with various supercritical reservoir simulators and steady-state subcritical and supercritical wellbore flow simulations. Battistelli et al. compared T2Well-EOS2H to T2Well-EWASG by modelling steady-state wellbore flow in two geothermal wells, W2 and KD13, referencing comparative literature (Barelli et al., 1982; James, 1975) used by Vasini et al. (2018).

3. 3D NUMERICAL MODEL DEVELOPMENT

The TOUGH2 model grid developed for this study (Figure 2) spans an area of 15 km x 13 km. It features large blocks set at 1 km x 1 km and is refined in the main upflow area to 500 m x 500 m. The depth of the model grid extends to 3.5 km, with vertical thicknesses ranging from 500 m for the last three bottom layers to 50 m near the

surface. The total number of blocks for this model is 6,580. This setup was conducted following best practices in constructing the 3D numerical model (O'Sullivan et al., 2023; Nugraha et al., 2022) to facilitate the simulation of a convective hot geothermal system.

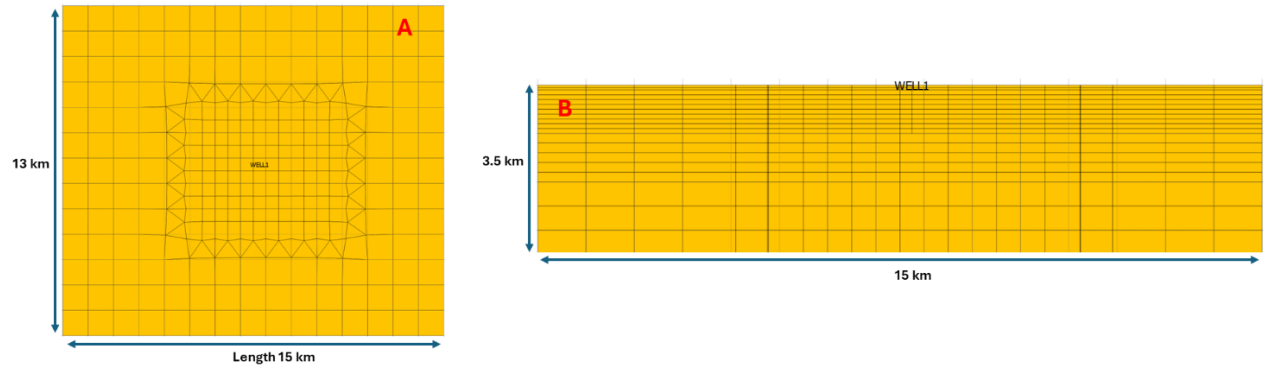

Figure 2: Top surface's plan view (A) and vertical cross-section (B) of the TOUGH2 model grid.

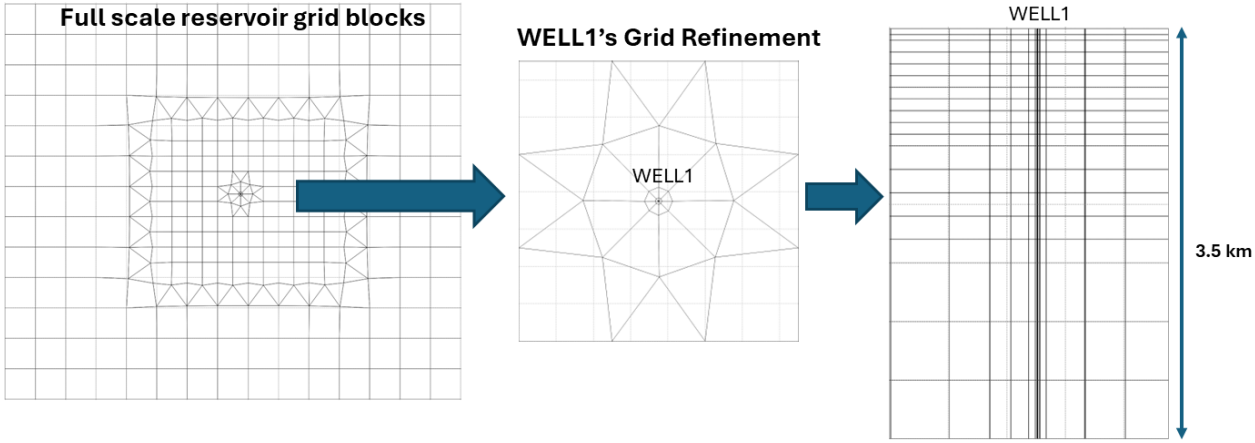

Figure 3: Local grid refinement surrounding the wellbore area WELL1 using optimized triangular refinement.

The trajectory of the planned production well (WELL1) is positioned at the center of the projected main upflow area. Utilizing the location of WELL1, we refined grid blocks surrounding the wellbore area through four stages of the optimal triangular scheme (Figure 3). This refinement was implemented to enable the radial flow of hot fluids during production scenario simulations and to ensure numerical stability by maintaining orthogonal connections among the refined blocks. As a result of this wellbore refinement, the total number of model grid blocks increased to 7,380.

As outlined in the previous chapter, T2Well is an extension of TOUGH2, equipped to conduct fully integrated wellbore-reservoir simulations. However, T2Well lacks the capabilities and computational efficiency of AUTOUGH2 (Yeh et al., 2012) for running a 3D model effectively. To ensure that the simulation process ran efficiently within a reasonable time frame, we aimed to keep the total number of model grid blocks under 10,000.

4. NATURAL STATE MODEL SETUP AND SIMULATION

4.1 Natural State Model Setup

Before utilizing the developed TOUGH2 model for natural state simulation, we categorized the model grid blocks into five distinct rock types, essential components of a convective geothermal system. As illustrated in Figure 4 below, we designated the last two bottom layers of the model as Basement (B0001), characterized by tight permeability. Adjacent to this, in the middle area of these two layers lies the Upflow (U0001), possessing vertical permeability to facilitate the upward flux of hot water to the reservoir zone. The Reservoir (R0001), located beneath the Claycap, exhibits high permeabilities in the X, Y, and Z directions, simulating the fractured zone. Above the reservoir zone and near the surface, the Claycap (R00A1) is defined by very tight permeability, indicative of the alteration zone. Surrounding the reservoir zone, the Outer zone (O0001) is typified by the permeability characteristics of volcanic rock. Detailed parameters of these five rock types are presented in Table 1.

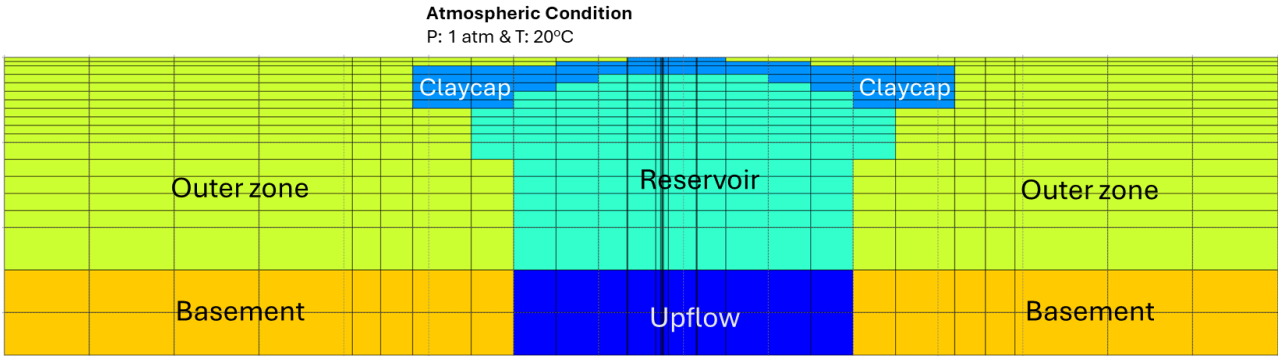

Figure 4: Rock type distribution within the TOUGH2 model and top boundary condition set up.

Table 1: Detailed parameters of the designated rock types.

	Name	DROK	POR	PER(1)	PER(2)	PER(3)	CWET	SPHT	FREQUENCY
1	0ATM1	2500	0.1	1.000000e-15	1.000000e-15	1.000000e-15	2.5	1000	368
2	O0001	2500	0.1	1.000000e-15	1.000000e-15	1.000000e-15	2.5	1000	4001
3	R00A1	2500	0.1	1.000000e-16	1.000000e-16	1.000000e-16	2.5	1000	785
4	B0001	2500	0.1	1.000000e-15	1.000000e-15	1.000000e-15	2.5	1000	538
5	R0001	2500	0.1	3.000000e-14	3.000000e-14	7.000000e-15	2.5	1000	1476
6	U0001	2500	0.1	1.000000e-15	1.000000e-15	5.000000e-15	2.5	1000	200

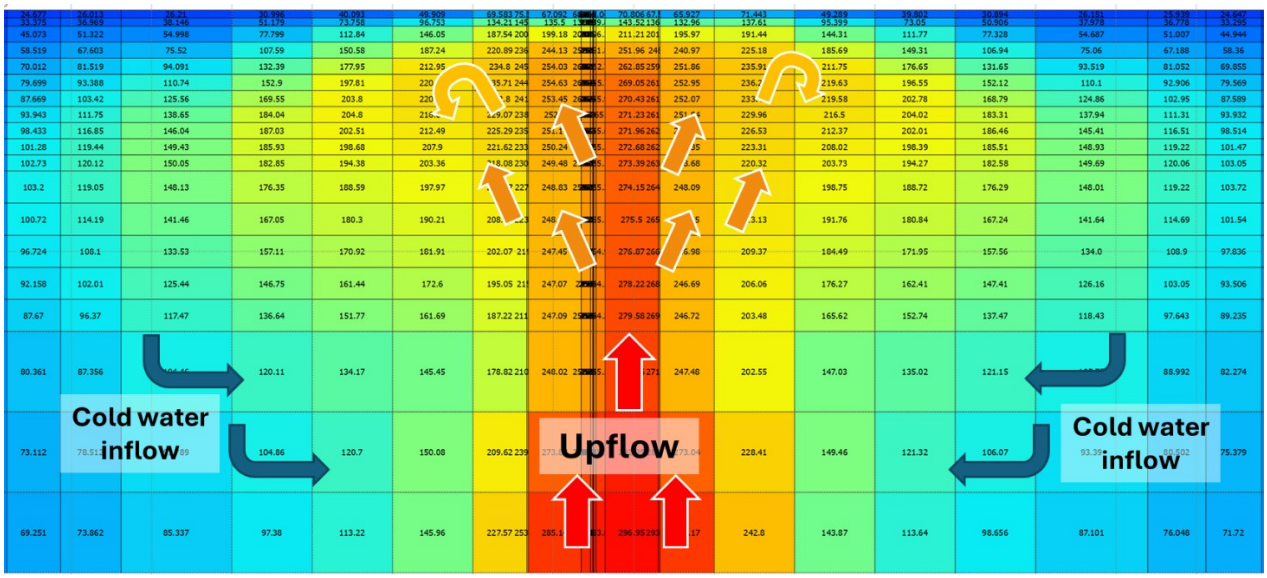

Figure 5: Simulated natural state temperature distribution of the synthetic geothermal model.

4.2 Boundary Condition Setup

Top boundary: At the top of the model, dry atmospheric conditions are assigned at the top surface blocks with a pressure of 1 atm and ambient temperature of 20°C. The equation of state, EOS1, is used in this model to describe pure water in its liquid, vapor, and two-phase states, which could simulate a convective hot geothermal system. An annual rainfall of 2,019.5 mm/year and an infiltration rate of 5% are used.

Side boundary: The side boundaries are presumed to be no-flow boundaries, i.e., no heat or mass entering or exiting the system. The side boundaries are far away (3 - 4 km) from the geothermal reservoir area.

Base boundary: The upflow of the geothermal system is represented by a hot water flux in the Upflow zone blocks, with a total constant mass input of 66.81 kg/s and an enthalpy ranging from 1,200 to 1,300 kJ/kg.

4.3 Natural State Simulation

The natural state model was executed over a simulated period of 3.17 x 10^6 years to achieve steady-state conditions. The simulation results (Figure 5) illustrate the temperature distribution within the reservoir zone, exhibiting a gradient from approximately 270°C in the deeper regions to about 250°C in the upper areas of the reservoir. The dynamics of the hot fluids are characterized by their upward movement from the Upflow blocks,

facilitated by the permeability structures embedded within the 3D model. Along their ascent, these fluids engage in thermal mixing with the saturated water, forming a characteristic convective plume of a liquid-dominated geothermal system. Subsequently, the hot fluids are redirected horizontally toward the periphery of the Reservoir zone, guided by the overlying Claycap's profile.

Over time, as the fluids traverse horizontally, they begin to cool and descend toward the deeper segments of the reservoir model. A cyclical process ensues where the cooling fluids mix anew with rising hot fluids from the Upflow blocks, effectively replenishing the Reservoir zone. Figure 6 depicts the static pressure and temperature around the wellbore location of WELL1, which is designated as the production target zone for the subsequent tightly coupled wellbore-reservoir simulation.

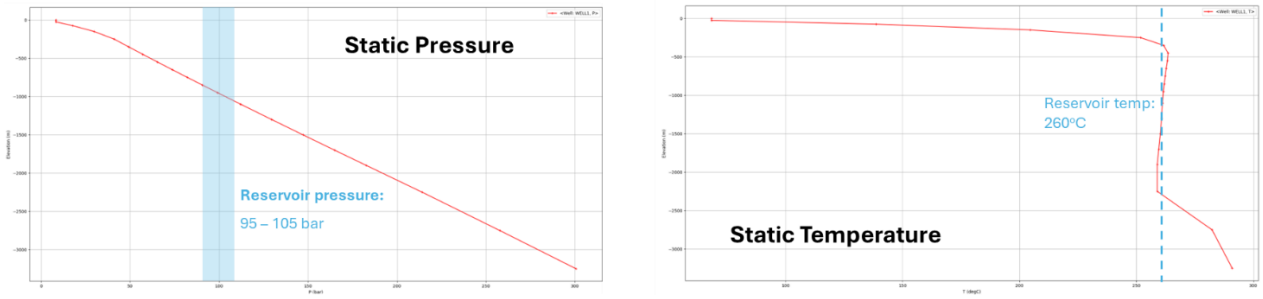

Figure 6: The profiles of static pressure (left) and temperature (right) around the wellbore location of WELL1.

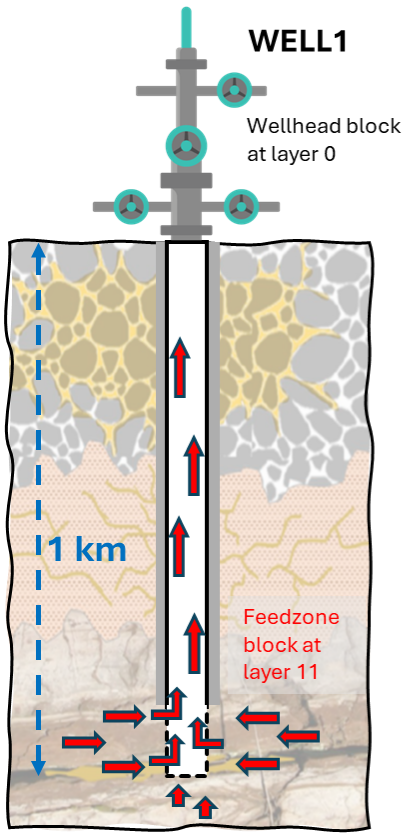

Wellbore Parameters

Parameter(s)	Value	Note
Length	1000 m	Vertical Wellbore
Diameter	9-5/8 inch	Production Casing
Wellhead Pressure	6.5 bar	
Atmospheric Temp	20°C	
Feedzone Depth	900 m - 1000 m	Single feedzone
Pipe Roughness	0.046 mm	Steel Pipe

Figure 7: Conceptual design (left) and wellbore parameters (right) of WELL1.

5. TIGHTLY COUPLED WELLBORE – RESERVOIR MODEL SETUP AND SIMULATION

5.1 Production Model Setup

WELL1 was designated as the production well in the production model by integrating specific wellbore parameters into the Natural State model. The conceptual design of WELL1, as depicted in Figure 7, targets the upper part of the reservoir at a depth of 1,000 meters. For WELL1, a 9 5/8 inch production casing is employed. The bottom block of WELL1, located at layer 11, is designated as the feedzone and features a thickness of 100 meters. A pipe roughness value of 0.046 mm was selected for this model, reflecting the typical roughness

associated with steel pipes. Furthermore, wellhead parameters are established at the surface block (layer 0) of WELL1, maintaining a constant pressure of 6.5 bar.

5.2 Tightly Coupled Wellbore-Reservoir Simulation

The production scenario was conducted over 3.156 x 10^7 seconds (approximately one year), during which the wellbore and reservoir were fully integrated. Figure 8 illustrates the simulation results across this one-year production period. Initially, WELL1 exhibited a high fluid flow rate of 271.56 kg/s. This rate rapidly decreased to 123.49 kg/s after just 132 seconds of production and diminished further to 42.19 kg/s after two hours. Beyond this point, the flow rate stabilized significantly, maintaining an average of 40.85 kg/s throughout the remainder of the year. Concurrently, the enthalpy profile of the produced fluids remained relatively consistent. The initial enthalpy was recorded at 1,148 kJ/kg, which only slightly decreased to 1,118 kJ/kg by the end of the year. This tightly coupled wellbore-reservoir simulation effectively captured the three distinct production phases of WELL1: transient, late transient, and pseudo-steady state conditions.

Furthermore, we can observe the detailed parameters of the fluids produced from this simulation, such as pressure, temperature, enthalpy, and mass flow profiles along the wellbore, as shown in Figure 9. The enthalpy profile slightly changes along the wellbore due to the thermal exchange between the wellbore blocks and the surrounding formations via conductive heat flow. This phenomenon is also in line with the temperature profile of the hot fluids along the wellbore, where the temperature is decreasing from initially 212°C in the feedzone to 164°C in the wellhead. The pressure along the wellbore is also declining from 19.2 bar in the feedzone to 6.5 bar in the wellhead due to the flow restriction inside the wellbore. From all those parameters, we can conclude that the condition of produced hot fluids is already two-phase when entering the wellbore through the feedzone, and it is expanding more due to the pressure decline while flowing upward to the surface, separating the steam and hot water.

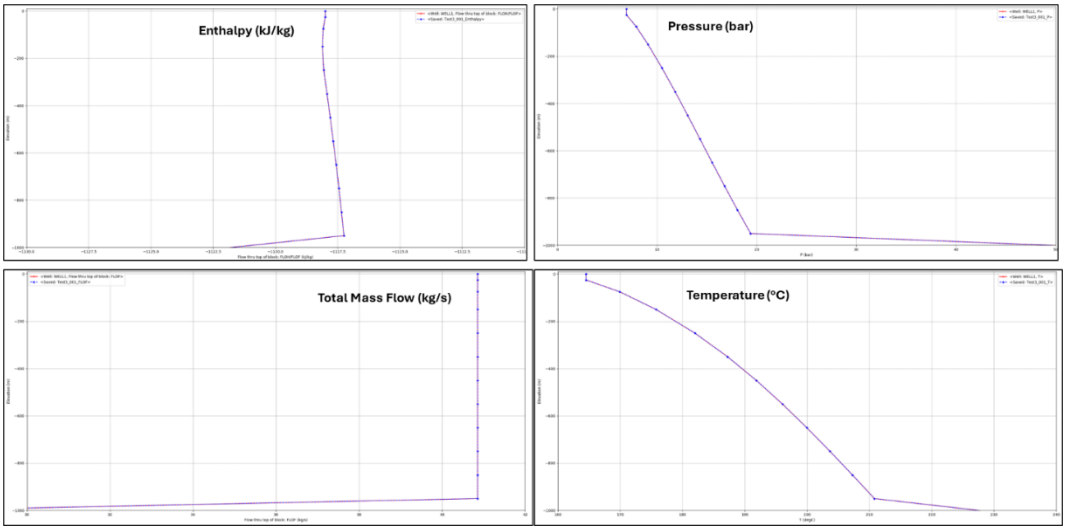

Figure 9: General workflow of the geothermal modelling process for resource assessment of an exploration field.

6. CONCLUSION

This project has successfully developed a full-scale 3D geothermal model for tightly coupled wellbore-reservoir simulations. The model's input setup requirements for a single vertical production well in a fully integrated wellbore-reservoir simulation have been addressed, yielding reliable simulation results. Through this fully integrated simulation using the T2WELL simulator, we were able to observe the common behavior of a geothermal production well. All produced fluid parameters along the wellbore can be visualized using the TIM tool. However, the historical production data need to be extracted and visualized using a different tool, such as an Excel spreadsheet. T2WELL also effectively simulated the three distinct production phases of WELL1: transient, late transient, and pseudo-steady state conditions.

The authors are planning further research to conduct various wellbore-reservoir coupling simulations using T2Well. These studies will explore how minimizing the reservoir grid meshes attached to the wellbore model impacts the simulation results and compare these results with those from the tightly coupled simulation in this project. The goal is to ensure that the simulation outcomes from other coupling methods are comparable in quality to those obtained from the fully coupled full-scale 3D reservoir model.

Some lessons learned in this research regarding the production model setup include:

1. Setting the volume of the Wellhead block at 1 x 10^{50} m^3 is crucial to ensure that the one-year production simulation runs smoothly until the end of the time steps.
2. The porosity and gas saturation of the wellhead element's initial conditions (incon) should be set at 99.99% and 0.99, respectively. The porosity parameter in the wellhead element represents the percentage of the wellbore aperture during the simulation, while the gas saturation represents the maximum allowable steam expansion in the wellhead block.
3. The incon temperature of the wellbore cells should align with the wellbore temperature derived from the Natural State simulation.

ACKNOWLEDGEMENTS

The authors thank our partner, Lawrence Berkeley National Laboratory (LBNL), for their collaboration and making research licenses available.

The Design of COI (Cloud Control of Instrumentation) for Manpower Productivity and Carbon Credit Reduction Behavior at 55MW Geothermal Power Plant

Faris Abdillah, Nova Gandika and Mochammad Fa'iq Khasmadin

PT Geo Dipa Energi Unit Patuha, Bandung, Indonesia

faris@geodipa.co.id, nova@geodipa.co.id, faiq@geodipa.co.id

Keywords: Manpower Productivity, Carbon Credit Reduction, Cloud Control of Instrumentation

ABSTRACT

The geographical location of the PT Geo Dipa Energi Patuha geothermal field is located in an area that has extreme weather with a temperature range of 9-20^{o}C with predominantly rainy weather. However, the mobilization monitoring process to the steam field area requires fuel which will cause exhaust emissions. The duration of mobilization by the plant operator will require an accumulated time of around 18 hours in one day or an accumulated time of around 22 days (about 3 weeks) in one month. To ensure the availability of existing control equipment in the control room to work optimally. This situation is the best way to maximize the performance of monitoring in the control room with a fully automation and digitalization system for instrument equipment in the power plant and steam field area. That system is called "COI (Cloud Control of Instrumentation)". The COI will implement 5.0 technology and will be the first integrated system on a geothermal power plant in Indonesia. The work process of the COI (Cloud Control of Instrumentation) system is implementing Long Distance of Control Instrumentation. There are several devices synchronized to process instrumentation parameter readings in the steam field and power plant area. The input readings from the system come from the installed sensors and it is transferred in the form of data to the cloud, then the COI and DCS (distribution control system) controller will process the data to be displayed on each HMI (human machine interface). On the other hand, instrumentation devices will work automatically with remote control to carry out the data transfer processes, data acquisition, and initiate troubleshooting problems (parameter reading data will be stored in the cloud system to facilitate the analysis and troubleshooting process). This feature will make it easier to carry out the troubleshooting method, so that the work execution process in the field will be more efficient and exactly right. This method has proven effective in increasing work efficiency, human resource efficiency and reducing carbon emissions in the environment. The results of implementing this program can reduce carbon emissions by up to 98.35kg CO2 with fuel cost efficiency of up to 24 million. On the other hand, worker productivity will increase by around 84%. The savings from this program for the company reached 288 million IDR per year (fuel consumption).

1. INTRODUCTION

Indonesia is a country that has geothermal potential of 29.5 GW which will continue to increase along with exploration (Agency for the Assessment and Application of Technology, 2020). Patuha Geothermal is a power producer with a capacity of 60MW. The form of savings made is by making continuous improvement efforts. This plant has been operating since 2014 by relying on 10 active wells with a dry phase (PT Geo Dipa Energi - Patuha, 2019) and additional for another 2 wells of 7A and 7B (PT Geod Dipa Energi – Patuha, 2023).

The new GDE project for Patuha 2 will add mileage for the monitoring of instrument equipment in the well pad area carried out by the operator team, The COI was inspired by the existence of the Patuha project 2. At the GDE Patuha 1 mileage to the activity of 182,325 KM / Year requires a total of 14,025 liters of fuel / year, then the possible cost required for monitoring instrument equipment activities is IDR 204 million and generates CO2 as much as 91 Kg / year.

Referring to fuel consumption that requires 14,025 litter of fuel per year producing 91 kg per year, COI provides a solution to reduce solar usage and reduce carbon emissions, as much as 9,375 liters per year and 60.94 Kg CO2/year and save IDR 136 million per year. The efficiency of manpower can finally be better personalized with the COI which makes the monitoring activities of instrument equipment can be done from a distance (Control room) can also streamline the scope of work as an operator and integrated directly with the cloud technology that can be synergized with digitization technology 4.0. In other words, the free time of operators who are licensed with COI technology can be utilized for them to perform other activities such as deepening process understanding, improving skill and ability and making the latest innovations for the benefit of the company.

2. METHODS

2.1 Research Method

This research begins with raising issues that are happening at the Patuha Geo Dipa Energy unit. The issue is an effort to reduce vehicle exhaust gas emissions and optimize work productivity. After the issue is determined, observation work and research study are carried out. Data Schematic, Data Communication, Data Material, Data Fuel Consumption, Data Time Sheet. The function of the research and design of this tool is first to provide information related to the amount of material investment. Calculation and analysis of the relationship between COI and manpower productivity, as well as the number of emissions that can be reduced. The research flowchart was included in Figure 1.

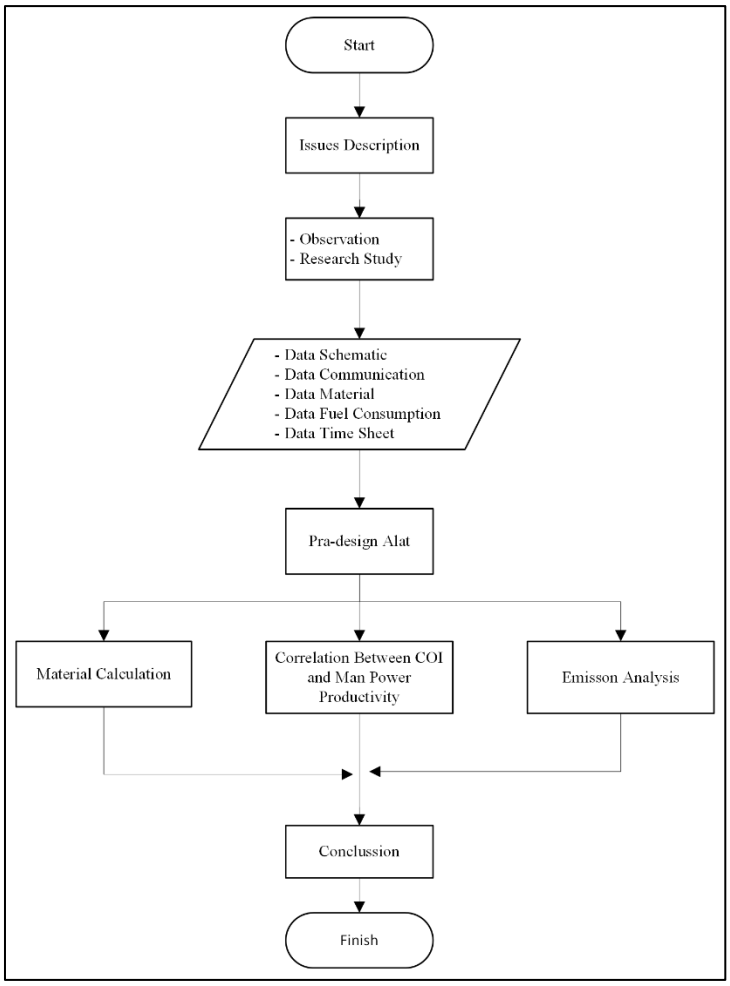

Figure 1: Research Flowchart.

2.2 Economic Analysis

The calculation of economic value in this research focuses on the cost savings used for purchasing fuel and the calculation of compensation and benefits for workers in relation to time and the annual electricity production value of the company. The analysis of fuel value calculation employs a simple analysis by determining the value of lost working hours and the price of fuel oil.

Potential Fuel Cost Savings = Lost working hours * fuel price.

Then, the calculation of lost time productivity value of manpower against electricity production can be analyzed simply by using the variable of lost time per hour, compensation value, and benefits per hour.

Lost Money and Time: lost work * hourly wage

The investment analysis calculation for COI equipment is conducted using the budget planning method adjusted with the self-assessment pricing method (HPS).

2.3 Emission Analysis

The method for calculating the reduction of emission values can be determined using variables X and Y, where variable X represents the accumulated value per km from fuel usage, while variable Y represents the emission content value from the vehicle's fuel. This company has been using fuel products from Pertamina under the brand "pertaminadex," a type of diesel fuel. Based on data from manufacturing, it shows that the content of that type of fuel is CO g/km (0.50); HC+Nox (0.30 g/km); Nox (0.25 g/km); and PM (0.025 g/km).

Emission: X * Y

X = accumulation

Y = rate

3. RESEARCH OF STUDY

3.1 COI Description of System

The COI (Cloud Control of Instrumentation) is a system that can be used to support works such as calibration and monitoring without requiring manpower coming directly to the field. It can help increases manpower productivity as well as help reduces the emissions. The COI is integrated into the system, i.e. 1. The engineering station is useful as a station that collects equipment data on the fields, configures the system and implements control algorithms. 2. The operation station is useful as a machine interface that provides feedback about what is being done or done, in addition to it can also display the command given by the control system, through this system also, by the operator is given the command to the instrument in the field. 3. The Cloud Control of Instrumentation workstation is a tool that is added and integrated with the engineering station used for: a. configuration management: - Remote configuration - User Security - Multiple Communication Protocols - Device Dashboards - Bulk Transfers - Smart Commissioning b. Diagnostic and Monitoring: - Comprehensive connectivity - Online Monitoring with Alert Monitor - DTM Launcher - Device viewer. c. Calibration Management: - calibration connections to field instrumentations. - Create test schemes -Create calibration routes - Calibrations reporting. d. Paperless Documentation: - Paperless Configuration - Paper without Calibrating Management - Paperless drawings and notes. 4. The field control system becomes the brain of the DCS, where control functions are performed, such as PID control, comparison control, ratio control, simple arithmetic operations and dynamic compensation. 5. Remote I/O is an input Output mechanism for measuring and controlling devices, allowing peripherals to communicate directly with the CPU, even remotely. 6. The field instruments, divided into sensors and final control elements.The sensors commonly used are flow meter, pressure, temperature, and level. Whereas final control elements can be controlling valve and on/off valve. The Topology of the COI has been included in Figure 2.

3.2 Description of Issues

The issues raised by this innovation start from the searches and facts in the field related to the use of motor vehicles for monitoring activities carried out by the operators of the team that is said to take a lot of time every day, then the emissions generated by the motor vehicles used in the monitoring activity above also became the issue of the COI technology that we poured on this innovation, in addition to the 2 things above is how much time can be better utilized by the team operators when realizing this technology COI for research and development time, improvement of individual skill and ability of each field operator. The distance and time it take to monitor instrument equipment on the ground is so far and long, so when there is an emergency moment it will slow down to conduct investigation and mitigation, with the COI technology related above can be the answer to facilitate and accelerate operations at the time.

3.3 Emission

Air pollution is the entry or introduction of living things, substances, energy and or other components into the air and or alteration of the order (composition) of the air by human activity or by natural processes so that the air quality becomes less or can no longer function according to its purpose. The transport sector associated with congestion generates emission gases in the air are 1. Carbon dioxide (CO2) Gases produced by perfect combustion of motor vehicles and plant fuels as well as gases from forest fires. 2. Carbon monoxide (CO) Gases that are colorless, odorless, and toxic. 4. PM (Material Particular) is the most visible and most dangerous air pollutant. This is a. aerosol: particles that fade and float in the air b. fog ‘mist’: aerosols that are fragments of water and are in the atmosphere c. smoke ‘smoke’: Aerosols which are mixtures of solid and liquid grains and flying fading in air d. dust ‘dust’: an aerosol of solid fragments and floating in air 5. Pb (Timbal) Heavy metals used by humans to increase combustion in motor vehicles. The result of such combustions is a lead oxide in the form of dust or particle that can be inhaled by human beings.

The number of emissions generated by the transport sector is influenced by the 1. speed of the vehicle. The flow of low-speed motor vehicles will lead to increased concentrations of carbon dioxide (CO) and hydrocarbon (HC) particles, which are more dangerous to health than high speed vehicles. These vehicles will also produce more emissions of exhaust gases containing Nitrogen Oxide (NOx). Provision of vehicle speed brakes in settlements or hallways, often referred to as "sleeping police," is a source of pollution. 2. Old vehicles age the machine is not functional/perfect due to maintenance and limited vehicle spare parts are no longer produced. Therefore, the age limitation of vehicles, especially for public transport, should be considered as one of the solutions. The older vehicles, especially those less wellined, the greater the potential to contribute air pollutants. 3. Traffic conditions High traffic volumes tend to give the largest proportion of air pollution. Moreover, the biggest potential pollution by motor vehicles is traffic congestion. Therefore, traffic regulation, traffic alarms, and strong measures against vehicle violations can help overcome traffic jams and thus reduce air pollution. 4. The road's geometry has resulted in increased fuel consumption of the vehicle, increasing air pollution due to the emissions of such vehicles. 5. The type of vehicle as well as the type of fuel used by each vehicle.

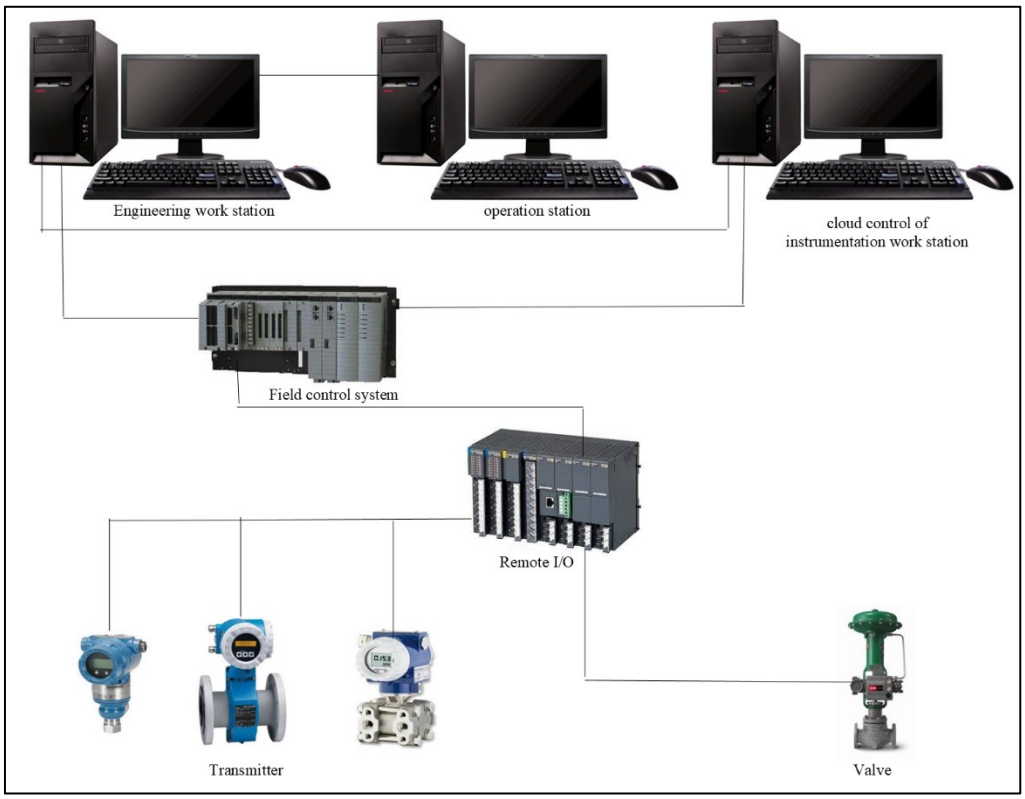

Figure 3: Topology of COI.

3.4 Working Efficiency

The routine monitoring of instrument equipment, which is usually performed by field operators six times a day, indicated has no impact on the increase in GWh and rather takes a lot of time at the time of mobilization to the production well area. By using it, the COI can help to perform routine monitoring of instrument equipment with a faster time flow without eliminating the accuracy of instrument readings because the COI can perform self-loop checks to ensure the reliability of the instruments. Meanwhile, 28 people divided into 4 groups also face the issue of long free time, which makes them standby without productivity. The free time gained after the COI can be used for continuous learning time or for conducting research for continuous improvement.

4. RESULT AND DISCUSSION

4.1 Emission Analysis

The type of vehicle used by this company is diesel, while the fuel used is Pertadex. (pertamina dex). The operational number of this vehicle is only one, and it is used repeatedly to monitor parameters in the steamfield. Although the company has chosen fuels with low carbon emissions, fossil energy still fundamentally has the potential to pollute the environment. The calculation of emission levels in this study is examined in terms of carbon monoxide, unburned fuel, NOx, and particulate matter. Based on the results of the emission value calculations presented in the graph shown in Figure 3. This calculation is carried out by comparing the emission values before and after the implementation of the program. There was a decrease in CO emissions of 60,938 g/km

from 91.163 g/km to 30,225 g/km after the implementation of the program. Meanwhile, the levels of HC+NOx experienced a decrease of 36,563 g/km from 54,698 g/km to 18,135 g/km. Then, the NOx levels decreased by 30,469 g/km from an initial 45,581 g/km to 15,112 g/km. Meanwhile, the particulate matter levels decreased by 3,047 g/km from 4,558 g/km to 1,511 g/km.

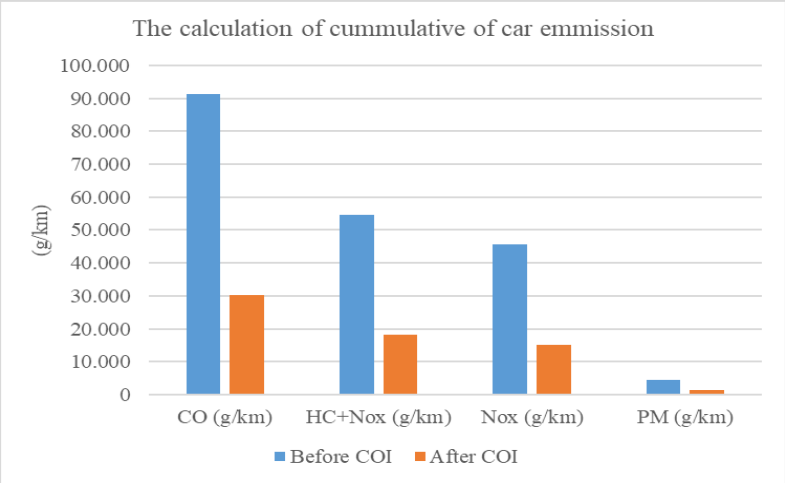

Figure 3: Comparison Chart of Emission Values Before and After COI Implementation.

The impact of the decrease in emission levels is a reduction in the mobility of vehicle operations. The implementation of COI affects the release of job tasks that can be monitored through the COI program features. A comparison of vehicle mobility before and after the implementation of the program is presented in Table 1. There is a decrease of 9,375 liters, from an initial 14,025 liters to 4,650 liters. The results of the COI program implementation are directly proportional to fuel savings and a reduction in carbon emissions.

4.2 Economic Analysis

4.2.1 Economic Analysis in Fuel Sector

The impact of the implementation of the COI program on fuel usage is inversely related. The greater the reduction in time and kilometers, the greater the savings, because the non-massive use of vehicles impacts fuel consumption. The comparison of annual fuel consumption values before and after the implementation of the COI program is presented in Table 1. The fuel consumption value before the COI program was implemented was 14,025 liters/year. Meanwhile, after the implementation of the COI program, it was around 4,650 liters/year. The total cost savings from fuel due to the implementation of the COI program is 136.4 million IDR.

Table 1: Vehicle Operational Data (Yearly).

No	Condition	Type of Vehicle	Fuel Category	Monitoring Time (h)	Fuel Consumption (liter)	Driving Range (km)	Price Fuel (million IDR)
1	Before COI	Double Cabin	Dexlite-Diesel	2,244	14,025	182,325	204,06
2	After COI	Double Cabin	Dexlite-Diesel	744	4,650	60,450	67,66

Before the implementation of the COI, based on a survey conducted among workers, it was found that the average work productivity value ranged from 36% with productivity levels reaching up to 80%, while the remaining 36% had productivity values below 60%, as shown in Figure 4. This shows a gap between the compensation and hourly benefits received by workers and their productivity value. The implementation of this program will increasingly affect workers' productivity, as the amount of leisure time increases. This will impact the relationship between the compensation received by employees and the productivity they deliver. To avoid a gap between compensation and productivity, based on a survey of workers, the implementation of COI has made employees more interested in participating in R&D and Continuous Learning and Improvement programs. This data was obtained from a survey presented in graphical form shown in Figure 5.

4.2.3 Economic Analysis COI Program

The investment amount for the COI program is around IDR 179,200,000. This figure is the result of calculations and surveys conducted in the marketplace. The total investment value includes the VAT. Details of the total investment value for this program are presented in Table 2. Meanwhile, the payback value of this program's investment refers to fuel savings, while the economic value from carbon credit sales and the savings on the human

resources side are disregarded. The Payback value is obtained by subtracting the investment value from the savings value in the fuel sector. Based on these calculations, the payback period for this system lasts only 17 months. The results of the payback value calculations are presented in Table 3.

4.2.2 Economic Analysis from Human Resources

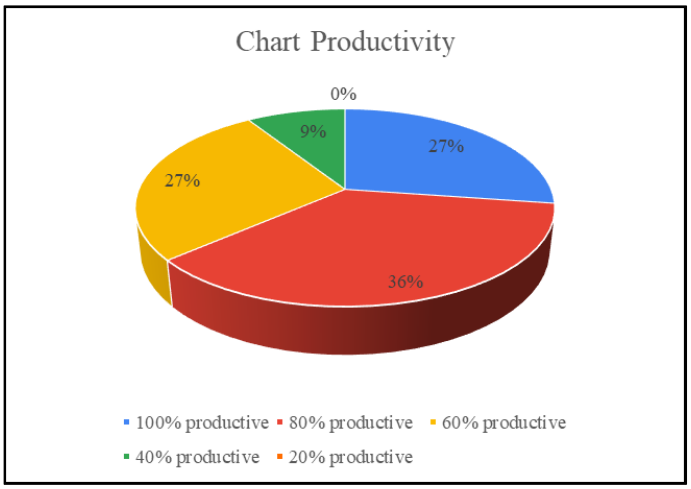

Figure 4: Worker Productivity Chart.

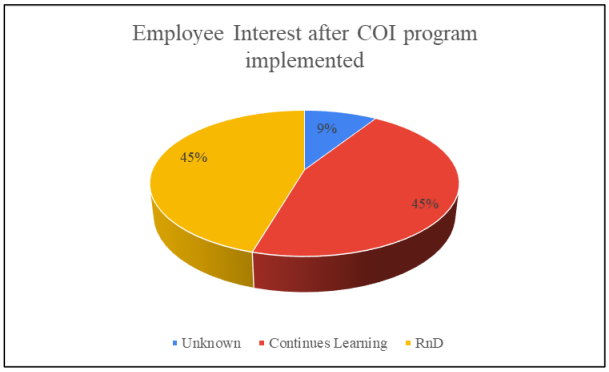

Figure 5: Chart of Employee Interest in Spending Free Time.

Table 2: Total Investment for COI.

No	Item	Qty	Unit	Price (IDR) /Unit	Total Price (IDR)
1	Software Management	1	Ea	80,000,000	80,000,000
2	PC COI	1	Ea	36,000,000	40,000,000
3	Communication Module	3	Ea	5,000,000	15,000,000
4	Kabel LAN	60	m	20,000	1,200,000
5	Installation Design and Risk Analysis (Technical Advisor)	1	Lot	30,000,000	30,000,000
6	Maintenance Cost	1	Lot	17,000,000	17,000,000
				Total	179,200,000
				PPN (11%)	19,712,000
				Grand Total	198,912,000

4.3 Manpower Productivity Analysis

The electricity production data at this plant tends to fluctuate over the course of a year, as seen in Figure 4. The average electricity production value is around 43.44 GWh. The lowest generation value is in February, while the highest generation value is in March. Compared to the lost time value, which remains constant in January, March, May, July, August, October, and December. The relationship between the productivity value of manpower and generation based on conditional data (adjusting to the generation value, the higher it is, the greater the lost time value, and if energy generation decreases, the lost time value becomes lower). The relationship between generation

and energy production is inversely proportional. Another comparison of the relationship between the COI program and manpower productivity is by reducing worker lost time. Based on the questionnaire from the employees, they are more interested in R&D and Continuous Learning and Improvement. Under the following conditions, the relationship between the implementation of the COI program and manpower is a win-win solution; workers can improve their skills and enhance their resilience for improvement and learning.

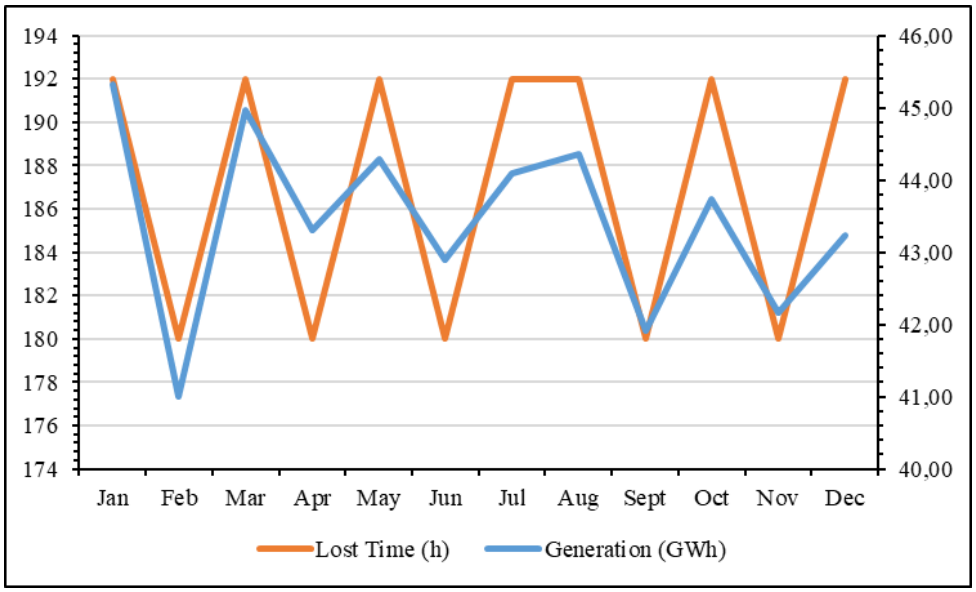

Figure 6: Comparison Chart of Generation (GWh) and Lost Time Productivity.

Table 3: The Scenario of Investment Return.

No	Month	Investment	Savings
1	January 25	198,912,000	187,545,333
2	February 25	187,545,333	176,178,667
3	March 25	176,178,667	164,812,000
4	April 25	164,812,000	153,445,333
5	May 25	153,445,333	142,078,667
6	June 25	142,078,667	130,712,000
7	July 25	130,712,000	119,345,333
8	August 25	119,345,333	107,978,667
9	September 25	107,978,667	96,612,000
10	October 25	96,612,000	85,245,333
11	November 25	85,245,333	73,878,667
12	December 25	73,878,667	62,512,000
13	January 26	62,512,000	51,145,333
14	February 26	51,145,333	39,778,667
15	March 26	39,778,667	28,412,000
16	April 26	28,412,000	17,045,333
17	May 26	17,045,333	5,678,667

5. CONCLUSION

Indonesia has a 29.5 GW geothermal potential, with Patuha Geothermal, a 60MW power producer, operating since 2014. The new GDE project for Patuha 2 will add mileage for monitoring instrument equipment in the well pad area. COI technology, inspired by Patuha 2, can reduce fuel consumption and carbon emissions by IDR 136 million per year. COI allows monitoring activities from a distance, streamlines operator scope, and integrates with cloud technology. This allows operators to focus on process understanding, skill improvement, and innovation for the company's benefit. The technology also allows operators to use their free time for other activities. The research

focuses on reducing vehicle exhaust gas emissions and optimizing work productivity at Patuha Geo Dipa Energy unit. It includes observation work and research on data schematics, communication, material, fuel consumption, and timesheets, aiming to calculate COI and reduce emissions. The Cloud Control of Instrumentation (COI) is a system that supports calibration and monitoring without requiring direct field manpower. It includes an engineering station for collecting equipment data, a machine interface for feedback, and a workstation for configuration management, diagnostic and monitoring, calibration management, and paperless documentation. The field control system functions as the DCS's brain, performing functions like PID control, comparison control, ratio control, and dynamic compensation. Remote I/O allows peripherals to communicate directly with the CPU. Field instruments are divided into sensors and final control elements, such as flow meters, pressure, temperature, and level. The COI can improve routine instrument equipment monitoring by ensuring faster time flow and accuracy without compromising reading accuracy. This method also allows for self-loop checks, reducing standby time for 28 people divided into 4 groups, allowing for continuous learning and research for improvement. The company uses diesel fuel, with a diesel engine and a dex fuel tank. The operational fuel tank is used for monitoring parameters in the steamfield. The study reveals a significant impact on carbon emissions from various sources, including carbon monoxide, unburned fuel, nox, and particulate meters. The implementation of the COI program significantly impacts the reduction of carbon emissions and the increase in fuel consumption. The study concludes that the COI program is crucial for environmental protection. The implementation of COI program has a significant impact on fuel consumption, with a decrease in consumption from 14,025 liters before COI implementation to 4,650 liters after. The cost of fuel from COI implementation is 136.4 million IDR. A survey showed that 36% of workers have a high productivity, while 60% have a low productivity. Implementing COI will also affect worker productivity, allowing for more time for R&D and continuous learning and improvement. The COI program's investment amount is IDR 179,200,000, based on market research and surveys. The program's payback is based on the reduction of waste, economic credit utilization, and human resource management. The payback period is only 17 months. The plant's production data is fluctuating, with a total output of 43.44 GWh. The COI program's productivity relationship with generation is based on the reduction of lost time workers. The program's implementation is a win-win solution, allowing employees to improve skills and increase learning opportunities.

Keywords: geothermal, low-medium temperature, optimization, techno-economic

ABSTRACT

The development of geothermal power plants in Indonesia had reached an installed capacity of 2,413 MW by the end of 2023, which is equivalent to 11% of Indonesia's geothermal potential of 23 GW. However, the development of geothermal energy in Indonesia is still predominantly focused on high-temperature resources, with only 8.29 MW (0.3%) of the total installed capacity coming from low-medium temperature resources. Among the multidimensional challenges facing the Indonesian geothermal industry, the development of low-medium temperature geothermal resources is hindered by less attractive economic viability because these resources require the use of downhole pumps to discharge the fluid and the more expensive binary plant technology compared to flash plants. Despite this, 9 low-medium temperature geothermal fields with development plans totaling up to 430 MW are included in Indonesia's National Strategic Project (PSN) pipeline until 2030. Therefore, optimization from a techno-economic aspect is necessary to increase the economic attractiveness of developing low-medium temperature geothermal resources in Indonesia. This study aims to identify potential techno-economic optimization initiatives and to test the impact of these initiatives on reducing the levelized cost of electricity (LCOE) from low-medium temperature geothermal resources. Three potential initiatives, such as targeting shallow outflow wells, utilizing high-temperature electric submersible pumps (ESPs), implementing well stimulation, and employing modular plants, were identified through literature studies on the development of such resources in the United States. Thus, by applying these techno-economic optimization initiatives, it is hoped that the economic attractiveness of developing low-medium temperature resources can be enhanced and made competitive with the maturely developed high-temperature resources in Indonesia.

1. INTRODUCTION

Since its initiation during the first geothermal power plant (GPP) commissioning in Kamojang, West Java, in 1983, Indonesia's GPP development had achieved an installed capacity of 2,413 MW from 50 GPP units by the end of 2023, representing 11% of the country's geothermal potential of 23 GW. (ThinkGeoEnergy, 2024; Al Asy'ari, et al., 2023). However, the GPP development in Indonesia remains largely concentrated on high-temperature resources, with only 8.29 MW (0.3%) of the total installed capacity derived from low-medium temperature resources (GRG-Geoenergis, 2024b) despite having the potential of these resources of more than 9.6 GW (Putriyana, et al., 2022). The first commercial operation date (COD) of low-medium temperature resources GPP was achieved in 2013 at the Mataloko geothermal field with an installed capacity of 2.5 MW (EBTKE, 2020). The subsequent low-medium temperature resources GPP COD events were achieved after a decade, which were Sokoria GPP Unit 1 (5 MW) in 2022 and Sokoria GPP Unit 2 (3.29 MW) in 2023 (ThinkGeoEnergy, 2024). Nevertheless, 9 low-medium temperature GPP projects with a total planned development capacity of 430 MW have been identified as Indonesia's National Strategic Project (PSN) until 2030 (PLN, 2021).

The slow development of low-medium temperature geothermal resources in Indonesia is influenced by both general and specific causes. Generally, multi-dimensional challenges hinder geothermal development in Indonesia across all temperature ranges, as shown in Figure 1 (PLN, 2020). From a funding perspective, geothermal projects often face low bankability during high-risk exploration stages and licenses without fund access. Land and infrastructure present further obstacles, including time-consuming land acquisition, lack of existing infrastructure during early exploration, and remote locations. Additionally, social and environmental challenges such as community rejection, Environmental & Social Impact Assessments (ESIA), Land Acquisition & Resettlement Action Plans (LARAP), and forestry permit compliance add complexity. Project delays are further exacerbated by the slow awarding of Geothermal Working Area (WKP) licenses and the limited purchasing ability of Indonesia's sole electricity offtaker, PLN, necessitating prolonged negotiations between developers, PLN, and the government (Pambudi & Ulfa, 2024). Technical issues also play a significant role, including subsurface

uncertainties, low quality and availability of exploration data, and a shortage of skilled personnel. Specifically, low-medium temperature resources face challenges due to the lack of expertise in their exploration and development, as well as less attractive economic viability due to the higher costs of required technologies like binary plants and downhole pumps compared to those used for high-temperature resources (Yudha, et al., 2022). Consequently, techno-economic optimization initiatives are urgently needed to enhance the economic attractiveness of developing low-medium temperature geothermal resources in Indonesia.

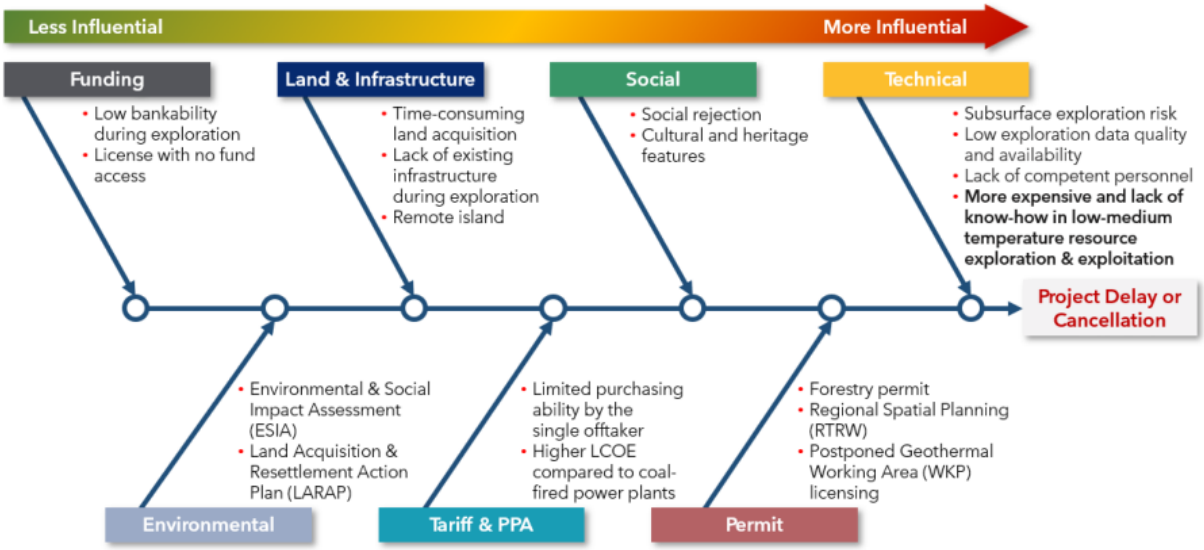

Figure 1: Challenges of Geothermal Development in Indonesia (Pambudi & Ulfa, 2024; Yudha, et al., 2022; PLN, 2020).

Some researchers have pioneered the technological or the techno-economic studies of low-medium temperature geothermal resources in Indonesia. (Febrianto, et al., 2019) summarized the experience on pumped geothermal well projects worldwide as well as improved the previous research by (IFC, 2013) about the effects of productivity index on the pumped geothermal well power output by performing an updated wellbore modeling with more appropriate technical assumptions for the conditions in Indonesia. (Prabowo, et al., 2021) delved more into the technical analyses of downhole pump engineering design for the application in the Tulehu geothermal field, Maluku, within the scope of the reservoir, production well, and the power plant through an analytical analysis of the well testing results to characterize the well's productivity, a calculation of the downhole pump system design, and a calculation of the binary plant's performance. The study revealed that the downhole pump is optimally set at 600 mMD with a potential to produce geothermal fluid at a rate of 173.8 t/h, equivalent to a binary plant net power output of 1.38 MW.

The first comprehensive evaluation of low-medium temperature geothermal resources development in Indonesia was attempted by (Ikhwan, et al., 2021) from the geoscience, technology, and social perspectives. The emphasis of the study was comparing the permeability control and characteristics of low-medium temperature resources in Indonesia and the U.S. with actual geothermal field case studies. A brief overview of pumped geothermal well technology and the potential social issues due to the proximity of such resources to the community settlement were also discussed. Another comprehensive evaluation of low-medium temperature geothermal resources in Indonesia was conducted by (Putriyana, et al., 2022), focusing on the use of statistical data to geologically characterize, locate the regional distribution, and quantify the resource potential of low-medium temperature geothermal resources in Indonesia. Additionally, the study reviewed the existing technologies for low-medium temperature resources, namely binary plant and downhole pump, by performing technical comparisons, such as comparing the organic Rankine cycles with the Kalina cycles for binary plants and comparing the lineshaft pumps with the electric submersible pumps for downhole pumps. Other technologies to optimize low-medium temperature geothermal resources' economic feasibility, such as well stimulation and modular power plant, are also mentioned in the study despite briefly.

The present study aims to identify potential techno-economic optimization initiatives and to test the impact of these initiatives on reducing the levelized cost of electricity (LCOE) from low-medium temperature geothermal resources. Therefore, byy achieving the aim of the study, the following research gaps on the previous studies on techno-economic aspects of low-medium temperature geothermal resources in Indonesia are expected to be fulfilled:

1. **United States experience in developing low-medium temperature resources**: the study by (Putriyana, et al., 2022) lacks the extraction of lessons learned of low-medium temperature geothermal resources development from the global experience. Meanwhile, the present study focuses on extracting the lessons learned from the United States since the U.S. have been developing low-medium temperature resources for more than 40 years with an installed capacity of 1,207 MW, accounting for 33% of the total U.S. installed capacity of 3,615 MW in 2023 (ThinkGeoEnergy, 2024; NREL, 2021).
2. **Transferrable knowledge from high-temperature resources development**: the study by (Putriyana, et al., 2022) lacks the evaluation of the geothermal field development experience that Indonesia have accumulated for the past 40 years, despite still focusing on high-temperature resources, which can be the stepping stones to develop low-medium temperature resources in the future. Meanwhile, the present study evaluates the initiatives from high-temperature resources development in Indonesia with actual field case studies, such as well stimulation in the Salak (Pasikki, et al., 2010) and Wayang Windu (Mulyadi, 2010) geothermal fields, outflow zone development in the Sibayak (Firanda, et al., 2024), Muara Laboh (Stimac, et al., 2019), and Ulubelu (Hochstein & Sudarman, 2015) geothermal fields, and modular power plant construction, to identify how these initiatives can be transferred to optimize low-medium temperature resources development.
3. **Emphasis on pumped geothermal well optimization**: the study by (Ikhwan, et al., 2021) did not correlate the permeability control and characteristics of low-medium temperature resources with the performance of downhole pumps reviewed in the study. Meanwhile, pumped well is a crucial element in the low-temperature geothermal power system to discharge the fluid due to the absence of the flashing process as the flow drive mechanism (Aydin & Merey, 2021; Sanyal, 2005). Therefore, the present study highlights the influence of permeability in controlling the performance of pumped geothermal wells based on the reservoir deliverability and well flow performance analyses.

Furthermore, to achieve the aim of the present study, the following research questions have to be addressed:

1. What is the current status of low-medium temperature geothermal resources development in Indonesia and the U.S.?
2. What are the techno-economic initiatives that can be learned from the low-medium temperature geothermal resources development experience in the U.S.?
3. What are the techno-economic initiatives that can be learned from the high-temperature geothermal resources development experience in Indonesia that can be transferred to optimize low-medium temperature geothermal resources development?
4. How is the impact of the identified techno-economic optimization initiatives on the LCOE of low-medium temperature geothermal resources?

2. POTENTIAL AND CURRENT DEVELOPMENT STATUS IN THE UNITED STATES AND INDONESIA

The potential and current development status of geothermal resources in the U.S. and Indonesia should be analyzed as a foundational knowledge that will provide a framework for identifying the techno-economic optimization initiatives for low-medium temperature geothermal resources. Nevertheless, the analysis is started by first understanding the classification of geothermal resources based on the temperature class and the system type hence the subsequent analysis throughout the paper can be made based on a consistent resource classification and thus an appropriate techno-economic analysis can be applied according to the resource characteristics.

2.1 Geothermal Resource Classification

Before delving into the techno-economic optimizations of low-medium temperature geothermal resources, understanding the classification of geothermal resources based on resource temperature and system type is crucial. This classification provides a clear framework for assessing the viability and potential of different geothermal projects. By categorizing resources according to their temperature, it becomes easier to determine the most suitable technologies and approaches for harnessing these resources efficiently. Additionally, knowing the type of geothermal system, whether it involves high-temperature or low-medium temperature resources, helps in planning and executing exploration, development, and operational strategies effectively for each resource class.

2.1.1 Based on the Resource Temperature

The classification of geothermal resources based on temperature, as depicted in Figure 2, reflects the evolving understanding of geothermal resources and technological advancements in geothermal resource exploitation. Historically, classifications by (Muffler & Cataldi, 1978; Hochstein, 1990; Hochstein, 1990; Bendritter & Cormy, 1990; Nicholson, 1993) primarily divided geothermal resources concerning their direct or indirect utilization capabilities, often based on their potential for exploitation. These classifications identified resource categories like "low," "intermediate," and "high" temperatures, with direct utilization typically involving lower temperatures and

indirect utilization involving higher temperatures. However, advancements in geothermal technology have shown that even low-medium temperature resources can now be effectively utilized for power generation, challenging earlier classifications. For example, binary power plants and the use of pumped wells have made it possible to generate electricity from resources previously considered suitable only for direct use.

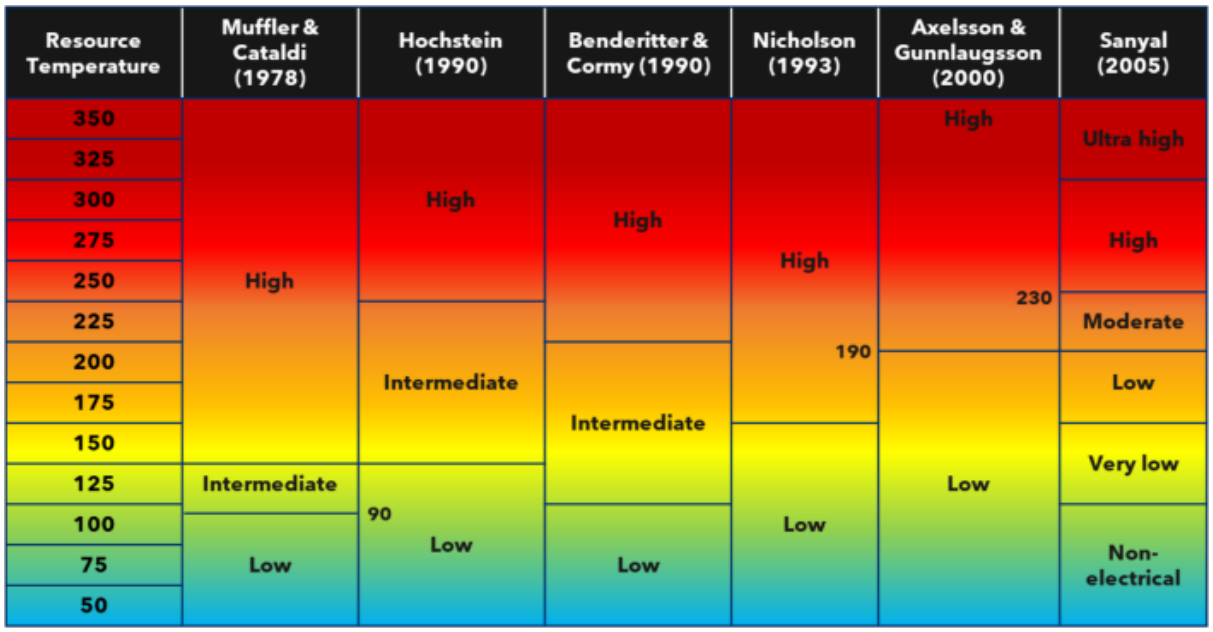

Figure 2: Geothermal Resource Classification Based on Temperature (Sanyal, 2005; Axelsson & Gunnlaugsson, 2000; Nicholson, 1993; Bendritter & Cormy, 1990; Hochstein, 1990; Muffler & Cataldi, 1978).

Meanwhile, (Sanyal, 2005) introduced a more comprehensive classification scheme that considers not only the resource temperature but also factors such as the steam fraction in the reservoir's mobile fluid phase, applicable power generation technology, production mechanisms, well productivity factors, and operational challenges. This new scheme enables a more precise and technology-suited division of temperature classes. For instance, Sanyal's classification acknowledges that "very low" temperature resources can be utilized for electricity generation using binary power plants and pumped wells, expanding the potential uses of geothermal resources beyond what was previously considered feasible. This shift in classification reflects the growing capability of modern geothermal technology to harness energy from a wider range of geothermal conditions, emphasizing the importance of considering technological advancements in resource assessment and utilization.

Due to the more comprehensive and technology-suited classification, the resource temperature classification in present study primarily refers to the Sanyal's classification. However, considering that the present study focuses on the low-medium temperature resources without needing the narrow temperature class range as in Sanyal's classification compared to the, the present study implements the following simplification in the resource temperature classification:

1. **Low-temperature**: 100 to < 190°C.
2. **Medium-temperature**: 190 to < 230°C.
3. **High-temperature**: higher than 230°C including steam-dominated fields.

Table 1: Geothermal Resource Classification by Sanyal (2005).

Temperature Class	Resource Temperature (ºC)	Mobile Fluid Phase in the Reservoir	Production Mechanism	Fluid Phase at the Wellhead	Well Power Output	Applicable GPP Type	Typical Operational Problem
Non-electrical grade	< 100	Compressed liquid	• Artesian self-flowing • Pumped	Compressed liquid	Depending on the reservoir flow capacity and static water level	Direct use	n/a
Very low	100 to < 150	Compressed liquid	Pumped	• Compressed liquid (if pumped) • Steam-liquid mixture (if self-flowing)	2-4 MWe	Binary	n/a
Low	150 to < 190	Compressed liquid	• Pumped • Self-flowing (at the higher temperature end of the range)	• Compressed liquid (if pumped) • Steam-liquid mixture (if self-flowing)	3-5 MWe	• Binary • Double-flash • Hybrid	• Calcite scaling in production wells • Stibnite scaling in binary GPPs
Medium	190 to < 230	Compressed liquid	Self-flowing	Steam-liquid mixture	3-12 MWe	• Single-flash • Double-flash • Hybrid	• Calcite scaling in production wells • Alumino-silicate scaling in injection wells
High	230 to < 300	Compressed liquid; liquid-dominated two-phase	Self-flowing	• Steam-liquid mixture • Saturated steam	Up to 25 MWe	• Single-flash • Hybrid	• Silica scaling in injection wells • Corrosion • High NCG content

Temperature Class	Resource Temperature (ºC)	Mobile Fluid Phase in the Reservoir	Production Mechanism	Fluid Phase at the Wellhead	Well Power Output	Applicable GPP Type	Typical Operational Problem
Very high	300+	Liquid-dominated two-phase	Self-flowing	• Steam-liquid mixture • Superheated steam	Up to 50 MWe	Single-flash	• High NCG content • Corrosion • Silica scaling in injection wells • Silica scaling in production wells at lower wellhead pressures
Steamfield	240 (33.5 bara pressure; 2800 kJ/kg enthalpy)	Steam	Self-flowing	• Saturated steam • Superheated steam	Up to 50 MWe	Dry steam	• High NCG content • Corrosion

2.1.2 Based on the Type of Systems

In addition to the geothermal resource classification based on the resource temperature, the classification of geothermal resources based on system type is crucial for understanding the geological and hydrogeological settings that influence the exploitation of geothermal energy. According to the classification by (Ormat, 2022), geothermal systems are broadly categorized into volcanic, waning volcanic, basinal, and hot sedimentary systems, as illustrated in Figure 3.

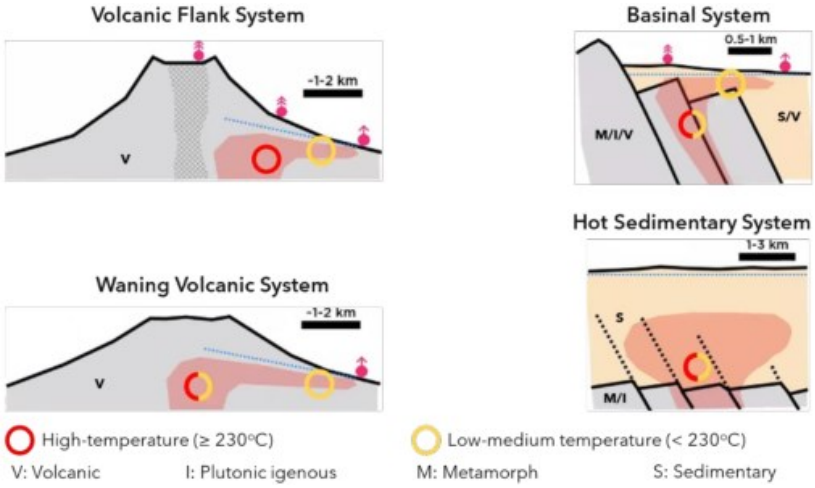

Figure 3: Geothermal Resource Classification Based on the Type of Systems (Ormat, 2022).

Volcanic systems, including arc volcanoes, shield volcanoes, and volcanic complexes, are typically associated with shallow magma bodies and volcanic rocks. These systems often feature steep terrains and upflow hydrogeology, with high-temperature resources, such as those found in Ulubelu and Dieng in Indonesia. In contrast, waning volcanic systems involve cooling intrusive bodies and similar steep volcanic terrains but are characterized by low to medium temperature classes, exemplified by fields like Danau Ranau in Indonesia. Furthermore, basinal systems, such as those found in the Basin and Range province, volcanic rift zones, and calderas, are influenced by amagmatic or magmatic bodies at varying depths. These systems, which can occur in volcanic, plutonic, igneous, metamorphic, or sedimentary rocks, typically feature flat to moderate terrains and upflow or outflow hydrogeology. High-temperature examples include Wairakei in New Zealand, while low to medium temperature examples include Tulehu in Indonesia and McGinness Hills in the U.S. Subsequently, hot sedimentary systems are characterized by amagmatic or deep magmatic bodies within plutonic, igneous, metamorphic, or sedimentary rocks in flat to moderate terrains with stratigraphic hydrogeology. These systems can host high-temperature fields like Salton Sea in the U.S. and low-temperature fields like Brawley in the U.S. The figures further illustrate the typical geological settings and temperature ranges for each system type, emphasizing the relationship between geothermal resource characteristics and their geological contexts. Table 2 summarizes the geothermal factors, host rock, terrain, hydrogeology, temperature class, and notable field examples of each geothermal system type.

2.2 Potential of Low-Medium Temperature Geothermal Resources in Indonesia

Indonesia possesses a considerable potential of low-medium temperature geothermal resources as much as 9,670 MW spread across 254 fields (Putriyana, et al., 2022), accounting for approximately 42% of Indonesia's total estimated geothermal potential of 23 GW (GRG-Geoenergis, 2024b). Furthermore, the regional distribution of these resources is illustrated in Figure 4. The majority of these resources are concentrated in Western Indonesia, amounting to about 5,834 MW, or 60% of the low-medium temperature resources, spread across Sumatra, Java, and Kalimantan. Notably, Sumatra alone harbors the largest share in this region with 3,419 MW, making up 36% of Indonesia's low-medium temperature geothermal resources. In contrast, Eastern Indonesia holds the remaining 3,836 MW, or 40% of the potential, which is distributed among regions like Bali and Nusa Tenggara, Sulawesi, Maluku, and Papua. Sulawesi stands out in this area, hosting the most numerous low-medium temperature geothermal fields in Indonesia with 85 fields and being the largest contributor in Eastern Indonesia with a capacity of 2,150 MW.

Table 2: Types of Geothermal Systems (Ormat, 2022; Moeck, 2014).

System Type	System Sub-Type	Geothermal Factor	Host Rock	Terrain	Hydrogeology	Temperature Class	Field Example
Volcanic system	Arc volcano, shield volcano, and volcanic complex	Shallow magma body	Volcanic	Steep	Upflow	High	• Ulubelu (Indonesia) • Dieng (Indonesia)
					Outflow	Low-medium	• Gunung Talang (Indonesia) • Gunung Sirung (Indonesia)
Waning volcanic system	-	Cooling intrusive body	Volcanic	Steep	Upflow	Low-medium	• Danau Ranau (Indonesia) • Jailolo (Indonesia) • Songa Wayaua (Indonesia) • Bittuang (Indonesia)
Basinal system	Basin and range, volcanic rift zone, and caldera	Amagmatic or shallow/deep/distal magmatic body	Volcanic, plutonic igneous, metamorph, or sedimentary	Flat-moderate	Upflow	High	• Wairakei (New Zealand) • Reykjanes (Iceland) • Olkaria (Kenya)
						Low-medium	• Bitung (Indonesia) • Tulehu (Indonesia) • McGinness Hills (U.S.)
					Outflow	Low-medium	• Salt Wells (U.S.) • San Emidio (U.S.) • Mammoth (U.S.) • Lower Steamboat (U.S.)
Hot sedimentary system	-	Amagmatic or shallow/deep/distal magmatic body	Plutonic igneous, metamorph, or sedimentary	Flat-moderate	Stratigraphic	High	• Salton Sea (U.S.) • Cerro Prieto (California)
						Low-medium	• Heber (U.S.) • Brawley (U.S.) • Unterhaching (Germany)

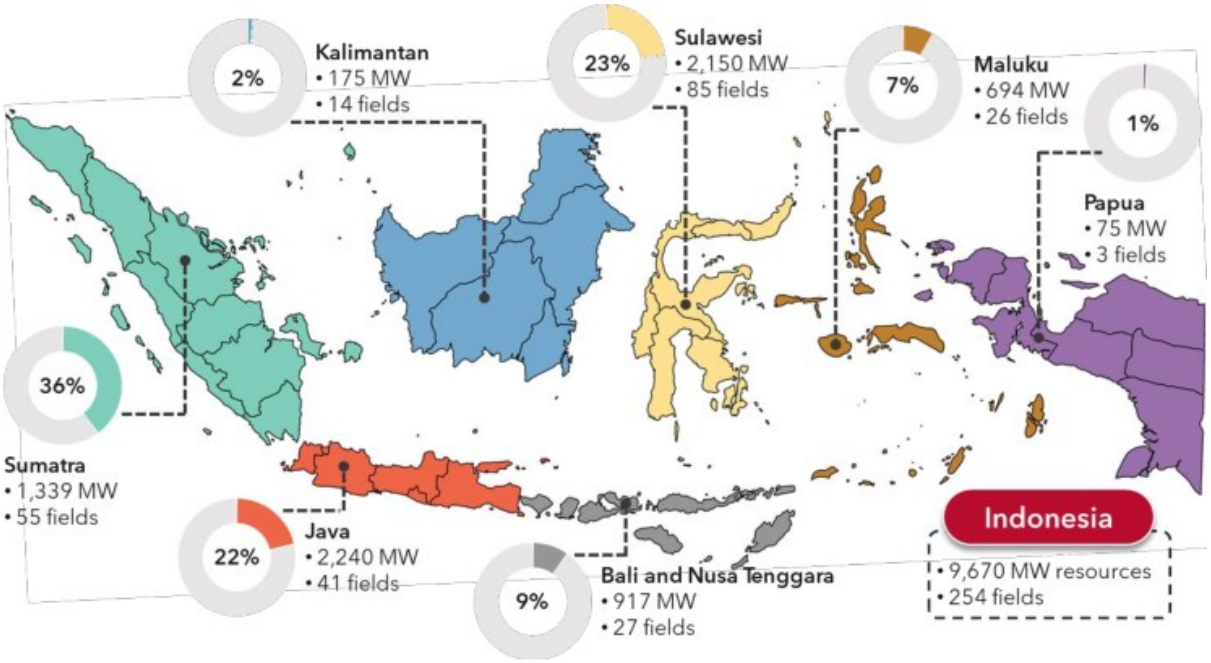

Figure 4: Low-Medium Temperature Geothermal Resources Distribution in Indonesia (Putriyana, et al., 2022). The Percentage Values Represent Each Region's Resource Portion to Indonesia's Total Low-Medium Temperature Resource.

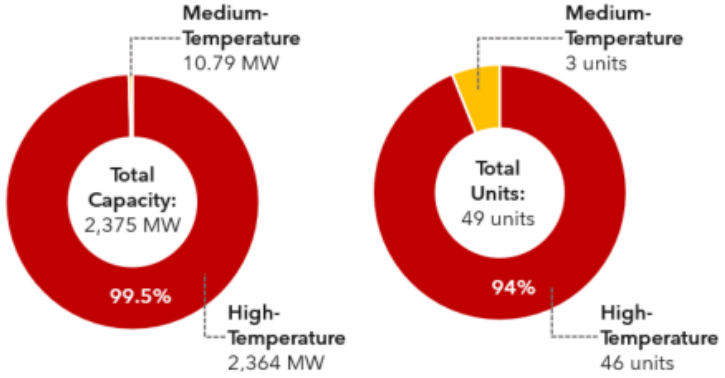
These regional distributions align with the findings of (Kenyon & Beddoes, 1997), which linked geothermal gradients to oil well temperatures, and the heat flow gradient study by (Hamilton, 1973) that further indicated the geothermal potential in each region. The geothermal gradients, mostly ranging from 2–3°C/100 m in the Sumatra-Java outer-arc basin and typically around 3°C/100 m in East Kalimantan, are indicative of the varying geothermal activity across the regions. These gradients help in identifying potential areas for development and provide insights into the geothermal energy capacity that can be harnessed. In areas with higher gradients like the West Java and Madura Basins, where they often reach 4–5°C/100 m, and in the Barito Basin of Southeast Kalimantan, which exhibits gradients of about 3-4 °C/100 m, the potential for geothermal extraction is notably higher (Putriyana, et al., 2022).

2.3 Historical Geothermal Development in Indonesia

Since the commercial operation date (COD) of the first GPP in Indonesia at the Kamojang geothermal field in 1983, the focus on high-temperature resources has remained predominant in the country's geothermal development strategy. As of December 2023, high-temperature geothermal power plants contribute a significant 2,375 MW, which accounts for 99.5% of the total installed geothermal capacity in Indonesia, as shown in Figure 5. In contrast, low-medium temperature resources have seen a relatively limited development, with only 10.79 MW of installed capacity distributed across three units, which only accounts for 0.1% of the low-medium temperature geothermal resources potential. This includes a single unit at Mataloko with a capacity of 2.5 MW, which was the first medium-temperature geothermal power plant (GPP) commissioned in 2013, which is 30 years after the first GPP in Indonesia. Additionally, the Sokoria geothermal field in Eastern Nusa Tenggara saw the commissioning of two units in 2022 and 2023, adding a combined capacity of 8.29 MW. This situation underlines that despite having a considerable potential of low-medium temperature geothermal resources, Indonesia has yet to optimally develop these resources.

The evolution of GPP technology utilization in Indonesia over the years is illustrated in Figure 6, marking significant milestones and technological shifts. Initially, the geothermal sector in Indonesia, starting with the first power plant at Kamojang in West Java in 1983, primarily utilized dry steam and later, single-flash technology as the most dominant GPP technology in terms of the installed capacity and the number of units. It took over three decades after the first plant's commissioning for Indonesia to implement more complex technologies. The first double-flash unit began operation in 2021 at Rantau Dedap, and the combined flash-binary cycle was first adopted at Sarulla Unit 1 in North Sumatra in 2017. These later additions illustrate a move towards exploiting more efficient technologies. Binary GPP, the last GPP technology to be commercially utilized in Indonesia, was first used in 2022 as a bottoming cycle (0.5 MW) at the Lahendong GPP in North Sulawesi. However, it is important to note that binary technology had been part of combined flash-binary systems at the Sarulla and Sokoria GPPs integrated as a combined flash-binary cycle. Respectively, Units 1 (110 MW) and 2 (110 mw) of the combined

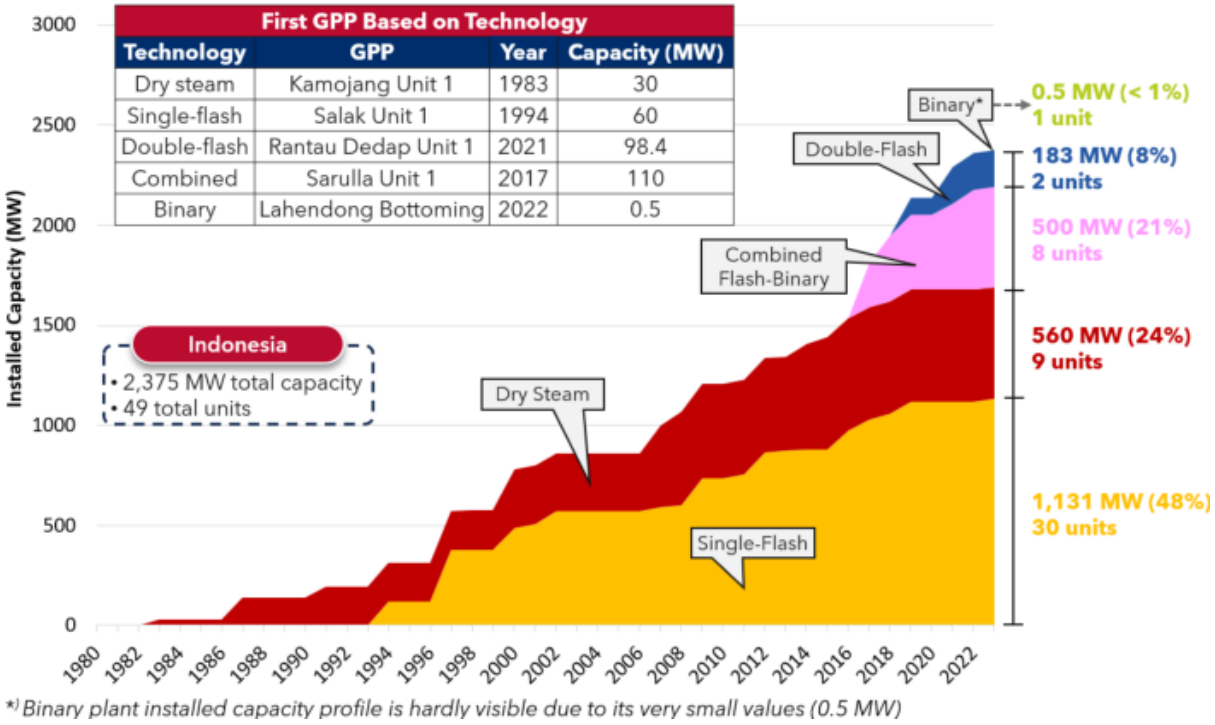
cycle Sarulla GPP was commissioned in 2017 and the Unit 3 (110 MW) was commissioned in 2018. Meanwhile, the Units 1 (5 MW) and 2 (3.29 MW) of the combined cycle Sokoria GPP were commissioned in 2022 and 2023, respectively.



First GPP Based on Resource Temperature				
Temperature Class	GPP	Year	Capacity (MW)	Technology
High	Kamojang Unit 1	1983	30	Dry steam
Medium	Mataloko	2013	2.5	Single-flash

Figure 5: Current Geothermal Development in the Indonesia Based on Resource Temperature as of December 2023 (ThinkGeoEnergy, 2024; Al Asy'ari, et al., 2023; DiPippo, 2016).

First GPP Based on Technology			
Technology	GPP	Year	Capacity (MW)
Dry steam	Kamojang Unit 1	1983	30
Single-flash	Salak Unit 1	1994	60
Double-flash	Rantau Dedap Unit 1	2021	98.4
Combined	Sarulla Unit 1	2017	110
Binary	Lahendong Bottoming	2022	0.5



*) Binary plant installed capacity profile is hardly visible due to its very small values (0.5 MW)

Figure 6: Geothermal Development in the Indonesia Based on Power Plant Technology (ThinkGeoEnergy, 2024; Al Asy'ari, et al., 2023; DiPippo, 2016).

2.4 Future Geothermal Project Pipeline in Indonesia Based on Resource Temperature

In addition to the already developed geothermal fields, the Indonesian government has identified a list of fields requiring further analysis for potential future geothermal development. These prospects are outlined in the National Electricity Supply Business Plan (RUPTL) 2021 – 2030, in which the future geothermal project pipeline can be categorized into three ranks:

1. **Rank 1**: the projects identified as National Strategic Projects (PSN) which is already included in Neraca Daya or power grid so they supposedly become the most prioritized project to develop. There are about 22 fields included here that will supply about 1.5 GW power with expected COD year is already listed in RUPTL 2021 – 2030.
2. **Rank 2**: the projects that also already included in power grid, but no specific fields are assigned. The supply power is around 710 MW.
3. **Rank 3**: the potential projects that are not included in power grid and has no expected COD year stated in RUPTL 2021 - 2030. There are 80 fields included here with total capacity of around 4.3 GW.

By evaluating the RUPTL's Ranks 1, 2, and 3 project pipeline combined, as shown in Figure 7, most of the geothermal future pipeline projects in Indonesia are dominated by low-medium temperature resources development, amounting to 58 out of 94 fields (62%). Additionally, the region of Sumatera possess the highest amount of future pipeline project fields (30 fields) as well as the highest amount of low-medium temperature future pipeline project fields (16 fields). This strategic distribution indicates a significant role for Sumatra in Indonesia's geothermal expansion efforts, especially for low-medium temperature resources.

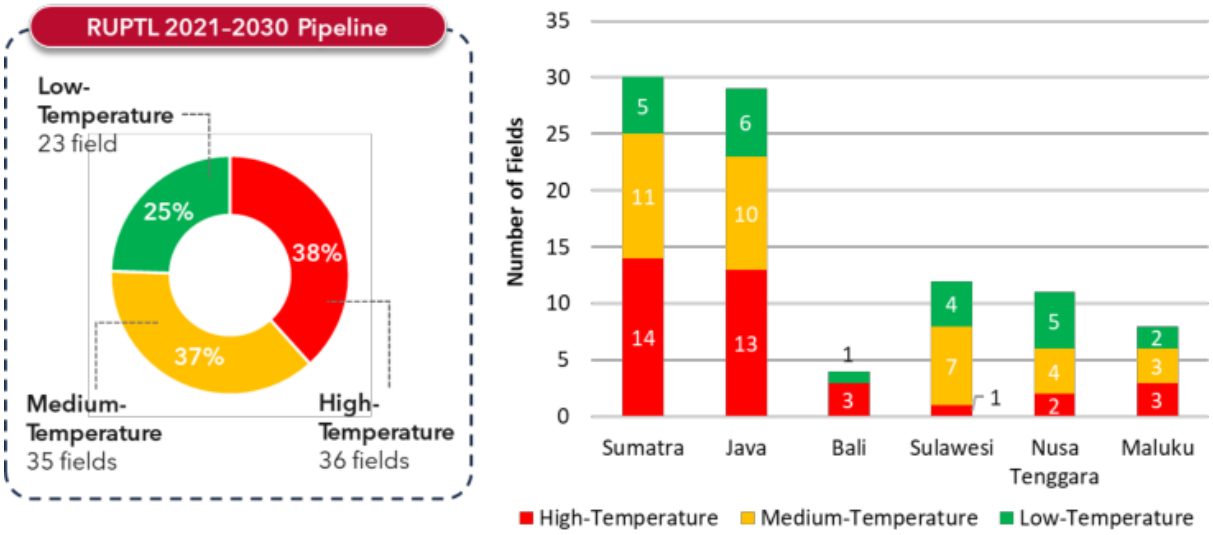


Figure 7: Indonesia's Geothermal Project Pipeline Based on RUPTL 2021 – 2030 (PLN, 2021; GRG-Geoenergis, 2024b).

Furthermore, Figure 8 shows that the Rank 1 pipeline projects in Indonesia are primarily focused on high-temperature fields, which constitute 13 out of the 22 fields (59%). However, when looking specifically at exploration projects within this ranking, there is a notable shift towards low to medium-temperature fields, which make up 9 out of the 16 exploration fields (62%). This trend indicates a growing interest in exploring and developing more low to medium-temperature green (undeveloped) fields in the future, reflecting a diversification in the types of geothermal resources being targeted for development in Indonesia. Notably, Sumatra has a significant focus on exploring high-temperature fields with 4 out of 6 fields to be explored and developed, while Java is prominent in medium-temperature exploration with 5 out of 8 fields to be explored. Most of the exploration projects will also be concentrated in Java, amounting to 8 (50%) out of the 16 Rank 1 exploration projects. Meanwhile, a low-temperature geothermal field is expected to be explored in the Nusa Tenggara region at the Oka Ile Ange geothermal field.

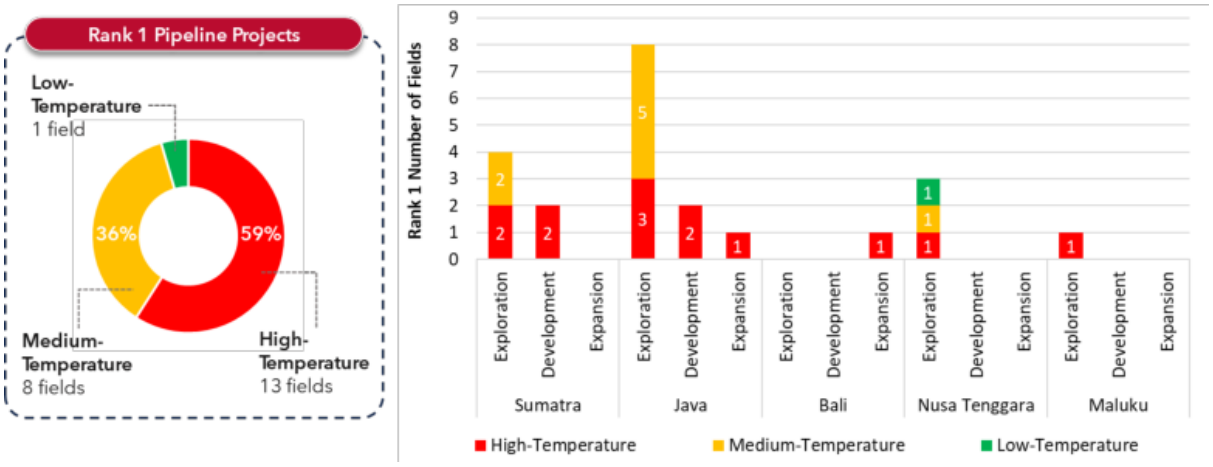

Figure 8: Indonesia's Rank 1 (National Strategic Project) Geothermal Project Pipeline Based on RUPTL 2021 – 2030 (PLN, 2021; GRG-Geoenergis, 2024b).

The 22 geothermal fields included in the Rank 1 pipeline projects in RUPTL 2021 – 2030 are classified further based on the geologic factor and the resource temperature, as shown in Table 3. The Sumatra region features projects in the Jaboi, Sungai Penuh, Danau Ranau, Hululais, Kepahiang, and Rajabasa geothermal fields, showcasing a range of medium to high temperatures due to the region's subduction and young volcanism.

Similarly, Java has numerous high-temperature projects such as those in the Rawa Danau, Cibuni, Candradimuka, Ungaran, Ijen, and Telaga Ngebel, with some medium and low-temperature fields like Tangkuban Perahu, Cisolok-Cisukarame, Tampomas, Baturaden, and Guci. The Bedugul project in Bali is another high-temperature field, while Maluku's Tulehu field is notable for its hybrid geologic setting combining young volcanism and fault systems. Nusa Tenggara includes fields like Atadei and Mount Sirung, with a mix of medium and high temperatures, and Oka Ile Ange, which represents a low-temperature field.

Table 3: Rank 1 Pipeline Projects Based on the Geologic Factor and Resource Temperature (GRG-Geoenergis, 2024b).

No	Region	Geothermal Field	Geologic Factor	Resource Temperature (°C)	Temperature Class	References
1	Sumatera	Jaboi	Hybrid (young volcanism and fault systems)	Min: 187 °C (sillica conductive) Max: 327 °C (gas geothermometry)	Medium	(Dwipa, et al., 2006; EBTKE, 2017; Nugraha & O'Sullivan, 2019)
2	Sumatera	Sungai Penuh	• Subduction • Young volcanism	250-280 °C (gas geothermometry)	High	(Hochstein & Sudarman, 2008; Sukhyar, et al., 2010; Darma, 2016; EBTKE, 2017)
3	Sumatera	Danau Ranau	• Subduction • Young volcanism	200-220 °C (Na-K-Mg)	Medium	(Afiat, et al., 2020; Idianto, et al., 2021; Rera, et al., 2021)
4	Sumatera	Hululais	• Subduction • Young volcanism	225-285°C (gas geothermometry from Kawah Biru and Kawah Hitam) >300oC (gas geothermometry from Kawah Belerang Atas)	High	(Kamah, et al., 2015; EBTKE, 2017; Nurseto, et al., 2021)
5	Sumatera	Kepahiang	• Subduction • Young volcanism	250 °C (gas geothermometer fumarole of Kaba Crater)	High	(EBTKE, 2017; Nurdyanto, et al., 2019; Nurseto, et al., 2021)
6	Sumatera	Rajabasa	• Subduction • Young volcanism	260-265 °C (Way Merak) 300-325 °C (gas geothermometry)	High	(Darmawan, et al., 2015; EBTKE, 2017)
7	Java	Rawa Danau	• Subduction • Young volcanism	260-270 °C (gas geothermometry)	High	(EBTKE, 2017; Syah, et al., 2019; Sumotarto, et al., 2019)
8	Java	Cibuni	• Subduction • Young volcanism	305 °C	High	(Layman & Soemarinda,2003)
9	Java	Tangkuban Perahu	• Subduction • Young volcanism	200-285 °C (Na-K geothermometry)	Medium	(Hochstein & Sudarman, 2015; Gaffar, 2018)
10	Java	Cisolok-Cisukarame	• Subduction Young volcanism	185-212°C (Na-K geothermometry)	Medium	(Mandradewi & Herdianita, 2010; Sumartha, et al., 2020)

No	Region	Geothermal Field	Geologic Factor	Resource Temperature (°C)	Temperature Class	References
11	Java	Tampomas	• Subduction • Young volcanism	187-208 °C (Silica geothermometry) (Direktorat Jendral EBTKE, 2017); 160-175 °C (silica geothermometry), 170 ± 10 °C (Na/K geothermometry)	Low	(EBTKE, 2017; Permadi, et al., 2022)
12	Java	Candradimuka	• Subduction • Young volcanism	250°C - 289°C (gas geothermometry)	High	(Bagaskara, et al., 2021)
13	Java	Ungaran	• Subduction • Young volcanism	>300 °C (gas geothermometry) Gradient temperature 10.4°C /100 m (thermal gradient well USL-1)	High	(Phuong, et al., 2012)
14	Java	Baturaden	• Subduction • Young volcanism	204-210 °C (Na-K-Mg geothermometry)	Medium	(EBTKE, 2017; Harijoko & Juhri, 2017; Iswahyudi, et al., 2020)
15	Java	Guci	• Subduction • Young volcanism	170-190 °C (K-Na-Ca and Na-K-Mg geothemometry); 331-382°C (Na/K geothermometer) 187-196°C (silica-enthalphy method)	Low	(Harijoko & Juhri, 2017; Iswahyudi, et al., 2020; Harijoko, et al., 2021)
16	Java	Ijen	• Subduction • Young volcanism	250-300 °C (in EBTKE, 2017)	High	(EBTKE, 2017; Daud, et al., 2019)
17	Java	Telaga Ngebel	• Subduction • Young volcanism	250-260 °C	High	(EBTKE, 2017; Yudiantoro, et al., 2020)
18	Bali	Bedugul	• Subduction • Young volcanism	280-320 °C	High	(Darma, et al., 2010)
19	Maluku	Tulehu	Hybrid (young volcanism and fault systems)	> 230 °C	High	(Daud, et al., 2022)
20	Nusa Tenggara	Atadei	Hybrid (young volcanism and fault systems)	~ 221°C (gas geothermometry)	Medium	(EBTKE, 2017; Prabata, 2018)
21	Nusa Tenggara	Oka Ile Ange	• Subduction • Young volcanism	148-173 °C	Low	(Nugraha, et al., 2018; EBTKE, 2017)
22	Nusa Tenggara	Mount Sirung	• Subduction • Young volcanism	260°C (H_2-CO_2 gas geothermometry)	High	(EBTKE, 2017; Putriyana, et al., 2021)

In contrast to Rank 1 projects, Figure 9 shows that Rank 3 pipeline geothermal projects in Indonesia primarily focus on low-medium temperature fields, which constitute 52 out of the 80 fields (65%). High-temperature fields still represent a significant portion, amounting to 28 out of 80 fields (35%). Sumatra has the highest number of low to medium-temperature Rank 3 fields, totaling 14, all in the exploration phase. Beyond Sumatra, other regions also feature prominently in the Rank 3 pipeline projects. Java has a balanced mix of high, medium, and low-temperature fields, with significant activity in both exploration and development phases. Bali's projects are mainly focused on medium-temperature fields, while Nusa Tenggara shows a substantial number of low and medium-temperature exploration projects. Sulawesi also has a diverse pipeline project resource temperature class, with a strong emphasis on low-medium temperature fields in the exploration phase. Maluku features a smaller number of projects, primarily in the exploration and development of low-medium temperature fields.

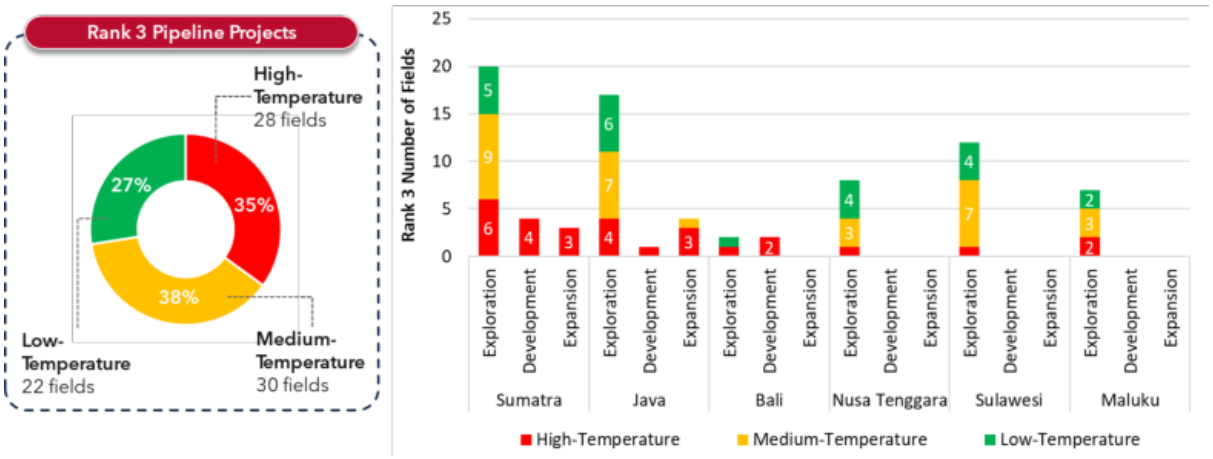

Figure 9: Indonesia's Rank 3 Geothermal Project Pipeline Based on RUPTL 2021 – 2030 (PLN, 2021; GRG-Geoenergis, 2024b).

2.5 Potential of Low-Medium Temperature Geothermal Resources in the United States

Figure 10 illustrates the distribution of low-medium temperature geothermal resources across the U.S. These resources, totaling 3.7 GW, represent 38% of the country's identified hydrothermal geothermal potential of 9.2 GW (USGS, 2008). The low-medium temperature resources are distributed across ten states, primarily in the west coast region (California, Oregon, and Washington), the Midwest (Nevada, New Mexico, Utah, Montana, Washington, and Colorado), and Alaska. Nevada stands out as the state with the largest low-medium temperature geothermal resources as much as 1,339 MW from 55 fields. In comparison, Indonesia has significantly larger identified low-medium temperature geothermal resources, totaling 9.7 GW. However, the number of identified fields is quite similar, with Indonesia having 254 fields compared to the 236 fields in the U.S. Despite Indonesia's greater resource potential, its utilization of these geothermal resources lags far behind that of the U.S.

2.6 Historical Geothermal Development in the United States

As of 2023, the installed geothermal power plant (GPP) capacity in the U.S. remains predominantly driven by high-temperature resources, which account for the majority of the 3,615 MW total capacity. Historically, the first high-temperature GPP commenced commercial operations in 1960 with the Geysers 1 plant in California, marking the beginning of geothermal energy utilization in the U.S., as shown in Figure 11. Over the decades, high-temperature resources have continued to be the backbone of geothermal energy production, contributing 2,408 MW across 45 plants, which represents 67% of the total installed capacity. In contrast, the development of geothermal power from low to medium-temperature resources began later, with significant advancements occurring in the mid-1980s. The first medium-temperature GPP was initiated with the Beowawe plant in Nevada in 1985, while the initial low-temperature plant started operations with the Wabuska 1 plant, also in Nevada, in 1984. These categories of geothermal resources have seen substantial growth over the last two decades, with low-temperature resources contributing 866 MW (24%) from 45 plants and medium-temperature resources adding 341 MW (9%) from 11 plants. This trend indicates a shift in the recent geothermal development in the U.S. in the last 20 years, focusing more on exploiting low to medium-temperature resources.

In terms of the GPP technology, as shown in Figure 12, the installed GPP capacity in the U.S. is predominantly driven by dry steam technology, which has been a cornerstone of geothermal energy production since the commissioning of the Geysers 1 plant in California in 1960. Dry steam plants currently contribute 1,477 MW across 18 plants, making up 40% of the total installed capacity.

However, in the last 20 years, there has been a significant shift towards binary technology, which now accounts for a substantial portion of the geothermal capacity. As of 2023, binary GPPs represent 1,298 MW, or 36% of the

total installed capacity, spread across 58 plants. The first binary GPP was commissioned in 1984 with the Wabuska 1 plant in Nevada. This technology has become more prevalent due to its ability to efficiently harness low-medium temperature geothermal resources. Flash plants, including single-flash, double-flash, and triple-flash technologies, collectively account for 27% of the installed capacity. Among these, double-flash plants are the most utilized, contributing 860 MW (24%) across 20 plants since the first double-flash GPP began operations in 1985 with the Heber 1 plant in California. Single-flash and triple-flash plants have smaller shares, with 60 MW (2%) from 4 plants and 55 MW (1%) from 1 plant, respectively. Overall, the GPP technology in the U.S. has seen a steady increase in the adoption of binary plants, while dry steam and double-flash technologies continue to play significant roles.

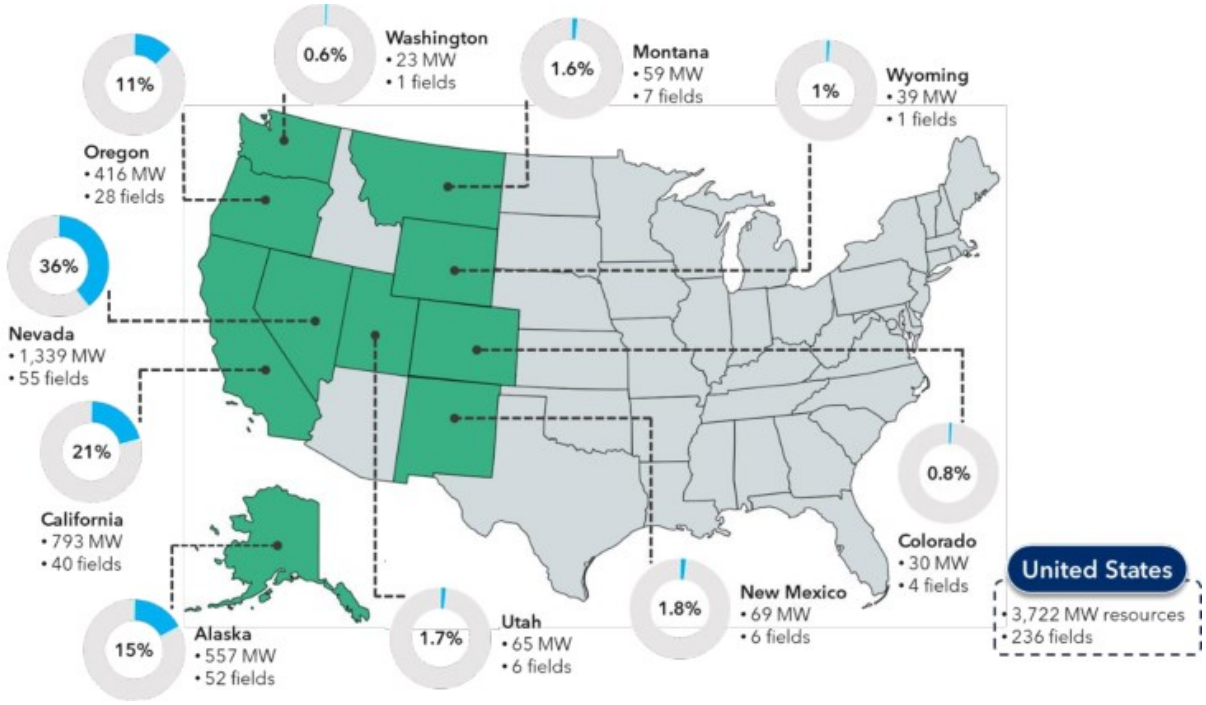

Figure 10: Low-Medium Temperature Geothermal Resources Distribution in the U.S. (USGS, 2008). The Percentage Values Represent Each State's Resource Portion to the Entire U.S. Resource.

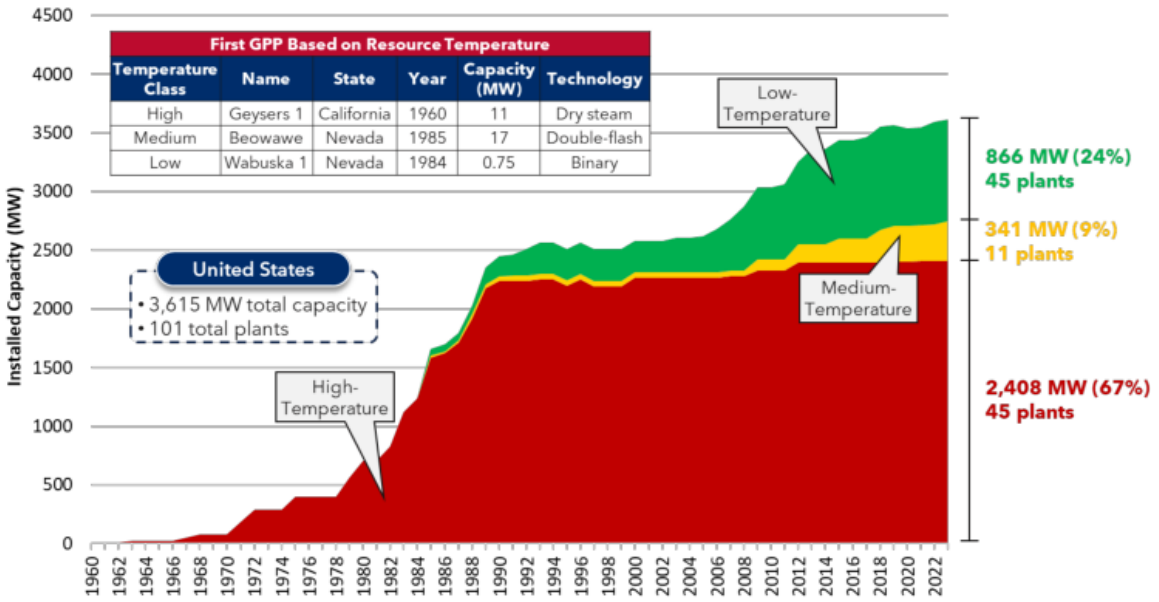

Figure 11: Geothermal Development in the U.S. Based on Resource Temperature (NREL, 2021; ThinkGeoEnergy, 2024).

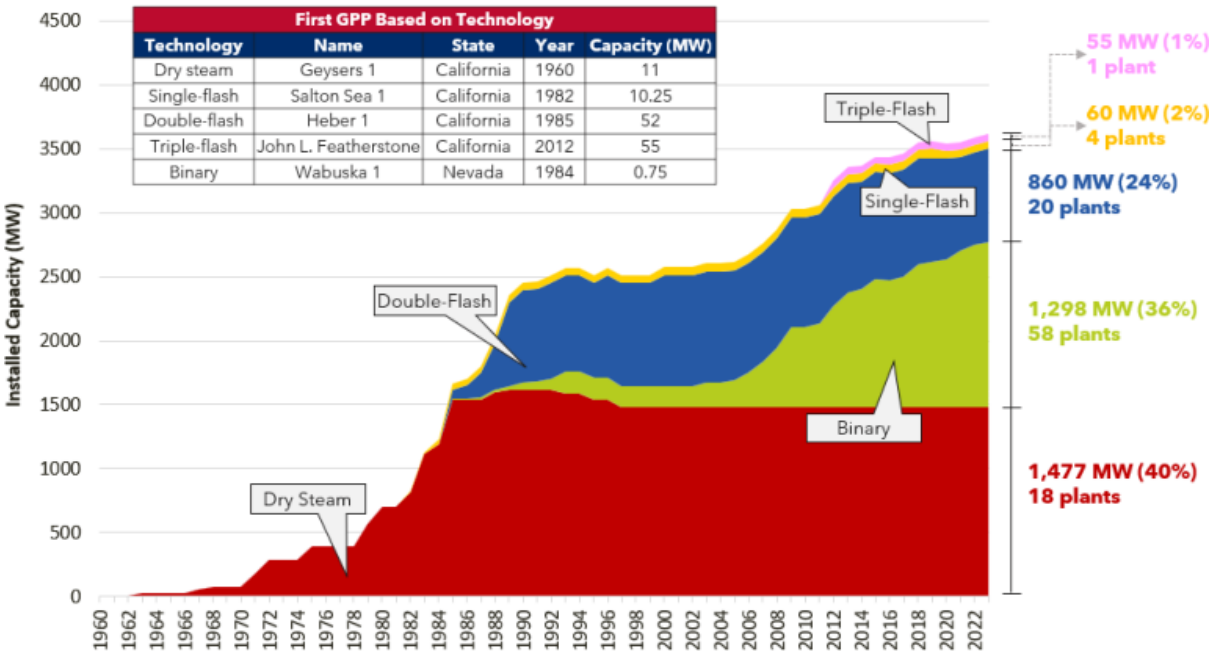

Figure 12: Geothermal Development in the U.S. Based on Power Plant Technology (NREL, 2021; ThinkGeoEnergy, 2024).

Furthermore, as shown in Figure 13, high-temperature GPPs are predominantly powered by dry steam technology, which accounts for 1,477 MW across 18 plants, making up 61% of the high-temperature capacity. In terms of the flash plants for high-temperature resources, double-flash technology is preferred over single-flash technology. Double-flash plants contribute 633 MW from 17 plants, while single-flash plants contribute 60 MW from 4 plants. This preference indicates the efficiency and effectiveness of double-flash technology for the high-temperature resources. Additionally, while mostly being used for low-medium temperature resources, binary plants are also utilized for high-temperature resources, contributing 182 MW from 5 plants, which include the binary plants in the Dixie Valley (Nevada), North Brawley (California), Puna (Hawaii), and Roosevelt (Utah) geothermal fields. For medium-temperature resources, binary technology is the dominant choice, representing 95% of the installed capacity with 324 MW from 10 plants. A small portion of double-flash technology is also utilized, contributing 17 MW from 1 plant. Similarly, in low-temperature geothermal fields, binary technology is the primary technology used, accounting for 92% of the installed capacity with 792 MW from 43 plants. Double- flash technology plays a minor role in these fields, with 74 MW from 2 plants. Overall, the distribution of geothermal power plant technologies in the U.S. reflects a strategic alignment with resource temperatures, optimizing the use of dry steam and double-flash technologies for high-temperature resources and binary technology for low to medium-temperature resources.

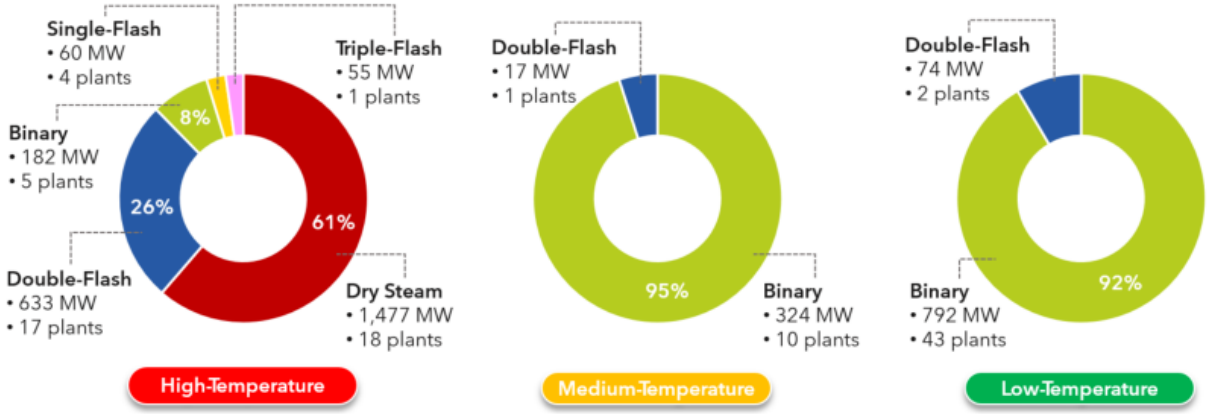

Figure 13: GPP Technology Installed Capacity Portion Based on Resource Temperature in the U.S. as of December 2023 (NREL, 2021; ThinkGeoEnergy, 2024).

Figure 14 illustrates the efficiency of geothermal power plants (GPP) based on reservoir temperature and enthalpy for different technologies: single-flash, double-flash, and binary (Zarrouk & Moon, 2014). Binary technology demonstrates its versatility across a wide range of temperatures, from low to medium. It maintains competitive

efficiency, starting at around 3% at 100°C and reaching nearly 8% at 230°C. This versatility makes binary plants an excellent choice for both low and medium-temperature resources. Double-flash technology can be applied to both the upper limit of low-temperature and the medium-temperature range. Its efficiency starts at about 5% at 190°C and approaches 7% at 230°C. While double-flash plants are efficient in these temperature ranges, binary plants generally exhibit higher efficiency at lower temperatures and remain competitive at medium temperatures, slightly lower than double-flash but higher than single-flash. Single-flash technology, represented by the yellow line, shows lower efficiency compared to both binary and double-flash technologies, particularly at higher temperatures. However, it is still a viable option for certain applications within the geothermal sector. This figure underscores the importance of selecting the appropriate GPP technology based on reservoir temperature to maximize efficiency, with binary plants demonstrating significant versatility across a broad temperature range.

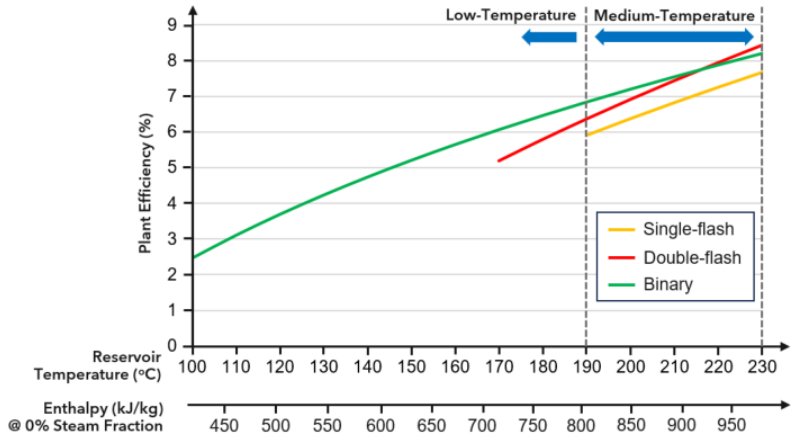

Figure 14: GPP Efficiency Based on Reservoir Temperature/Enthalpy for Different GPP Technologies (Zarrouk & Moon, 2014; Sanyal, 2005).

As of December 2023, the distribution of low-medium temperature binary GPP in the U.S. shown in Figure 15 reveals Nevada as the leader in installed capacity. Nevada holds the majority share, with a total installed capacity of 753 MW across 29 plants, accounting for 67% of the nation's total capacity. This dominance correlates with Nevada's abundant low-medium temperature geothermal resources compared to other states. California is the second-largest contributor, with 246 MW of geothermal capacity from 14 plants, representing 22% of the U.S. total for low-medium temperature binary plants. This significant contribution underscores California's role in the country's geothermal energy landscape. Other states also contribute to the overall geothermal capacity, albeit on a smaller scale. Utah has 45.3 MW from 2 plants, making up 4% of the total, while Oregon contributes 38.1 MW from 4 plants, accounting for 3%. Idaho adds 18 MW from 1 plant (2%), New Mexico provides 15 MW from 1 plant (1%), and Alaska has 1.1 MW from 2 plants, representing 0.01% of the national total. Overall, the total installed capacity for low-medium temperature binary GPPs in the U.S. is 1,116 MW, distributed across 53 plants. This figure highlights the varied contributions of different states, with Nevada and California playing the most significant roles.

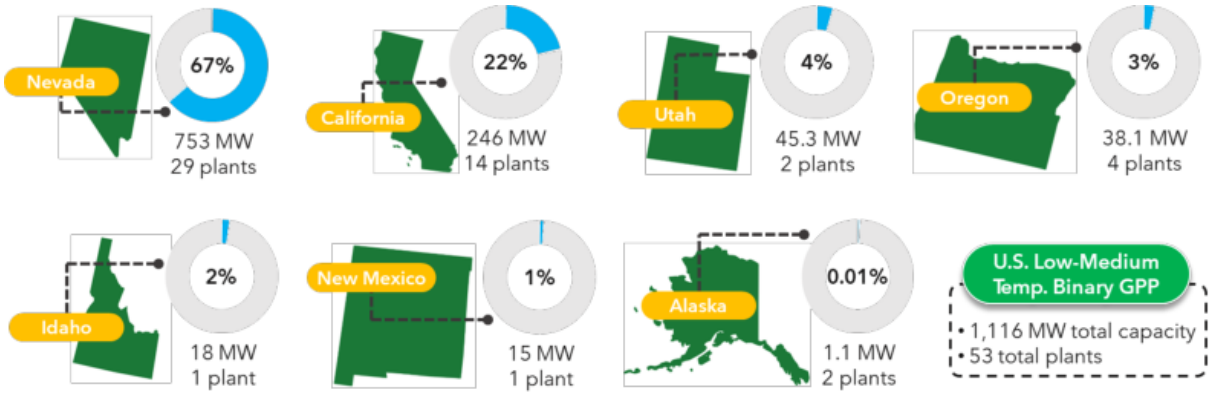

Figure 15: Low-Medium Temperature Binary GPPs' Installed Capacity Distribution in the U.S. as of December 2023 (NREL, 2021; ThinkGeoEnergy, 2024). The Percentage Values Represent Each State's Portion to the Entire U.S.

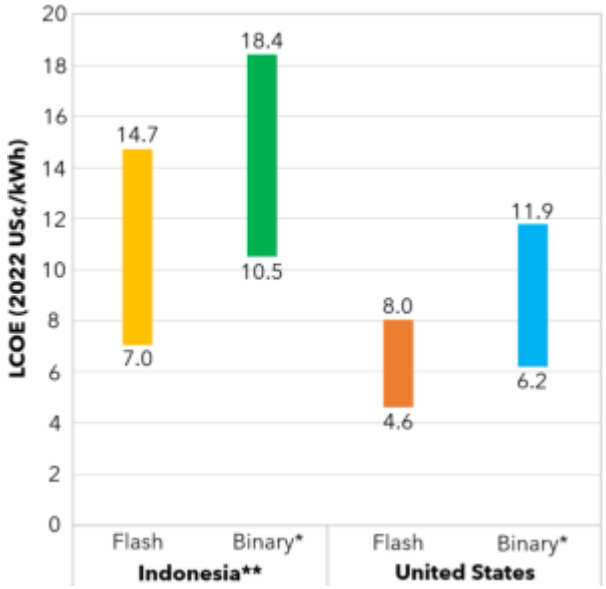
2.7 Comparison of Low-Medium Temperature GPP LCOE in the U.S. and Indonesia

The Levelized Cost of Electricity (LCOE) is a metric indicating the price at which electricity must be sold for the system to achieve break-even at the end of its operational lifetime (Papapetrou & Kosmadakis, 2021). It accounts for initial capital investment, ongoing operational and maintenance costs, and the expected energy output over the plant's lifetime and is formulated in Equation (1):

$$\text{LCOE}=\frac{\sum_{t=0}^{n}\frac{I_t+M_t}{1+r^t}}{\sum_{t=0}^{n}\frac{I_t+E_t}{1+r^t}} \quad (1)$$

where, t refers to the t-th year with t=0 means the start of the plant construction, n is the operational lifetime (year), It is the capital expenditures (USD) in year t, Mt is the fixed and variable operating expenditures (USD) in year t, r is the discount rate (or the weighted average cost of capital), and Et is the electricity generation (kWh) in year t. LCOE serves as an important tool for techno-economic analysis, helping stakeholders assess and compare the economic viability of low-medium temperature geothermal resources against other energy options. This aids in making informed decisions for techno-economic optimizations of low-medium temperature geothermal resources development. Figure 16 compares the LCOE for GPP between Indonesia and the U.S., focusing on both flash and binary technologies for low-medium temperature resources. In the U.S., the LCOE for flash technology is lower, ranging from 4.6 to 8.0 US¢/kWh, and for binary technology, it ranges from 6.2 to 11.9 US¢/kWh according to the 2023 Geothermal Annual Technology Baseline developed by (NREL, 2023). Meanwhile, the LCOE values for Indonesia are estimated using the LCOE calculator developed by (IESR, 2023) based on inputs such as capital expenditure (CAPEX), fixed operational expenditure (OPEX), capacity factor (CF), project life, and the weighted average cost of capital (WACC). The CAPEX for flash plants ranges from 4.7 to 8.0 million USD/MW , while for binary plants, it ranges from 7.1 to 10.0 million USD/MW (GRG-Geoenergis, 2024a). The fixed OPEX is set at 0.05 million USD/MW per year for flash plants and at 0.065 million USD/MW per year for binary plants. The capacity factor varies from 70% to 90%, with a project life of 30 years and a WACC of 10% (IESR, 2023). The calculation results show that, for Indonesia, the LCOE for flash technology ranges from 7.0 to 14.7 US¢/kWh, while for binary technology, it ranges from 10.5 to 18.4 US¢/kWh. Overall, the figure highlights that the LCOE for geothermal power is generally lower in the U.S. compared to Indonesia, particularly for binary technology. Furthermore, binary technology shows a wider range of costs in both countries, reflecting the variability in factors influencing the LCOE.



*) Only low-medium temperature binary GPP

**) Based on LCOE calculator (IESR, 2023) using the following inputs:

Input	Unit	Flash		Binary	
		Min	Max	Min	Max
CAPEX	MUSD/MW	4.7	8.0	7.1	10.0
Fixed OPEX	USD/MW/year	0.05	0.05	0.065	0.065
CF	-	70%	90%	70%	90%
Project life	Year	30	30	30	30
WACC	-	10%	10%	10%	10%

Figure 16: Geothermal LCOE Comparisons Between Indonesia and the U.S. (GRG-Geoenergis, 2024a; IESR, 2023; NREL, 2023).

Figure 17 illustrates a simplified structure of the LCOE and CAPEX for geothermal power projects. One significant factor that can reduce the LCOE is the offset provided by fiscal incentives. In the U.S., two prominent fiscal incentives are the Production Tax Credit (PTC) and the Investment Tax Credit (ITC) provided by the federal government in addition to the other incentives, such as accelerated depreciation, bonus depreciation, and the state-level incentives (NREL, 2021).

1. **Production Tax Credit**: it was first implemented in 2004 through the American Jobs Creation Act of 2004, allowing geothermal developers to offset their tax liability using a per-kilowatt-hour tax credit. Initially, the credit period was 5 years but was extended to 10 years in 2005 by the Energy Policy Act (Oregon Tech, 2012). The PTC base rate started at 1.8 cents/kWh in 2004 and increased to 2.75 cents/kWh in 2022, subject to annual inflation adjustments (IRS, 2022).
2. **Investment Tax Credit**: it was first implemented in 1978 through the Energy Tax Act of 1978 (Oregon Tech, 2012). This credit allows geothermal developers to offset a portion of their tax liability based on a percentage of the total project cost of qualified geothermal projects, with the current ITC rate being 6% or 30% of the project cost, depending on the conditions met by the geothermal developer as stipulated by the Inflation Reduction Act of 2022 (The White House, 2023).

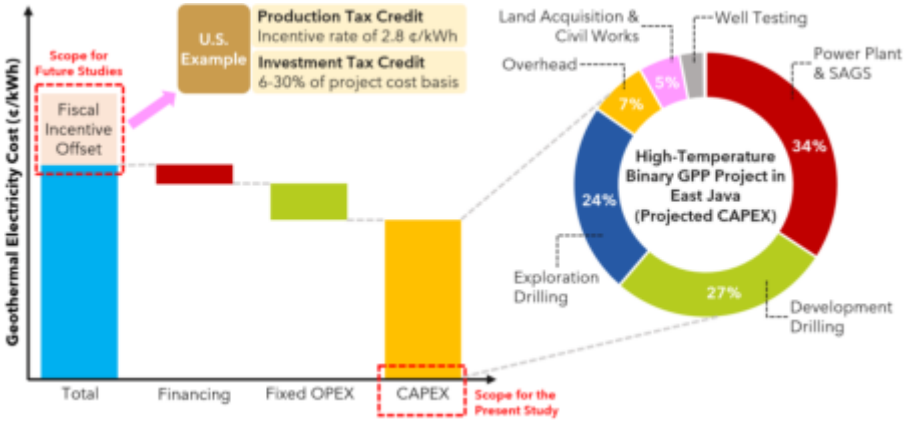


Figure 17: Simplified Geothermal LCOE and CAPEX Structure (IESR, 2023; GRG-Geoenergis, 2024a; NREL, 2021).

However, the current study does not include fiscal incentives, financing costs, and fixed OPEX within its scope. Instead, the focus of the current study is on optimizing the CAPEX to lower the LCOE for low-medium temperature geothermal resources, as CAPEX is the most significant component of the LCOE structure, as shown in Figure 17. Due to limited data availability, the authors faced challenges in breaking down the CAPEX for low-medium temperature geothermal resource development. Nevertheless, an example CAPEX breakdown from a high-temperature binary GPP project in East Java, Indonesia, provides valuable insights. It shows that the power plant, Steam Gathering System (SAGS), and drilling account for the majority of the CAPEX (GRG-Geoenergis, 2024a). Therefore, optimizing the costs associated with the power plant, SAGS, and drilling is crucial for improving the techno-economic feasibility of low-medium temperature geothermal resources. This focus on CAPEX optimization can significantly impact the overall techno-economic feasibility of low-medium temperature geothermal development projects.

3. LESSONS LEARNED FROM THE UNITED STATES AND THEIR POTENTIAL APPLICATION IN INDONESIA

Examining the lessons learned from the U.S. experience with low-medium temperature geothermal fields provides valuable insights into the potential techno-economic optimization initiatives that can be adopted into the Indonesian context. Additionally, Indonesia's experience with high-temperature fields also offers transferable knowledge that can be the foundation to adopt the initiatives from the U.S for the low-medium temperature fields. This section explores the lessons learned from the U.S. in developing low-medium temperature geothermal resources and how Indonesia can utilize their experience in developing high-temperature resources to adopt those lessons learned as potential optimization initiatives for Indonesia’s low-medium temperature resources.

3.1 Know-How in Utilizing Binary GPP and Pumped Well Technology

The development of low-medium temperature geothermal power plants (GPP) in the U.S. experienced two significant waves, with the first occurring in the 1980s-1990s and the second in the 2010s, in coincidence with the two significant waves of the overall GPP development in the U.S. Notably, the early involvement of leading developers such as Ormat, Cyrq Energy, Terra-Gen Power, and Open Mountain Energy, who commenced their initial operations during the first wave, played a crucial role in the resurgence of GPP development in the 2010s. Figure 18 indicates that by December 2023, these 4 developers collectively hold the majority of the installed capacity in the low-medium temperature GPP sector. The expertise and technological advancements accumulated by these companies during the first wave in the 1980s-1990s provided the know-how and experience for the subsequent development, especially during the second wave in the 2010s, thereby revitalizing the low-medium temperature GPP landscape in the U.S.

Developer	Low-Med Temp. GPP Capacity as of Dec 2023	First Low-Med Temp. GPP	Technology	COD Year
Ormat	886.9 MW (74%)	Steamboat 1	Binary	1985
Cyrq Energy	162.3 MW (14%)	Soda Lake 1	Binary	1987
Terra-Gen Power	91.5 MW (8%)	Beowawe	2-Flash	1985
Enel	26.8 MW (2%)	Salt Wells	Binary	2009
Open Mountain Energy	16.9 MW (1%)	Wabuska 1	Binary	1984
Others	14.5 MW (1%)	Wineagle	Binary	1988
Total	**1,198.9 (100%)**			

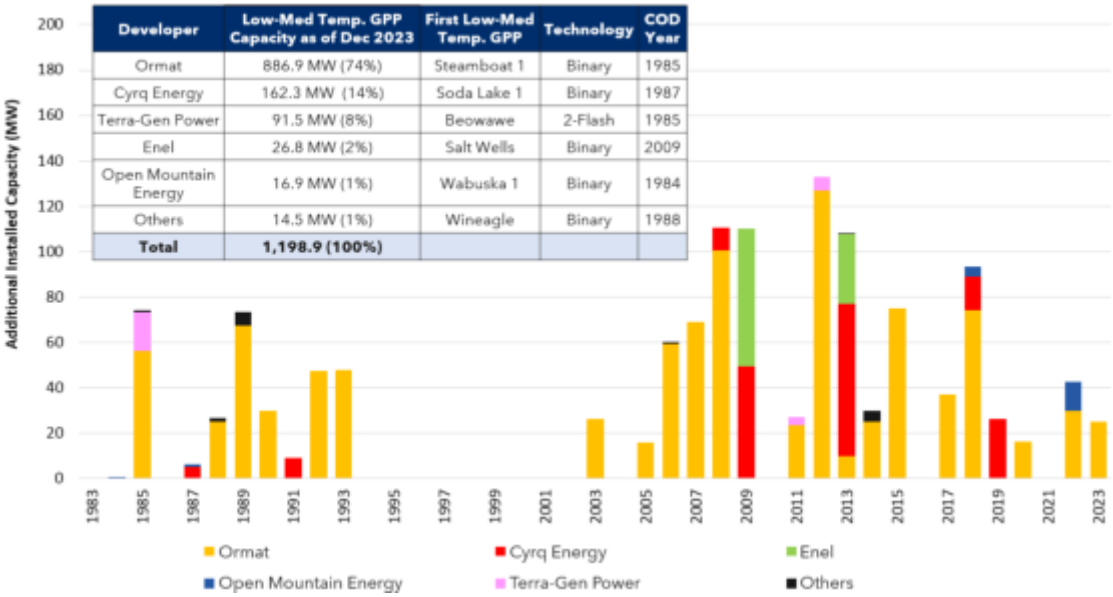

Figure 18: Low-Medium Temperature GPP Capacity Addition in the U.S. Based on the Developer Company (NREL, 2021).

Additionally, pumped geothermal wells are typically used to produce geothermal fluids from low-temperature resources due to the non-self-discharge characteristics of low-temperature geothermal wells excluding artesian wells and those with high NCG content, which might exhibit self-discharge (Sanyal, 2005). For a self-discharging geothermal well, the power output that can be achieved from that well is influenced by the well's productivity (flow rate and enthalpy) and the power plant's electric conversion efficiency. However, for a pumped geothermal well, the pumping power reduces the net power output that can be achieved from the well. Figure 19 illustrates the reservoir inflow performance relationship (IPR) and vertical lift performance (VLP) curves for a self-discharging well and a non-self-discharging well. IPR curve shows the reservoir's ability to deliver fluids to the wellbore under different bottomhole flowing pressure conditions. Meanwhile, VLP curve shows the required bottomhole flowing pressure to discharge the fluid from the bottomhole/feed zone to the wellhead at a given wellhead pressure (Kriptanto, 2024; Grant & Bixley, 2011). Well discharge occurs if the IPR curve intersects with the VLP curve (Guo, et al., 2017).

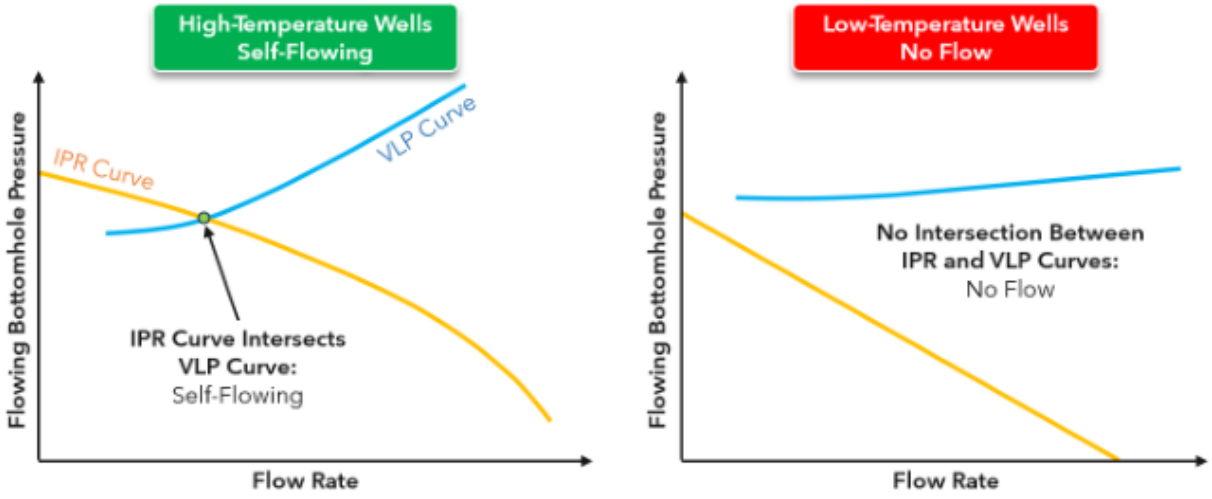

Figure 19: IPR and VLP Curves for High-Temperature Self-Flowing (Left) and Low-Temperature Non-Self-Flowing (Right) Geothermal Wells (Kriptanto, 2024; Zarrouk & McLean, 2019; Grant & Bixley, 2011).

It is possible that even in the reservoir's natural state, the IPR curve does not intersect with the VLP curve. It means that a well stimulation is needed since the beginning of the geothermal field's operation, such as using a downhole pump, implementing air compression or gas lifting methods, or performing permeability stimulations through fracturing or matrix acidizing (Mubarok & Zarrouk, 2017). Such case is typically found in low-temperature geothermal fields or high-temperature fields with a low natural permeability (Abrasaldo, et al., 2023).

Therefore, the drive mechanism of discharge from low-temperature geothermal wells is the pumping energy (Aydin & Merey, 2021; Sanyal, 2005). In another case, the IPR curve may intersect with the VLP curve during the early years of the field's operation, such as in high-temperature geothermal fields. The drive mechanism of discharge from high-temperature geothermal wells is the flashing process, which is the phase change of the geothermal fluid from liquid into a two-phase (steam and liquid mixture) due to a pressure drop causing the pressure to fall below the saturation pressure at the fluid's temperature (Budirianto, et al., 2020; Sanyal, 2005) However, as the reservoir pressure declines and a near-wellbore damage occurs, the IPR curve may "fall" until the IPR curve no longer intersects with the VLP curve, hence the well can no longer discharge fluids and well stimulations may be needed (Kriptanto, 2024; Marfo, et al., 2024). The net power output from a pumped geothermal well is formulated in Equations (2) and (3):

$$\dot{W}_{net,well} = \dot{W}_{gross,well} - \dot{W}_{pump} = \dot{m} \times h_{wh} \times \eta_{plant} - \frac{100 \times \dot{m} \times \rho \times \Delta P_{pumping}}{\eta_{pump}} \tag{2}$$

$$\Delta P_{pumping} = P_{wh} + \Delta P_{loss,elevation} + \Delta P_{loss,friction} - P_{suction} \tag{3}$$

where $\dot{m}$ is the fluid mass flow rate (kg/s), h_{wh} is the enthalpy at the wellhead (kJ/kg), η_{plant} is the power plant's electric efficiency (%), ρ is the fluid density (kg/m^3), $\Delta P_{pumping}$ is the dynamic pumping pressure (bar), η_{pump} is the pump efficiency (%), P_{wh} is the wellhead pressure (bar), $\Delta P_{loss,elevation}$ is the pressure drop due to elevation differences between the pump setting depth and the surface elevation (bar), $\Delta P_{loss,friction}$ is the pressure drop due to friction losses (bar), and $P_{suction}$ is the pump suction pressure (bar). It can be inferred from Equation (2) that a higher net power output from a pumped geothermal well can be achieved by enhancing the well productivity, plant efficiency, and pump efficiency while the reducing dynamic pumping pressure (and, if possible, fluid density by aiming for a hotter feed zone) (Tonkin, et al., 2023).

The dynamic pumping pressure informs how much pumping pressure is required to achieve the desired wellhead pressure at a given pump suction pressure to counter the pressure drop due to elevation differences and friction (Prabowo, et al., 2021). The elevation pressure drop, frictional pressure drop, pump suction pressure, and Fanning friction factor are respectively formulated in Equations (4), (5), (6), and (7):

$$\Delta P_{loss,elevation} = 0.0981 \times H_{set,pump} \tag{4}$$

$$\Delta P_{loss,friction} = \frac{124.8 \times f_F \times v^2 \times H_{set,pump}}{386.04 \times D_{well}} \tag{5}$$

$$P_{suction} = P_{wf} - 0.0981 \times (H_{FZ} - H_{set,pump}) \tag{6}$$

$$f_F = \frac{1}{4} \times \left(\frac{1}{1.74 - 2\log(2 \times \varepsilon)} \right)^2 \tag{7}$$

where $H_{set,pump}$ is the pump setting depth (m), f_F is the Fanning friction factor, v is the fluid flow velocity (m/s), D_{well} is the well inner diameter (m), P_{wf} is the flowing bottomhole pressure (bar) determined from the well's inflow performance relationship (IPR) curve, H_{FZ} is the feed zone depth (m), and ε is the wellbore roughness (m). It can be inferred from Equation (4) that minimizing the pump setting depth can contribute to reducing the elevation pressure losses, leading to a lower dynamic pumping pressure and thus a lower pumping parasitic load.

Furthermore, the fluid flow rate flowing into wellbore from the reservoir is determined by the reservoir permeability (often expressed as PI or permeability index in kg/s/bar). In other words, the downhole pump cannot increase the flow rate at a given flowing bottomhole pressure and thus cannot "elevate" the IPR curve since it depends on the reservoir deliverability (Kriptanto, 2024; Abrasaldo, et al., 2023). Instead, by providing external pressure support to the well, the downhole pump contributes in reducing the required flowing bottomhole pressure for the well to discharge fluid, hence "lowering" the VPL curve, with the given reservoir inflow performance (IPR) aimed to restore the intersection between the IPR and VLP curves (Kurniawan, 2021; Prabowo, et al., 2021). The fluid mass flow rate flowing into the wellbore is formulated in Equation (8):

$$\dot{m} = PI \times (P_{res} - P_{wf}) = \frac{2 \times k \times h \times (P_{res} - P_{wf})}{B \times \mu \times \left(\ln\left(\frac{r_{res}}{r_{well}} \right) + S \right)} \quad (8)$$

where P_{res} is the reservoir pressure (bar), k is the reservoir permeability (Darcy), h is the reservoir thickness (m), B is the reservoir fluid compressibility (dimensionless), μ is fluid viscosity (Pa-s), r_{res} is the reservoir drainage radius (m), r_{well} is the wellbore inner diameter (m), and S is the skin factor. The produced fluid's pressure drop from the reservoir to the wellbore and wellhead pumped geothermal wells is shown in Figure 20, which can illustrate that downhole pumps work on the principle of providing an external pressure support to the well so that the well can discharge fluid despite the reservoir inflow performance (deliverability) declines.

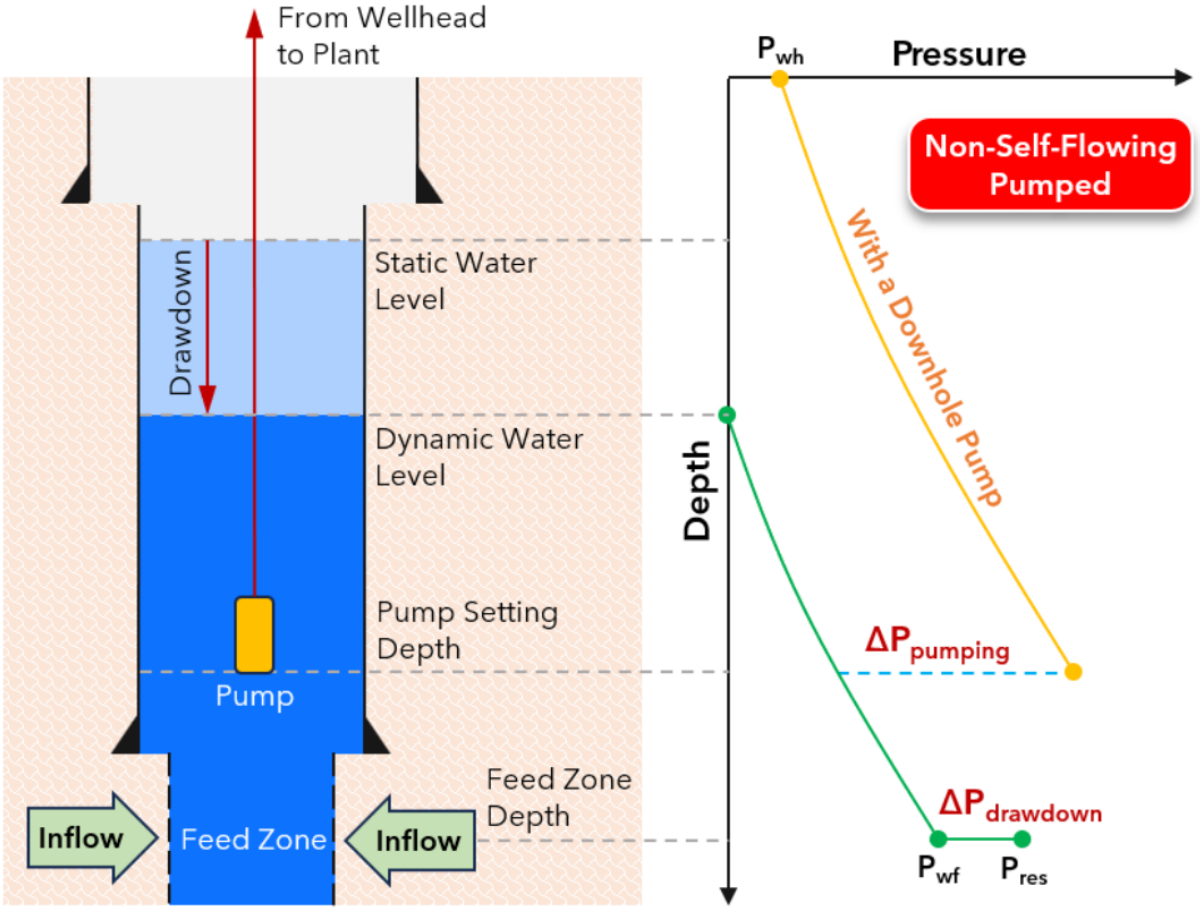

Figure 20: Pressure from the Reservoir to the Wellbore and Wellhead for Punped Liquid Geothermal Wells (Yearsley, 2023; Kurniawan, 2021).

Geothermal pumped-well power projects represent a growing niche within the broader geothermal industry, contributing around 1000 MW of installed generating capacity globally. Nevada, U.S., boasts the highest concentration of these projects, with approximately 15 fields totaling 724 MW of installed capacity, as shown in Table 4. The McGinness Hills project is the largest pumped-well facility globally, with an estimated capacity of 174 MW, followed by the Steamboat geothermal complex with 126.2 MW. Most projects in Nevada produce fluids within the 120-180°C range, though it also hosts the lowest reported resource temperature of about 100°C at Wabuska for any pumped-well geothermal power project worldwide. The prolific geothermal activity in Nevada's Basin and Range province is attributed to the region's high heat flow and extensional tectonic setting. Most geothermal activity in this area occurs along faults and is not associated with recent shallow magma sources. Extensional faulting is essential for creating productive geothermal systems, as fault zones facilitate the upflow of hot fluids and provide the high permeability for these systems. Generally, the productive feed zones are found at depths of 500-1500 meters.

There are two primary types of geothermal pumped wells, namely lineshaft pump (LSP) and electric submersible pump (ESP). The main difference between these two types lies in the location of their motors, as illustrated in Figure 21. In LSP systems, the motor is located at the surface, driving the pump impellers via a long shaft that extends down the well. This design allows for higher operational temperatures and lower wear due to the reduced rotational speed of the impellers. In contrast, ESP systems have their motors located downhole, directly connected

to the pump impellers. This configuration enables ESPs to handle higher pressures and flow rates and allows for more efficient directional drilling. However, ESPs are generally more expensive and require routine inspections due to their higher wear rates and operational complexities. Other than the motor equipment, the primary components, such as the pump impellers and screens, are similar between LSP and ESP systems.

Table 4: Operational Binary GPPs with Pumped Wells in Nevada (ThinkGeoEnergy, 2024; NREL, 2021; Febrianto, et al., 2019; Hernandez, et al., 2016; DiPippo & Kitz, 2015).

The comparison between LSPs and ESPs in geothermal applications reveals notable differences in their operational and environmental characteristics, as summarized in Table 5. LSPs can handle higher operating temperatures (up to 215°C) compared to conventional ESPs, which are typically limited to around 160°C, though the newer models by SLB, named Reda Thermal ESP, can handle up to 225° C (Kriptanto, 2024). LSPs operate at slightly lower pressures (⩽ 70 bar) and have a lower flow rate capacity (± 540 t/h) compared to ESPs, which can manage pressures (⩽ 75 bar) and higher flow rates (± 900 t/h). LSPs are limited to a maximum well depth of approximately 730 meters, whereas ESPs can be used in wells deeper than 1000 meters. Installation of LSPs is more time-consuming and requires surface-level motor drivers, while ESPs are quicker to install with downhole motors. LSPs are more efficient due to their lower rotational speeds, which also results in reduced wear compared to ESPs. However, ESPs are advantageous for directional drilling capabilities. In terms of cost, LSPs are less expensive in both capital and operational expenditures but require predictable maintenance schedules, whereas ESPs are more expensive and necessitate routine inspections. Additionally, LSPs pose an environmental risk due to the use of oil lubrication for shaft bearings, while ESPs do not have this impact. The choice between LSPs and ESPs depends on specific project needs, such as well depth, temperature, flow rate, and environmental considerations.

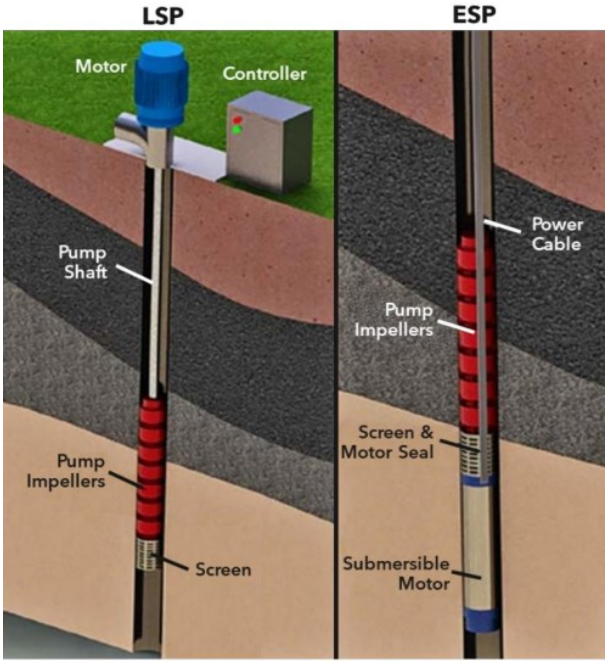

Figure 21: Primary Components of a Linesaft Pump (Left) and an Electric Submersible Pump (Right) (NREL, 2014).

Table 5: Comparison Between Lineshaft Pumps and Electric Submersible Pumps (Kriptanto, 2024; Febrianto, et al., 2019).

Parameter	Lineshaft Pump	Electric Submersible Pump
Operating temperature	High (≤ 215°C)	• Conventional: ≤ 160°C • SLB Reda Thermal ESP: ≤ 225°C
Operating pressure	Slightly lower (≤ 70 bar)	Slightly higher (≤ 75 bar)
Flow rate capacity	Lower (± 540 t/h)	Higher (± 900 t/h)
Maximum well depth	Limited to ≤ 730 m	Relatively deeper (> 1000 m)
Well deviation	Vertical well only	Directional well is possible
Installation time	Time-consuming	Relatively quick
Motor driver location	At the surface	Downhole
Pump and motor efficiency	Higher	Lower
Wear proneness	Lower (due to lower rotational speed)	Higher (due to higher rotational speed)
CAPEX and OPEX	Less expensive	More expensive
Maintenance schedule	Predictable	Routine inspection
Environmental impact	Present (due tue oil lubrication for shaft bearings)	None

To further compare the performance between LSP and ESP systems statistically, the empirical Mean Time Between Failures (MTBF) of LSPs is compared with the 17 geothermal ESPs summarized by (Lovekin, et al., 2021). MTBF, a reliability metric that estimates the average time a system or component operates before experiencing a failure, is a critical measure of reliability in LSP and ESP systems (Omrani, et al., 2021). The box plot in Figure 22 shows that, in general, ESPs tend to have shorter MTBF than LSPs. Specifically, the overall MTBF for LSPs is significantly higher, indicating greater reliability over time. The data further illustrate that as the operating temperature, flow rate, and depth increase, the MTBF for ESPs becomes shorter. ESPs used in low temperature environment (< 150°C), small flow rate (< 450 t/h), and shallow depth (< 300 m) conditions exhibit longer MTBF compared to those operating under higher temperature (≥ 150° C), larger flow rate (≥ 450 t/h), and greater depths (≥ 300 m). This trend suggests that more demanding operational conditions adversely affect the durability of ESPs.

Globally, the high-temperature high-flow rate Reda Thermal ESP developed by SLB has been installed in only one geothermal field, namely the Kizildere geothermal field in Turkey (Kriptanto, 2024). According to the case study information, the Reda Thermal ESP has been operating in the Kizildere geothermal field under challenging conditions, including temperatures up to 215°C and flow rates around 900 t/h. The ESP has successfully run for more than 600 days (almost 2 years) as of February 2024. However, this duration is still shorter than the mean and median MTBF for ESPs, which is 4.1 years. Consequently, while the Reda Thermal ESP has shown promising performance, its actual long-term durability remains uncertain.

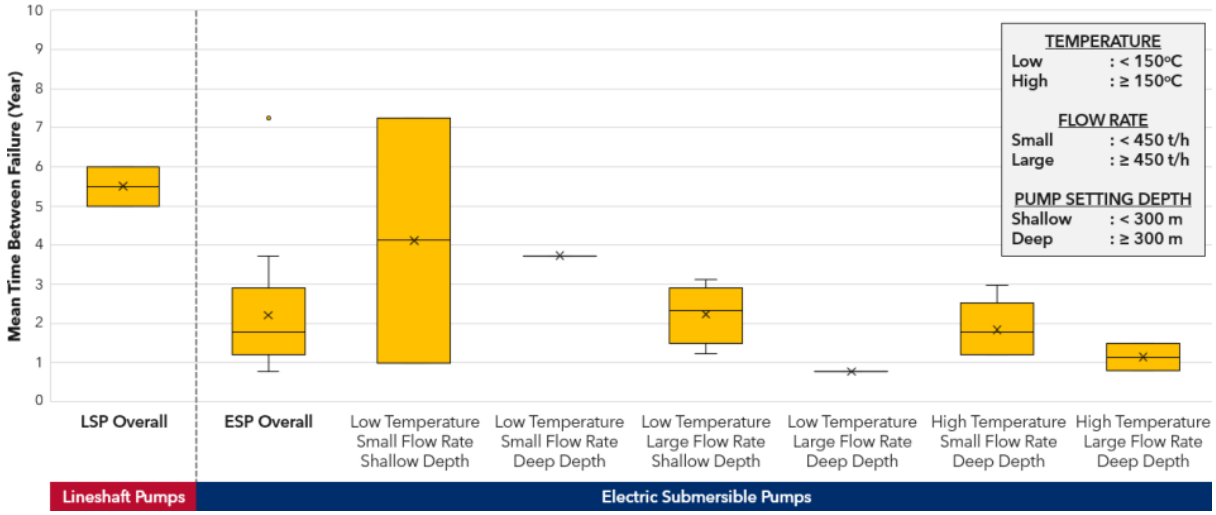

Figure 22: MBTF Comparisons Between LSP and ESP from 17 Geothermal Wells in the U.S. with an ESP Installed (Kriptanto, 2024; Lovekin, et al., 2021).

3.2 Developing the Shallow Outflow Zones

The development of low-medium temperature geothermal resources relies heavily on the downhole pump technology to discharge the non-self-discharging wells. As expressed in Equations (2) and (4), the net power output from a pumped geothermal well is influenced by the pump setting depth. The setting depth of a geothermal downhole pump is based on the principle that the pump inlet must be set sufficiently deep below the static water level so that the pump suction pressure is sufficiently high to prevent cavitation (boiling or the forming of bubbles) in the pump, which may damage the pump (Aydin & Merey, 2021; Prabowo, et al., 2021). To fulfill this principle, the following two parameters must be considered while determining the pump setting depth (Yearsley, 2023):

1. **Productivity index**: it determines the pressure drawdown (the difference between reservoir pressure and flowing bottomhole pressure), which influences the pump suction pressure value.
2. **Temperature**: it determines the saturation pressure of the geothermal fluid along the depth of the wellbore. Therefore, it becomes the crucial factor for limiting the allowable pressure drawdown. The higher the temperature, the higher the allowable pressure drawdown is for a particular depth throughout the wellbore.

The development of geothermal resources in Indonesia mainly focuses on producing from the reservoir at and around the hot upflow zone, aiming for a higher temperature and permeability (Firanda, et al., 2024; Stimac, et al., 2019; Hochstein & Sudarman, 2015). However, applying this approach for low-medium temperature resources may present drawbacks, such as the inability of the downhole pump's rating to meet the operating temperature and depth requirements as well as the smaller well power output due to the larger pump parasitic load because of the deeper hot upflow zone (Febrianto, et al., 2019). On the other hand, the peripheral outflow zone of a geothermal reservoir is typically not as hot as the central reservoir region around the upflow zone yet it is usually shallower especially in the volcanic geothermal systems (Ormat, 2022; Taborda, et al., 2022). Therefore, besides developing the hotter yet deeper upflow zone, developing the cooler yet shallower outflow zone in the low-medium temperature geothermal resources may provide the following benefits:

1. **Reduced drilling cost**: due to the shallower outflow zone, the required well depth can be reduced and thus the total drilling cost can be minimized (GRG-Geoenergis, 2024a; EBTKE, 2023; Purba, et al., 2020).
2. **Benign fluid**: fluids in upflow zones are typically more acidic and chemically aggressive due to high temperatures and pressure, which enhance mineral dissolution. In contrast, outflow zones have more benign fluids because they mix with cooler groundwater, leading to dilution and reduced chemical reactivity (Nayoan, et al., 2023; Pradipta, et al., 2023).
3. **Easier mobilization and demobilization**: since the outflow zone are usually located at lower elevation areas with a flatter terrain, mobilizing and demobilizing the equipment for drilling, power plant construction, and infrastructure preparation can become less challenging (GRG-Geoenergis, 2024c; Purba, et al., 2021).
4. **Allowing the use of downhole pump**: developing the shallower outflow zone allows for the use of LSPs, which performance is limited by the well depth (Putriyana, et al., 2022; Prabowo, et al., 2021).
5. **Increased well power output**: by lowering the depth of the static water level from the wellhead, the pump parasitic load can be minimized and thus the net power output can be maximized (Ormat, 2022;

Prabowo, et al., 2021). The possible well power output variations as a function of the static water level depth are illustrated in Figure 23.

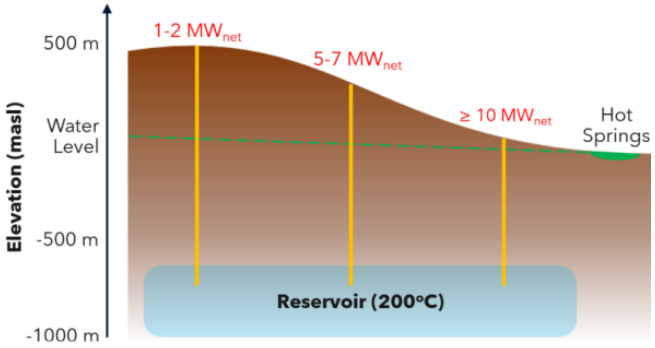

Figure 23: Pumped Well Output at Different Elevation Interval Between Wellhead and Static Water Level (Ormat, 2022).

Table 6: Examples of U.S. Experience in Developing the Outflow Zone in Low-Medium Temperature Geothermal Fields.

Parameter	Steamboat, Nevada	Mammoth, California
Resource Information		
Upflow temperature	175-200°C	180-200°C
Upflow temperature class	Low-medium temperature	Low-medium temperature
Main reservoir well depth	1,000-2,000 mMD	Not drilled due to mountaineous terrain
Developer	Ormat	Ormat
Development history	**1985:** Steamboat 1 (2 MW; binary; retired) Steamboat 1A (2.4 MW; binary; retired) **1988:** Steamboat Hills (16.3 MW; single-flash; retired) **2006:** Richard Burdette (30 MW; binary; online) **2007:** Galena 2 (13.5 MW; binary; online) Steamboat Hills Bottoming (5.5 MW; binary; online) **2008:** Galena 3 (30 MW; binary; online) Steamboat 2 (18.2 MW; binary; online) Steamboat 3 (18.2 MW; binary; online) **2020:** Steamboat Hills (16.3 MW; binary; online)	**1990:** MP-2 (15 MW; binary; online) PLES-1 (15 MW; binary; online) **2013:** MP-1 (10 MW; binary; online) **2022:** Casa Diablo IV (30 MW; binary; online)
Outflow Development		
Outflow temperature	150-175°C	130-200°C
Outflow temperature class	Low-temperature	Low-medium temperature
Outflow utilization	Production and reinjection areas	Production and reinjection areas
Outflow well depth	200-500 mMD	800-1,200
Literature source	(Ormat, 2022; NREL, 2021; Ayling, 2020)	(Ormat, 2022; Rutqvist, et al., 2021; NREL, 2021)

Table 6 summarizes the U.S. experience in developing the ouflow zone of low-medium temeprature geothermal fields. The advantages of developing shallower outflow zones, compared to deeper upflow zones, are apparent in the development experience gained in the Steamboat (Nevada) and Mammoth (California) geothermal fields. The depth of the outflow wells is evidently shallower than the upflow wells, which reduces drilling costs and allows reduction in downhole pump parastici load, optimizing operational efficiency and cost-effectiveness of low-medium temperature resources. The flatter terrain of outflow zones also eases drilling and equipment mobilization as well as the access to existing infrastructures.

3.2.1 Case Study #1: Steamboat, Nevada

The Steamboat geothermal field, located near Reno, Nevada, is geologically set within a complex of metamorphic rocks of sedimentary and volcanic origin, intruded by granitic rocks. These formations are further covered by younger volcanic rocks, approximately one million years old, which are believed to be the heat source for the geothermal system (Neupane, et al., 2015). The field is characterized by steep faults trending northeast and north, which contribute to the formation of a series of basins between the Carson Range and the Virginia Range. These

fault systems create conduits that control the geothermal fluid flow, resulting in a high-temperature resource with significant fracture permeability, particularly along the western and eastern sides of the reservoir (Klein, et al., 2007). The geothermal system at Steamboat features a conceptual model (Figure 24) where hot water ascends below the Upper Steamboat at about 200ºC, thus forming the upflow zone, then flows northeast at depths of 1,200-1,300 m into the outflow zone at the Lower Steamboat, where the fluids eventually discharge at the hot springs and into a shallow subsurface aquifer under Truckee Meadows (Ormat, 2022; Neupane, et al., 2015).

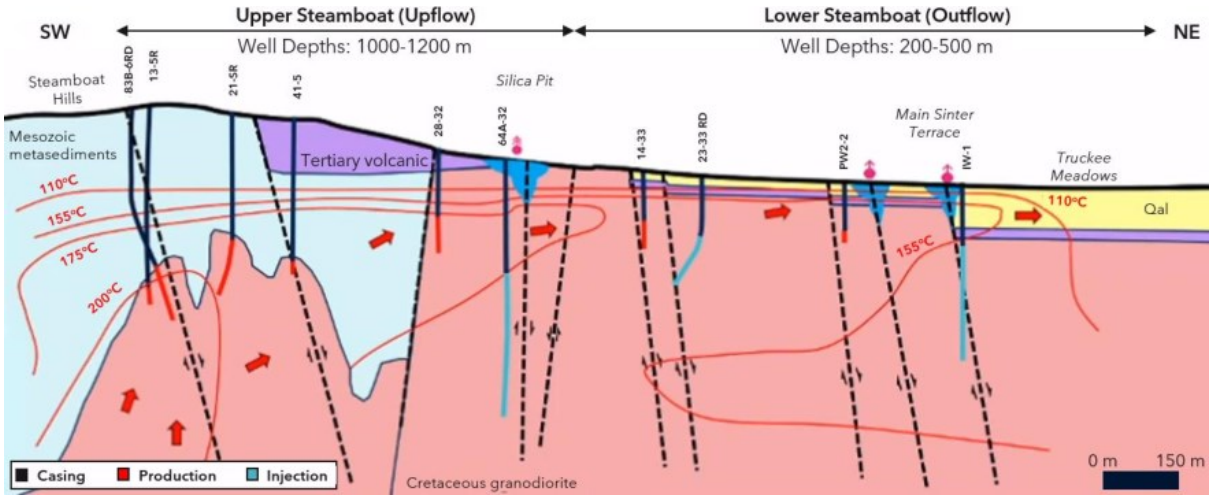

Figure 24: Conceptual Model of Steamboat Geothermal Field, Nevada (Ormat, 2022).

The Steamboat geothermal fields in Nevada have seen several development phases (ThinkGeoEnergy, 2024; NREL, 2021; Ayling, 2020). Initially, in 1985, the Steamboat 1 and Steamboat 1A binary plants were built with capacities of 2 MW and 2.4 MW, respectively, although these are now retired. Subsequently, the Steamboat Hills single-flash plant with the capacity of 16.3 MW was commissioned in 1988. Development picked up again in the mid-2000s: in 2006, the Richard Burdette plant (30 MW) became operational, followed by Galena 2 (13.5 MW) and Steamboat Hills Bottoming (5.5 MW) in 2007. The expansion continued in 2008 with Galena 3 (30 MW), Steamboat 2 (18.2 MW), and Steamboat 3 (18.2 MW). The most recent addition was Steamboat Hills (16.3 MW) in 2020 by retiring the existing Steamboat Hills single-flash plant and replacing it with a binary plant with pumped wells (Ormat, 2022). Furthermore, the well depths in the Steamboat fields vary between the upflow and outflow zones (Ormat, 2022). The upflow zone, located at Upper Steamboat, has wells that range from 1,000 to 1,200 meters deep, reaching temperatures of up to 200°C, as shown in Figure 24. Meanwhile, the outflow zone at Lower steamboat, which is used as both the production and reinjection areas, has shallower wells, ranging from 200 to 500 meters deep, with temperatures between 150 and 175°C.

3.2.2 Case Study #2: Mammoth, California

The Mammoth Geothermal Complex is strategically located at the base of a resurgent dome in the Long Valley Caldera. This dome formed due to the upward movement and swelling of the caldera floor, driven by activity in the magma chamber beneath it. The geothermal heat generated from this magma chamber causes groundwater to boil and turn to steam, resulting in fumaroles observable in areas like Fumarole Valley and Hot Creek, situated about 5 miles (8 km) to the northeast. The GPP development at the Mammoth geothermal field by Ormat has undergone significant development over the years (Robertson-Tait, et al., 2021; NREL, 2021). Initial developments began in 1990 with the installation of the MP-2 and PLES-1 binary plants, each with a capacity of 15 MW. Further expansion occurred in 2013 with the addition of the MP-1 plant, which has a capacity of 10 MW. The most recent development is the Casa Diablo IV plant, which came online in 2022, adding another 30 MW to the complex's capacity. The upflow zone in the West Moat area, characterized by low-medium temperature (180-200°C), has not been drilled due to the challenging mountainous terrain (Ormat, 2022). Consequently, development has been concentrated in the outflow zone at Casa Diablo, where production wells are drilled to depths ranging from 800 to 1200 meters, accessing reservoir temperatures between 130-200°C, as shown in Figure 25. The outflow zone also benefits from the use of pumped production wells, which help manage the calcite oversaturation conditions common in this area. Ormat is currently focusing on further expansion projects within the outflow zone, leveraging the existing infrastructure and favorable flatter terrain in the outflow zone (Ormat, 2022).

Meanwhile, Indonesia also has the experience in developing the outflow zone despite in high-temperature geothermal fields and the purpose of the development is currently limited to utilizing it as a reinjection area, as shown in Table 7, such as in the Muara Laboh (West Sumatra) and Sibayak (North Sumatra) geothermal fields

(Firanda, et al., 2015; Stimac, et al., 2019). Similar trends in the well depth can be observed, where the outflow wells are typically shallower than the upflow wells. However, the utilization of outflow zone for production can be expected in the future in the Ulubelu geothermal field, Lampung, in which the lower-temperature outflow zone, named Gunung Tiga, is currently being explored for future power generation (PGE, 2022).

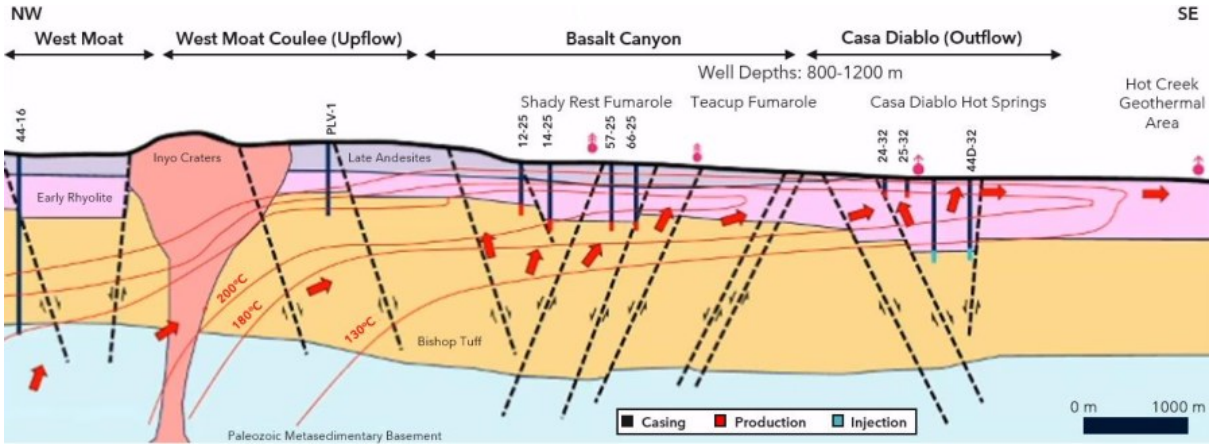

Figure 25: Conceptual Model of Mammoth Geothermal Field, California (Ormat, 2022).

Table 7: Examples of Indonesia's Experience in Developing the Outflow Zone in High-Temperature Geothermal Fields.

Parameter	Muara Laboh, West Sumatra	Ulubelu, Lampung	Sibayak, North Sumatra
Resource Information			
Upflow temperature	230-300°C	250-280°C	240-300°C
Upflow temperature class	High-temperature	High-temperature	High-temperature
Reservoir mobile fluid phase	Liquid-dominated	Liquid-dominated	Liquid-dominated
Terrain	Flat-moderate	Steep	Steep
Avg. main reservoir well depth	2,422 mMD	2,097 mMD	2,015 mMD
Developer	Supreme Energy	Pertamina Geothermal Energy	Pertamina Geothermal Energy
Development history	**2019:** Unit 1 (85 MW; double-flash) **Total capacity:** 85 MW	**2012:** Unit 1 (55 MW; single-flash) Unit 2 (55 MW; single-flash) **2016:** Unit 3 (55 MW; single-flash) **2017:** Unit 4 (55 MW; single-flash) **Total capacity:** 220 MW	**2008:** Unit 1 (10 MW; single-flash) **Total capacity:** 10 MW
Outflow Development			
Outflow temperature	160-220°C	150-240°C	150-230°C
Outflow temperature class	Low-medium temperature	Low-high temperature	Low-high temperature
Outflow utilization	Reinjection area	Still under exploration for future production	Reinjection area
Number of outflow wells	6 wells (reinjection)	None	3 wells (reinjection)
Avg. outflow well depth	1,925 mMD	None	1,690 mMD

3.2.3 Indonesia's Experience #1: Muara Laboh, West Sumatra

The Muara Laboh geothermal field, located in a pull-apart basin along the Great Sumatera Fault (GSF), features a complex geological and structural setting. The system is hosted in a stratigraphic sequence ranging from Paleozoic metamorphic rocks to Quaternary volcanic deposits, with significant Middle Miocene granitic intrusions. Structurally, the field is characterized by fault segments like the Siulak and Suliti faults, with dominant N-S, NW-SE, and NE-SW fracture trends controlling permeability and fluid flow (Mussofan, et al., 2018). The geothermal reservoir, divided into SW and NE sectors, exhibits moderate to high temperatures (230-300°C). The SW sector, associated with the Patah Sembilan volcano, features deep upflow zones and high permeability along intrusion margins, while the NE sector, with its steam cap near the Idung Mancung fumarole, has secondary upflow along faults and fractures. The NNW outflow zone, originating from fluid flow parallel to the GSF, extends to the Sapan Malulong hot springs. The system's fluids are low in salinity and non-condensable gases, indicating

deep meteoric recharge and fault-controlled circulation (Stimac, et al., 2019). Figure 26 shows the conceptual model of the Muara Laboh geothermal field.

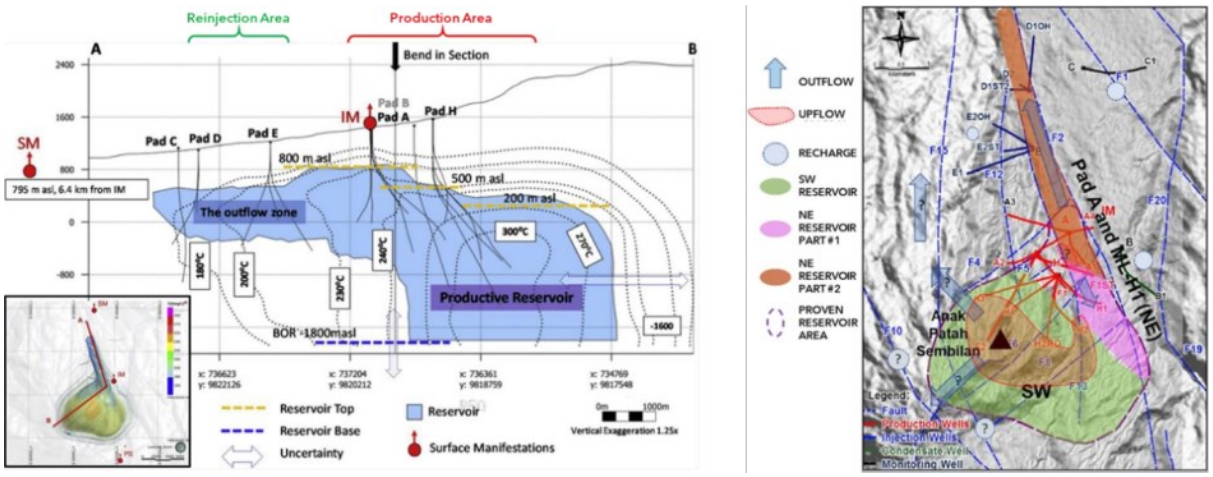

Figure 26: Conceptual Model of Muara Laboh Geothermal Field, West Sumatra (Stimac, et al., 2019).

The historical development of the Muara Laboh geothermal power plant began with the identification of its high potential during pre-feasibility studies conducted by Supreme Energy in 2008 (Stimac, et al., 2019). The first unit of the power plant, an 85 MW double-flash power station, was operational by 2019 (GRG-Geoenergis, 2024a; EBTKE, 2020). The NNW outflow zone of the field is currently utilized as the reinjection area, where six reinjection wells (D-1OH, D1ST2, D2, E1, E2OH, and E2ST) have been drilled in Pads D and E with a temperature of 160-220oC (Stimac, et al., 2019). The average outflow well depth of 1,925 mMD is shallower than the main reservoir wells, which average 2,422 mMD.

Furthermore, Muara Laboh is characterized by a geochemically compartmentalized reservoir (Alfiady, et al., 2021). The fluid chemistry in the outflow zone is characterized by low salinity, with chloride concentrations ranging from 400 to 1600 ppm and a benign chemical composition with low non-condensable gas (NCG) content of approximately 0.5 to 2 wt% in steam. The gas chemistry shows helium isotopic compositions (R/Ra) between 1.12 and 3.14, indicating contributions from near-surface crustal fluids and mixing between mantle and crustal fluid sources (Stimac, et al., 2019). Finally, despite not developing the outflow zone for production, the experience in drilling and developing the outflow zone for reinjection provides valuable experience and lessons learned about the permeability, hydrogeology, and fluid chemistry in the outflow zone for future development of low-medium temperature outflow zone in Indonesia.

3.2.4 Indonesia's Experience #2: Ulubelu Lampung

The Ulubelu geothermal field is known as a volcanic geothermal system with a large outflow structure, extending from the upflow zone near the dormant G. Rendingan stratovolcano to the south towards the Gunung Tiga outflow area and the further south Way Panas outflow area (Hochstein & Sudarman, 2015), as shown in Figure 27. The thermal manifestations are located on a steep terrain with a zonation pattern, with acidic SO4 springs found upstream, transitioning to neutral SO4-HCO3 springs mid-downstream, and finally to neutral Cl-SO4-HCO3 springs at the bottom where travertine deposits are present. The area was initially categorized as a caldera-type volcano or a volcano in a volcano-tectonic depression. This classification persisted into the early 1990s when detailed exploration surveys commenced in 1990, employing gravity, magnetic, DC- and MT resistivity methods. By 1995, three deep slim holes, each around 1.2 km, were drilled. The SL-3 slimhole well was presumed to be near the center of a volcano-tectonic depression reservoir. Although heat loss surveys were not conducted, the bottom hole temperatures in SL-3, showing an inverse profile with approximately 200°C at 0.95 km, did not indicate the presence of an 'upflow structure' for a high-temperature reservoir. Instead, the center of this structure is likely closer to the Rendigan stratovolcano.

The Ulubelu geothermal field has undergone significant development since 2012. Initially, two single-flash geothermal power plants (GPP) were established, each with a capacity of 55 MW. This was followed by the addition of two more units in 2016 and 2017, bringing the total capacity to 220 MW (ThinkGeoEnergy, 2024; GRG-Geoenergis, 2024a; EBTKE, 2020). All existing GPP developments are situated within the Ulubelu reservoir area, characterized by a high-temperature upflow (250-280°C) and steep terrain (GRG-Geoenergis, 2024b; Mubarok & Zarrouk, 2016). Meanwhile, the outflow zone in the Gunung Tiga area remains undeveloped. However, Pertamina Geothermal Energy is actively exploring this zone for future production potential. Based on the measured downhole temperature at a slimhole located at about 1 km from the Gunung Tiga prospect area, the subsurface temperature at the area can exceed 200°C (PGE, 2022). Meanwhile, the geoscience analysis suggests

that the outflow temperatur can range from 150 to 240oC (PGE, 2021) Therefore, the outflow zone has a wide temperature range class from low to high-temperature.

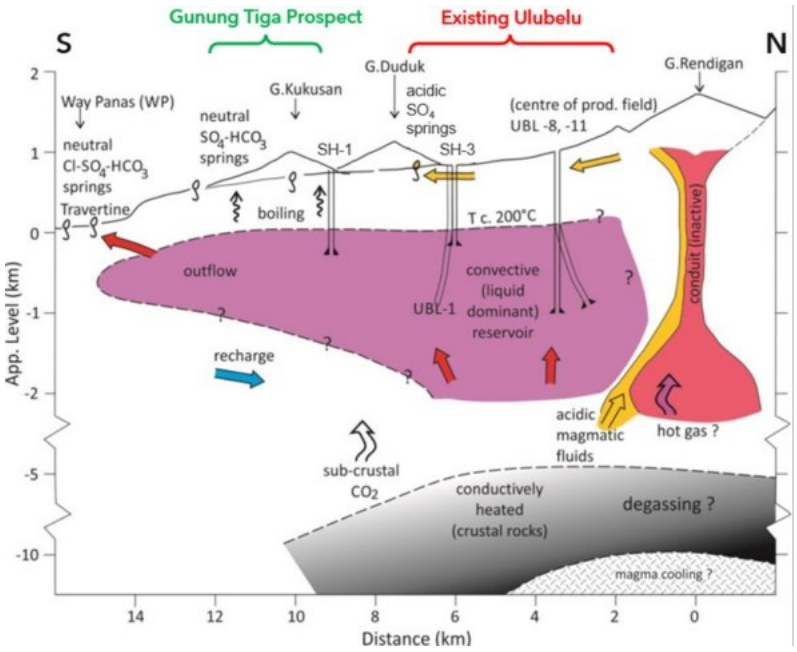

Figure 27: Conceptual Model of Ulubelu Geothermal Field, Lampung (Hochstein & Sudarman, 2015).

3.2.5 Indonesia's Experience #3: Sibayak, North Sumatra

The Sibayak geothermal field is located within the Singkut Caldera in North Sumatra, Indonesia, and is characterized by a volcanic-hosted geothermal system beneath Mount Sibayak (Firanda, et al., 2024; Atmojo, et al., 2001). The geological setting includes high temperatures ranging from 240ºC to 300ºC, primarily occurring in fractured zones of pre-Tertiary to Tertiary sedimentary rocks. The field's geothermal reservoir is dominated by hot liquid and is situated near the conduits of two small stratovolcanoes within the caldera. Extensive fractures and faults, such as the Tengkorak, Semangat Gunung, and Pariban Faults, enhance secondary permeability, contributing to the field's geothermal activity. The geothermal system's upflow zone is located directly beneath Mount Sibayak, while the outflow zone extends approximately 3 kilometers towards the E-SE direction, reaching the Karona hot springs. Furthermore, the field has a notable development history perfomed by Pertamina Geothermal Energy. In 2008, a 10 MW single-flash power plant (Unit 1) was commissioned, utilizing the field's high-temperature upflow zone with temperatures ranging from 240-300°C. The production wells reach an average depth of 2,015 meters measured depth (mMD), targeting the steeply terrained propylitic zone where the main geothermal resource is located. The outflow zon serves as a reinjection area, in which three reinjection wells, namely SBY-1, SBY-2, and SBY-9, are drilled to shallower depths, averaging around 1,690 mMD, compared to the deeper production wells near to the upflow zone shown in Figure 28 (Firanda, et al., 2015). The outflow zone is interpreted to have low-medium temperatures of 150-230°C based on the downhole measurements of the outflow wells and numerical modeling (Firanda, et al., 2024).

Furthermore, the permeability extent and depth distribution at Sibayak can be identified from the partial and total loss of circulation encountered during drilling as well as the feed zones identified from the water loss test. Most feed zones were found between -74 masl and -280 masl in many wells, while in SBY-5, they were identified at depths from -405 masl to -425 masl. The feed zones are likely controlled by local fractures and faults in the area, as well as the primary permeability of the metasediments. The injectivity index was highest in SBY-5 at 61.4 t/h/bar, and in SBY-6 at 55.4 t/h/bar, which are located in the central reservoir. The highest mass flow production was also observed in well SBY-5, with 173 t/h of brine and 35 t/h of steam. Meanwhile, the II values at the outflow wells (SBY-1, SBY-2, and SBY-9) are rather smaller compared to the central reservoir wells, each with an II of 4.3 t/h/bar, 5.4 t/h/bar, and 3.2 t/h/bar. Therefore, among these 3 wells, only SBY-2 that has the II value above the commercial II threshold of 5 t/h/bar. Nevertheless, it can be observed that the elevation of the major feed zone generally becomes higher (shallower feed zone) towards the outflow zone, as shown in Figure 29. The shallowest major feed zone and the second shallowest total lost circulation zone can be found at SBY-9 at the elevation of 360 masl and 490 masl, respectively (Firanda, et al., 2024).

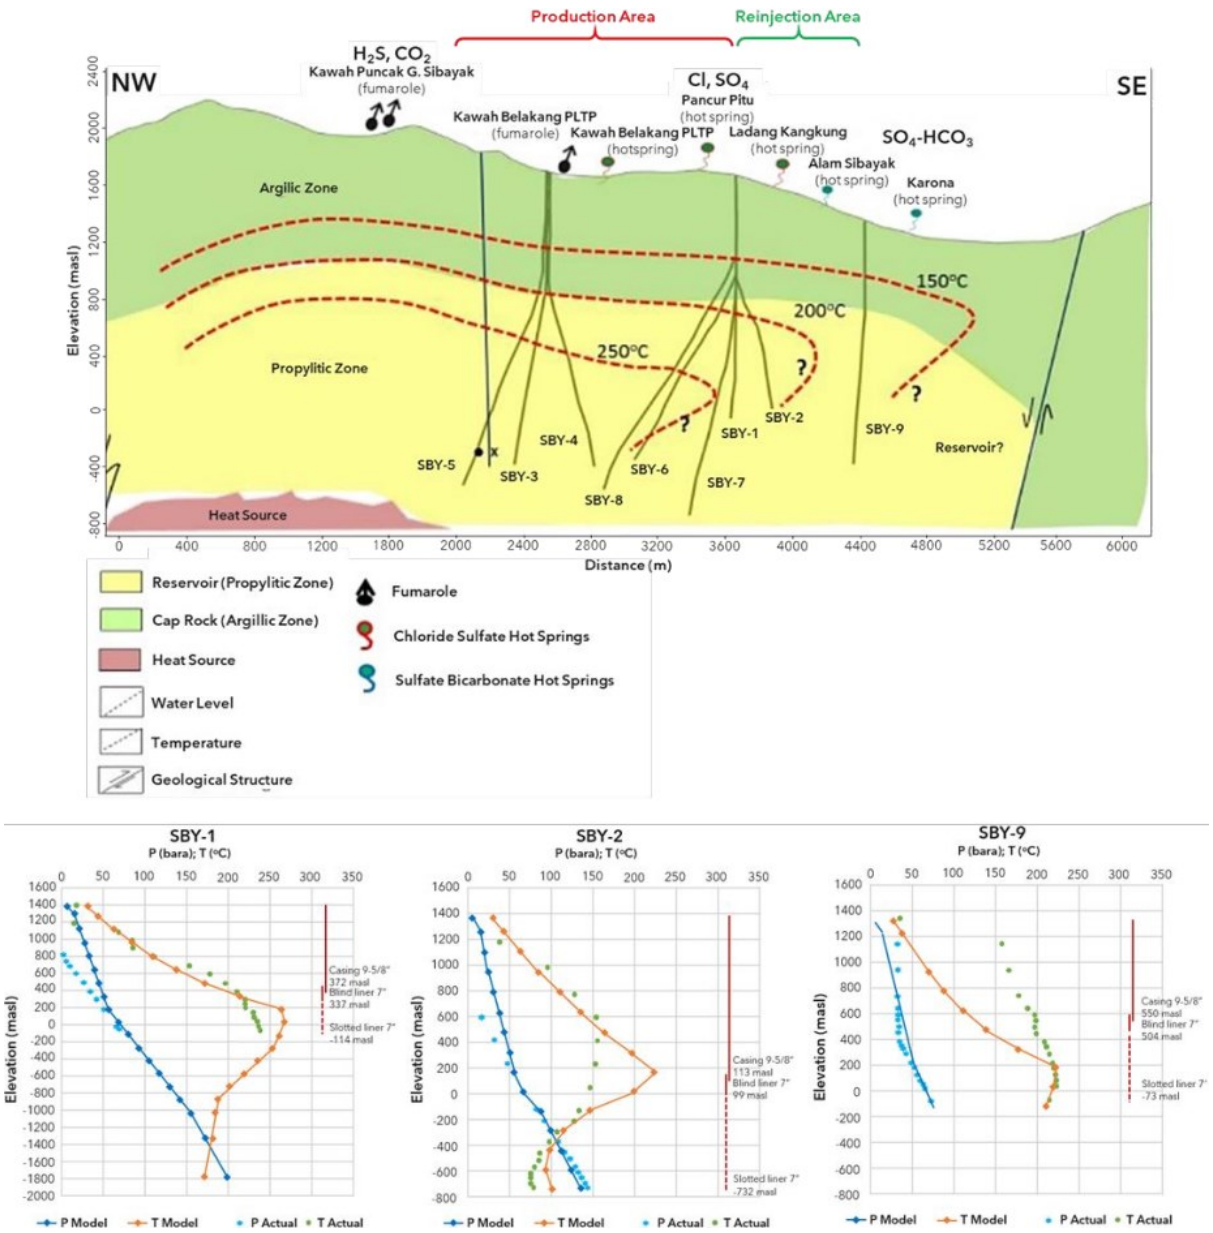

Figure 28: Conceptual Model of Sibayak Geothermal Field, North Sumatra (Top) and the Downhole Temperature & Pressure Profiles at Three Outflow Wells (Bottom) (Firanda, et al., 2024).

The permeability distribution at Sibayak provides the lessons learned that the development of low-medium temperature outflow may be challenged by the low permeability typically found at the boundary of a conventional hydrothermal reservoir in spite of the shallower feed zone depth. Consequently, the well targeting at the outflow zone has to consider the permeability target thoroughly to increase the probability of intersecting highly permeable zones. Otherwise, well stimulation techniques to improve the hydraulic connectivity to the main reservoir's permeable fracture networks might be needed.

3.3 Well Stimulation to Improve Permeability

Finding high permeability during drilling (well targeting) or improving permeability through well stimulation techniques is crucial to improve the techno-economic feasibility of low-medium temperature geothermal systems. The first reason why permeability is a significant parameter determining the techno-economic feasibility of a low-medium temperature geothermal systems is that permeability influences the net power output of a pumped geothermal well by determining the gross power output (determined by the mass flow of produced fluid) and parasitic load (determined by the pump energy required to discharge the well artificially). If a higher well power output can be achieved, a smaller number of wells is needed to support a certain GPP development capacity. Figure 30 illustrates how well output increases with higher operating temperatures and higher productivity indices (PI in L/s/bar). At lower temperatures (100-180°C), wells rely on pumped technology to achieve desired outputs. Beyond this temperature range, wells can transition to self-flowing mechanisms, especially with the utilization of

advanced downhole pumps like the SLB Reda Thermal ESP, which extends the operating temperature limit up to 215°C (Kriptanto, 2024). The productivity index indicates the reservoir's permeability, with higher values denoting more efficient fluid flow. For instance, wells with a PI of 30 l/s/bar exhibit significantly higher outputs compared to those with lower PIs. This relationship underscores the importance of both thermal and permeability characteristics in optimizing pumped well performance.

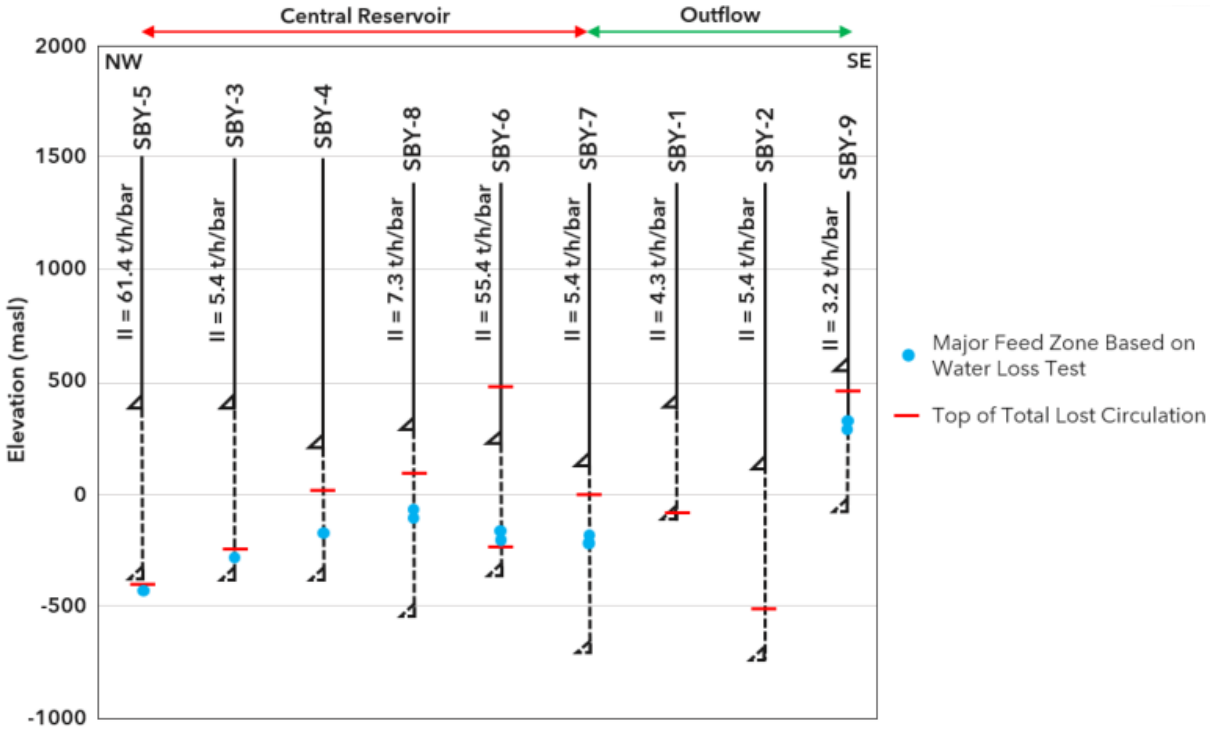

Figure 29: Major Feed Zones and Total Lost Circulation Zones at Sibayak Geothermal Wells (Firanda, et al., 2024).

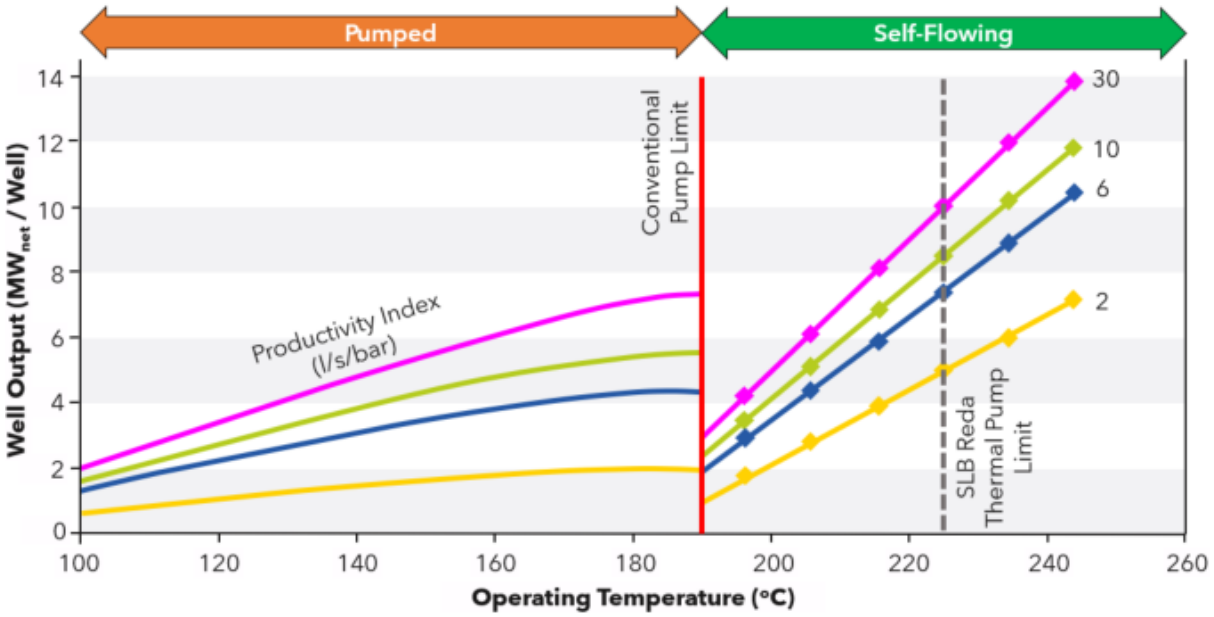

Figure 30: Well Power Output as a Function of Temperature and Productivity Index (Kriptanto, 2024; Febrianto, et al., 2019; IFC, 2013).

The influence of permeability and skin factor (due to the presence of permeable fractures) to the reservoir deliverability and the required pumping pressure by the downhole pump are illustrated in Figure 31. Given the PI correlation expressed by the Equation (8) and that the slope of a liquid-phase IPR curve is the negative of one over PI, the slope of the IPR curve becomes steeper as the permeability and/or skin factor decrease. Therefore, at a given flow rate inflow from the reservoir into the wellbore, the pumping pressure required to artificially

discharge the non-self-flowing well becomes higher as the reservoir permeability decreases due to the lower reservoir deliverability. In other words, wells with low permeability requires a higher pumping energy and thus results in a smaller well power output due to the higher pump parasitic load. Similarly, when the well intersects a permeable fracture zone (thus having a negative skin factor), the reservoir deliverability increases and thus the pumping pressure can be reduced. As a result, finding high permeability during drilling (well targeting) or improving permeability through well stimulation techniques is crucial to optimize the pumped well power output through an efficient artificial lift using downhole pumps.

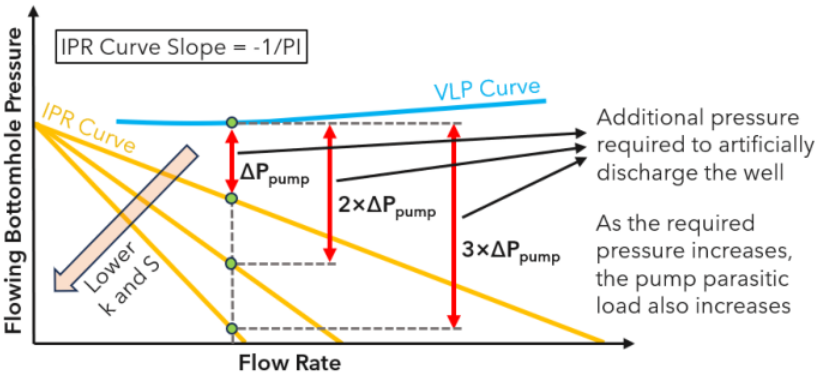

Figure 31: IPR Curve Variations as the Permeability (k) and Skin Factor (S) are Reduced for Liquid-Phase Geothermal Wells (Kriptanto, 2024; Zarrouk & McLean, 2019; Grant & Bixley, 2011).

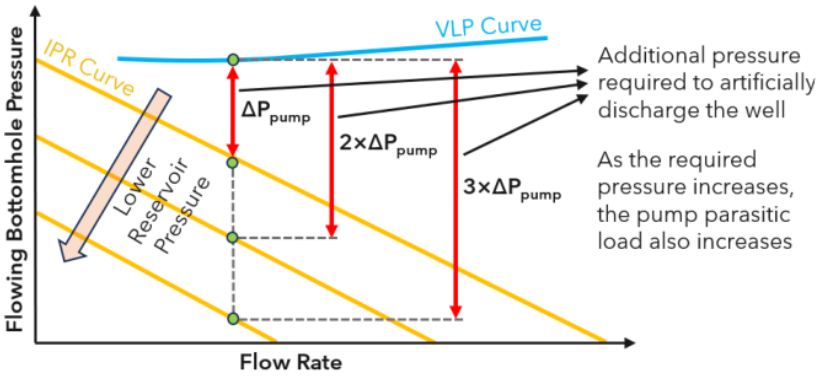

Figure 32: IPR Curve Variations as the Reservoir Pressure Decreases for Liquid-Phase Geothermal Wells (Kriptanto, 2024; Zarrouk & McLean, 2019; Grant & Bixley, 2011).

The second reason why permeability is important to improve the techno-economic feasibility of low-medium temperature geothermal systems is that permeability facilitates reservoir management by creating a sufficient injection capacity to provide reservoir pressure support and fluid replenishment. Therefore, the low-medium temperature geothermal resource can be sustainably extracted for a longer period and the downhole pump parasitic load can be minimized. As shown in Figure 32, as the reservoir pressure is depleted, the required pump energy to artificially discharge the well becomes higher, leading to a smaller well net power output. In this case, the IPR curve falls by not changing its slope since the reservoir deliverability decline is caused by reservoir pressure decline and the reservoir permeability and skin remain constant (constant PI value).

The binary geothermal power plant (GPP) system, as illustrated in Figure 33 (left), employs a closed-loop system at the surface to circulate the produced geothermal fluid. This system begins with hot brine being pumped from a production well to the surface, where it transfers heat to a secondary working fluid in a heat exchanger. The secondary fluid, typically an organic compound with a low boiling point, is vaporized and drives a binary turbine-generator to produce electricity. After passing through the turbine, the secondary fluid is condensed back into liquid form using an air-cooled condenser and recirculated back into the heat exchanger. Meanwhile, the cooled geothermal fluid is injected back into the reservoir through an injection well, ensuring that almost all of the produced fluid is reinjected, thereby minimizing environmental impact and sustaining the reservoir's pressure and thermal characteristics. Subsequently, Figure 33 (right) compares the fluid consumption per MW gross generated between low-medium temperature binary GPPs in the U.S. and high-temperature flash GPPs typically used in Indonesia. Binary GPPs, which operate at lower temperatures and utilize the binary cycle, consume a higher amount of geothermal fluid per MW gross generated compared to high-temperature flash GPPs. This difference underscores the importance of achieving sufficient injection capacity in binary GPPs through high permeability

reservoirs. High permeability ensures effective reinjection of geothermal fluids to maintain reservoir pressure and replenish the produced geothermal fluid.

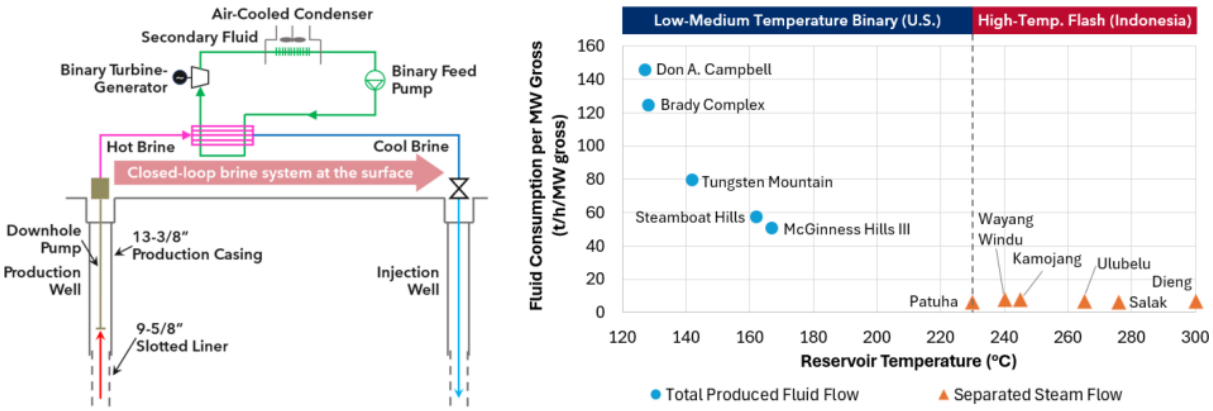

Figure 33: Binary Geothermal Plant with Pumped Well (Left); Comparison of Fluid Consumption of Geothermal Binary and Flash Plants (Right) (Ormat, 2022; NSA, 2020; Febrianto, et al., 2019).

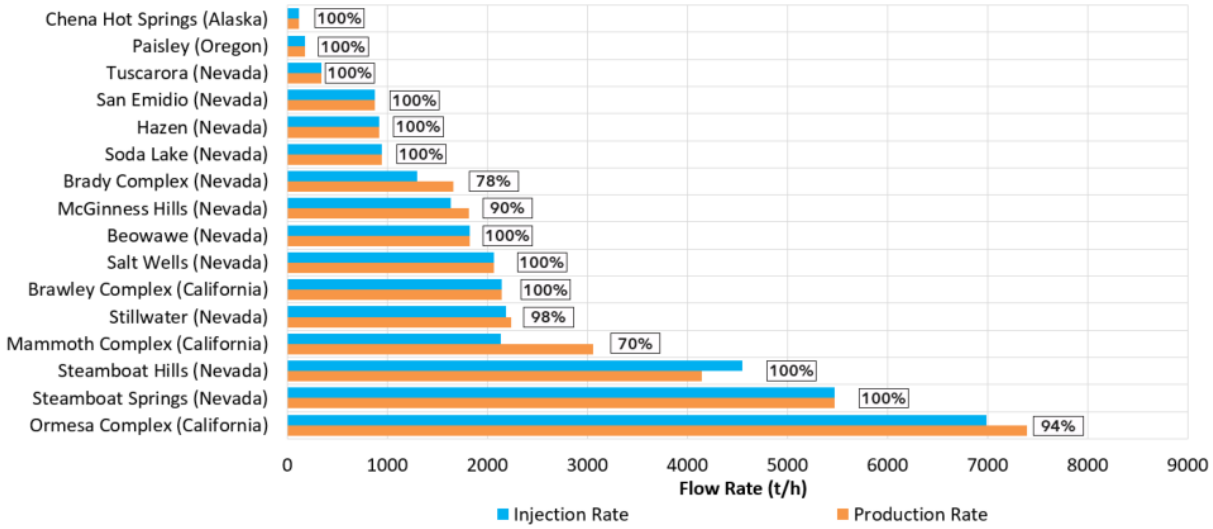

Figure 34: Injection-to-Production Flow Ratio in U.S. Low-Medium Temperature Geothermal Fields (Kamila, et al., 2021).

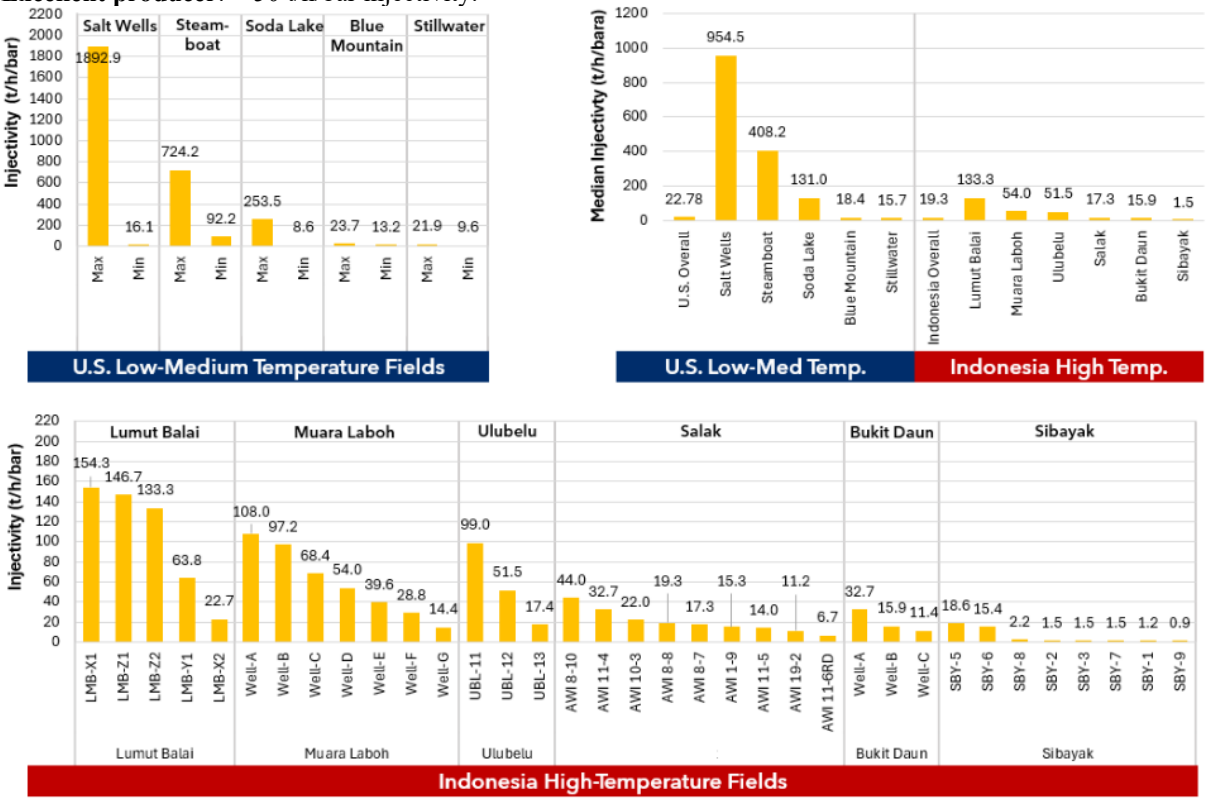
Furthermore, Figure 34 shows the ratio between the reinjected and produced geothermal fluid flow rates, denoted as the I/P ratio, for low-medium temperature geothermal fields in the U.S. According to (Kamila, et al., 2021), for low-medium temperature geothermal systems, maintaining a full reinjection or 100% I/P ratio is crucial for effective reservoir management by providing an adequate pressure support and fluid replenishment. This is evident as most of the low-medium temperature geothermal fields in the U.S., such as Brady Complex, McGinness Hills, and Steamboat Springs, achieve full reinjection (100% I/P ratio) due to the closed-loop system used in binary geothermal power plants (GPP). These systems ensure that the produced geothermal fluid is circulated and reinjected back into the reservoir, thereby sustaining reservoir pressure and preventing depletion. Therefore, achieving high permeability allows for a sufficient injection capacity to reinject 100% of the produced fluid, which is critical in preventing reservoir pressure decline and ensuring the continuous productivity of the geothermal system.

Injectivity index (II) is a measure of permeability that informs how much fluid flow rate that the well can accept at the given pressure differences between the reservoir pressure and the downhole pressure during injection expressed in t/h/bar (Luo, et al., 2023; Zarrouk & McLean, 2019). The II value can indicate the permeability of whether the geothermal well can be commercially utilized either as an injection well or a production well. The following II value classification can be used to evaluate the potential productivity of the well (Zarrouk & McLean, 2019)

1. **Poor (sub-commercial) producer**: < 5 t/h/bar injectivity.
2. **Moderate producer**: 5-50 t/h/bar injectivity.

3. **Excellent producer**: > 50 t/h/bar injectivity.



4.

5. **Figure 35: Permeability Comparisons Between Geothermal Fields in U.S. and Indonesia (Firanda, et al., 2024; Ikhwan, et al., 2021; Ikhwan, 2020; Mines, 2016; Mubarok & Zarrouk, 2016; Firanda, et al., 2015; Satya, et al., 2015; Rejeki, et al., 2010).**

Figure 35 compares the injectivity indices of geothermal fields in the U.S. and Indonesia. The injectivity index is significantly higher in U.S. low-medium temperature fields, such as Salt Wells and Steamboat, with maximum values reaching 1892.9 t/hr/bar and 724.2 t/hr/bar, respectively. In contrast, Indonesian high-temperature fields, like Lumut Balai and Muara Laboh, have much lower injectivity indices, with maximum values of 154.3 t/hr/bar and 108 t/hr/bar, respectively. This disparity in permeability is largely due to geological differences between the regions. The U.S. geothermal fields are often located in extensional tectonic settings, such as the Basin and Range province, where tectonic activity creates significant open fractures that enhance fluid flow (Ikhwan, et al., 2021). In contrast, Indonesian geothermal fields are primarily situated in compressional tectonic settings associated with subduction zones.

This geological environment tends to produce shear and strike-slip faults, which result in lower permeability compared to the extensional faults found in the U.S. The geological setting plays a critical role in determining the permeability of geothermal reservoirs. In the extensional regime of the U.S., tectonic activities create larger spatial displacements, leading to higher permeability magnitudes. Conversely, Indonesia's compressional regime results in more localized and less extensive faulting, limiting the permeability. This lower permeability in Indonesian geothermal fields poses challenges for an effective fluid reinjection for reservoir management and for an efficient artificial lift using the downhole pump.

Should the drilling fails to encounter sufficient permeability, one way to improve natural permeability is by creating man-made fractures through well permeability stimulation techniques, known as Enhanced Geothermal Systems (EGS). EGS span a range of resources, from low-permeability resources at existing conventional hydrothermal sites, known as "in-field" resources, to untapped, undeveloped deep (standalone) resources, as shown in Figure 36. The development and deployment of EGS technologies are expected to proceed in stages along this spectrum. Initially, EGS development will likely focus on in-field resources, converting sub-commercial wells into productive assets by applying EGS technologies, which create connections to productive conventional reservoirs and enhance heat recovery, reducing drilling costs and risks. The geothermal industry has experimented with in-field EGS with varying degrees of success, notably through innovative well stimulation and other improved EGS technologies. The U.S. Department of Energy's funded in-field EGS projects at low-medium temperature geothermal fields, such as Desert Peak, Brady's Hot Springs, Raft River, as well as commercial successes like Soda Lake, highlight the potential for further EGS improvements.

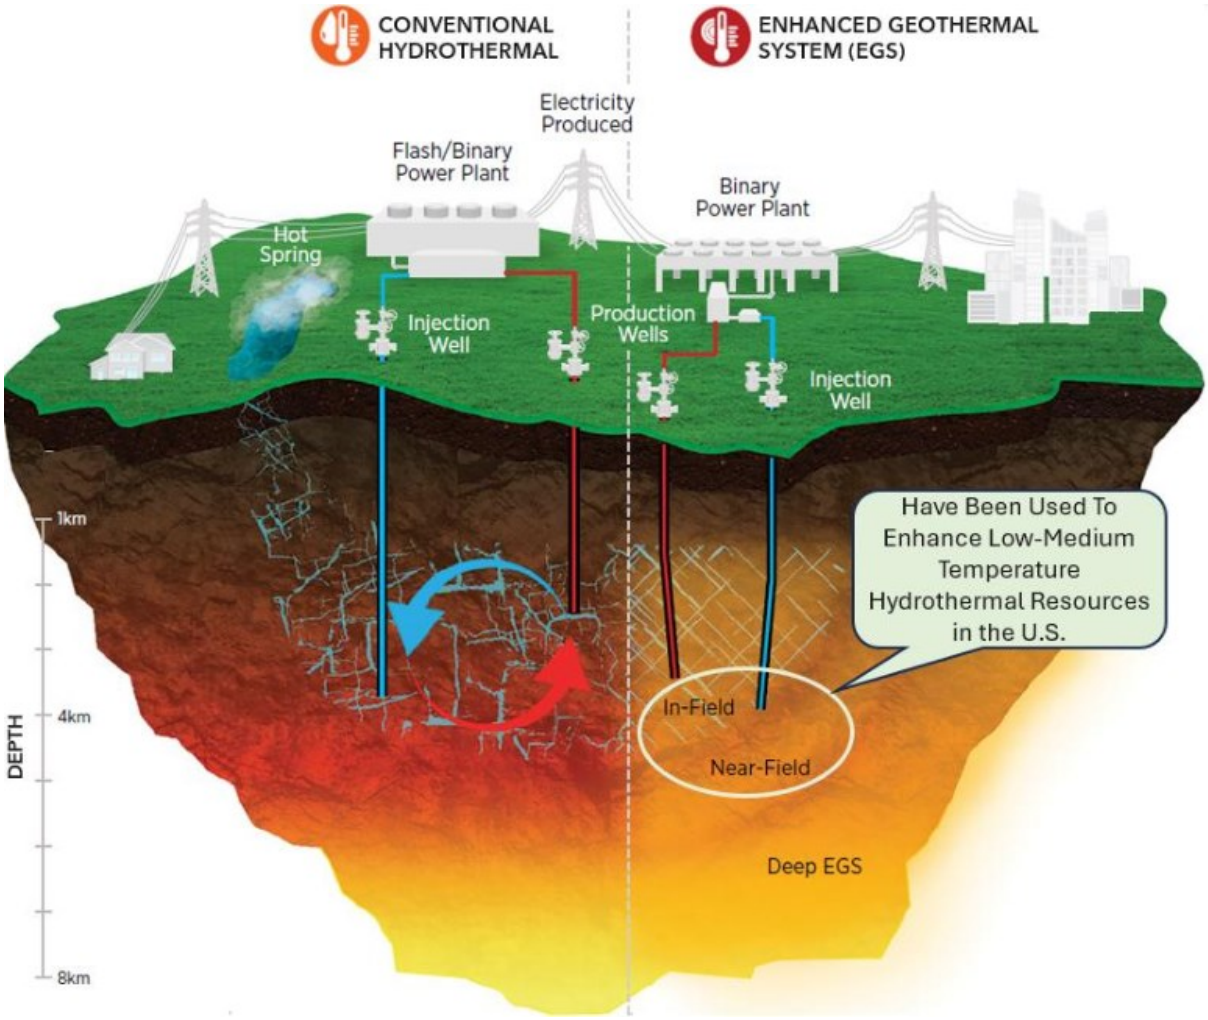


Figure 36: Types of Enhanced Geothermal Systems (U.S. DOE, 2019).

Once reliable in-field EGS resource capture is achieved, the next stage involves near-field EGS, targeting hot zones adjacent to conventional geothermal resources. These areas, typically hot due to nearby thermal anomalies but lacking permeability and fracture networks, can benefit from advanced EGS technology, expanding resource utilization beyond in-field environments and leveraging existing power-generating infrastructure. The final stage in EGS development focuses on deep standalone EGS resources. The progression from in-field to near-field to deep standalone EGS demonstrates a strategic approach to geothermal resource development, each stage building on the technological advancements and successes of the previous one. Table 8 summarizes the comparisons between in-field, near-field, and deep (standalone) EGS types.

Table 8: Comparison Between In-Field, Near-Field, and Deep (Standalone) EGS.

EGS Type	Description	Field/Project Example	Maturity
In-field	Creating permeability connections from sub-economic production or injection wells to a hydrothermal reservoir, thus enhancing heat sweep (for production wells) or pressure maintenance & fluid replenishment (for injection wells) from additional resource volumes.	**Low-medium temperature fields:** • Raft River, Idaho (Bradford, et al., 2015) • Soda Lake, Nevada (Lovekin, et al., 2017) **High-temperature fields:** n/a	Commercial
Near-field	Creating permeability connections between a hydrothermal reservoir and the low permeability yet hot & relatively well-characterized rock zones located in the margins of that hydrothermal reservoir.	**Low-medium temperature fields:** • Desert Peak, Nevada (Chabora, et al., 2012) • Brady's, Nevada (Drakos & Akerley, 2015) **High-temperature fields:** • Northwest Geysers, California (Garcia, et al., 2016)	Pilot
Deep (standalone)	Creating permeability and fluid circulation within hot dry rocks lacking natural permeability and reservoir fluid.	• Fervo Energy & Google, Nevada (Jiang, et al., 2023) • FORGE, Utah (Jiang, et al., 2023)	Pilot

The well stimulation techniques used for EGS are originally developed for the petroleum industry and have been adapted for geothermal applications as cost-effective alternatives to drilling new wells or re-drilling existing ones (Song, et al., 2023; Aqui & Zarrouk, 2011). In the petroleum sector, stimulation techniques have been utilized for over a century, primarily to enhance the economic viability of hydrocarbon resources by increasing the rate at which formations can deliver hydrocarbons (Gong, et al., 2023). Similarly, in geothermal applications, These techniques aim to enhance the connectivity between the wellbore and the natural fractures or faults within the reservoir, thereby improving the energy extraction efficiency, or creating a man-made reservoir in a hot dry rock lacking natural fractures or faults as a fluid flow pathway. Techniques such as hydraulic fracturing, acid fracturing, and thermal fracturing are the most commonly used to achieve these objectives besides the other techniques (Sharmin, et al., 2023; Li, et al., 2022). The available well stimulation techniques that can be used for EGS are as follows:

1. **Hydraulic fracturing**: it is used to create long, open, conductive fractures that extend deeper into the formation beyond the wellbore by applying hydraulic pressure to the rock formation until it surpasses the fracture breakdown pressure (Luo, et al., 2023; Aqui & Zarrouk, 2011). After the release of the hydraulic fracture, the fracture conductivity is maintained by either the proppant materials in the fracturing fluid, hydro-propping through a maintained injection above the fracture closure pressure, or the self-propping mechanism caused fracture surface roughness as a result of the shearing forces caused by a continuous injection below the fracture closure pressure (Lei, et al., 2023; Li, et al., 2021).
2. **Acid fracturing**: it is similar to hydraulic fracturing, sharing the same purpose of stimulating undamaged formations but by injecting acid at pressures higher than the formation fracture pressure to create or enhance fractures (Luo, et al., 2023; Aqui & Zarrouk, 2011). Its primary difference with the hydraulic fracturing is in the method of fracture creation and maintenance. To create fractures, acid fracturing relies on the dissolution and etching process performed above the formation fracture pressure. Meanwhile, to maintain fracture conductivity, it largely depends on the roughness formed on the fracture surfaces due to the etching process (Chen, et al., 2023; Deng, et al., 2022).
3. **Thermal fracturing**: it is a variation of hydraulic fracturing that, instead of using high hydraulic pressure to break the rock, uses cold fluid injection into the hot rock formation, causing thermal contraction and thus creating new fractures (Luo, et al., 2023; Peter-Borie, et al., 2019). The primary advantages of thermal fracturing over hydraulic or acid fracturing is the lower cost since the required pumping pressure is lower and it does not involve aggressive acid chemicals or chemically complex propped fracturing fluid. However, fracture closure is often a concern when designing a thermal fracturing treatment due to the restoration of thermal stress caused by the rock reheating after the well is put back into production since proppant is not utilized to maintain the fracture conductivity (Peter-Borie, et al., 2019). The mechanism of this reversible thermal contraction process is not fully understood yet the changes in rock strain seem to maintain the increased permeability (Li, et al., 2022; McLean, et al., 2016; Flores-Armenta & Alcalá, 2012).
4. **Shearing**: it involves injecting fluid at pressures lower than the minimum horizontal stress (Shmin) to reactivate or induce slip along existing fractures. This process does not create new fractures but rather reopens and allows movement along pre-existing fractures or faults (Mukuhira, et al., 2023). This technique is commonly used in scenarios where existing natural fractures can be reactivated to enhance fluid flow without creating new fractures (Bijay, et al., 2023; Luo, et al., 2023).
5. **Hydro-shearing**: it involves injecting fluid at pressures greater than the minimum horizontal stress (Shmin) to cause slip along existing fractures and potentially create new fractures (Li, et al., 2022). This process combines elements of both shearing and hydraulic fracturing, as it can activate existing fractures and also initiate new fractures. This technique can be used to reactivate existing fractures and create new fractures (Bijay & Ghazanfari, 2021).
6. **Deflagration (high energy gas fracturing)**: the near-wellbore formation damage is shattered and new small fractures are created using an intense gas wave generated by the vaporizing propellant, known as deflagration (Jiang, et al., 2023; McLean, et al., 2016; Aqui & Zarrouk, 2011).
7. **High-rate pulsed injection**: it involves the injection of fluid into the wellbore in rapid, high-pressure pulses rather than a continuous flow (Drakos & Akerley, 2015). The pulsed nature of the injection generates a series of pressure waves that propagate through the rock formation, creating or reactivating fractures (Zang, et al., 2024).
8. **Electric**: it employs electric current to stimulate the well, producing either electrothermal or electrodynamic effects. The electrothermal effect occurs in the near-wellbore zone, where heating with infrared, high frequency, or microwaves takes place. The electrodynamic effect cleans the bottom hole formation zone of clay particles, thereby restoring or enhancing the well's permeability (Ezzat, et al., 2022).
9. **Acoustic**: it utilizes a basic ultrasonic wave source, similar to those commonly used in everyday applications like descaling potable water filters or dental equipment. In geothermal applications, the

interaction between the acoustic field and the saturated porous rock can alter permeability or remove plugging materials (Covell, 2016).

Table 9: In-Field or Near-Field EGS Project Experience in the U.S. Low-Medium Temperature Geothermal Fields.

As the development of EGS continues to evolve, it is crucial to understand the practical applications and outcomes of various stimulation techniques in real-world scenarios. The following case studies provide insight into the in-field and near-field EGS project experiences within the U.S., particularly focusing on optimizing low-medium temperature fields, as summarized in Table 9. While the results summarized in Table 6 show that out of the three projects (Desert Peak, Brady's, and Raft River), only Raft River successfully achieved commercial permeability post-stimulation, all projects demonstrated significant improvements in injectivity and permeability. These outcomes highlight the potential for EGS techniques to optimize low-medium temperature resources and underscore the importance of the lessons learned from each project. The experiences gained from these projects offer valuable guidance for future EGS projects in both the low-medium and the high temperature geothermal fields.

3.3.1 Case Study #1: Desert Peak, Nevada (Hydraulic Stimulation)

Well 27-15 initially exhibited limited potential as a producer or injector, but its proximity to infrastructure, favorable bottomhole temperatures (180-195ºC), and demonstrated hydraulic connectivity to nearby injection wells made it a promising candidate for an EGS project (Akerley, et al., 2021). Located in the Desert Peak Geothermal Field in western Nevada and operated by Ormat Nevada Inc., this project received financial support from the U.S. Department of Energy's Geothermal Technologies Program (U.S. DOE, 2019). A multi-disciplinary team conducted a thorough investigation and identified the lower Tertiary Rhyolite unit (914-1,003 m deep) as the primary target for stimulation, as shown in Figure 37. The objectives of the EGS project were (Chabora, et al., 2012):

1. Develop and implement a site-specific EGS stimulation plan that showcases practical, cost-effective, and transferable techniques for other project settings.
2. Enhance hydraulic communication between well 27-15 and the existing production field to commercially acceptable levels.
3. Demonstrate the overall power plant production benefits achieved through this project.

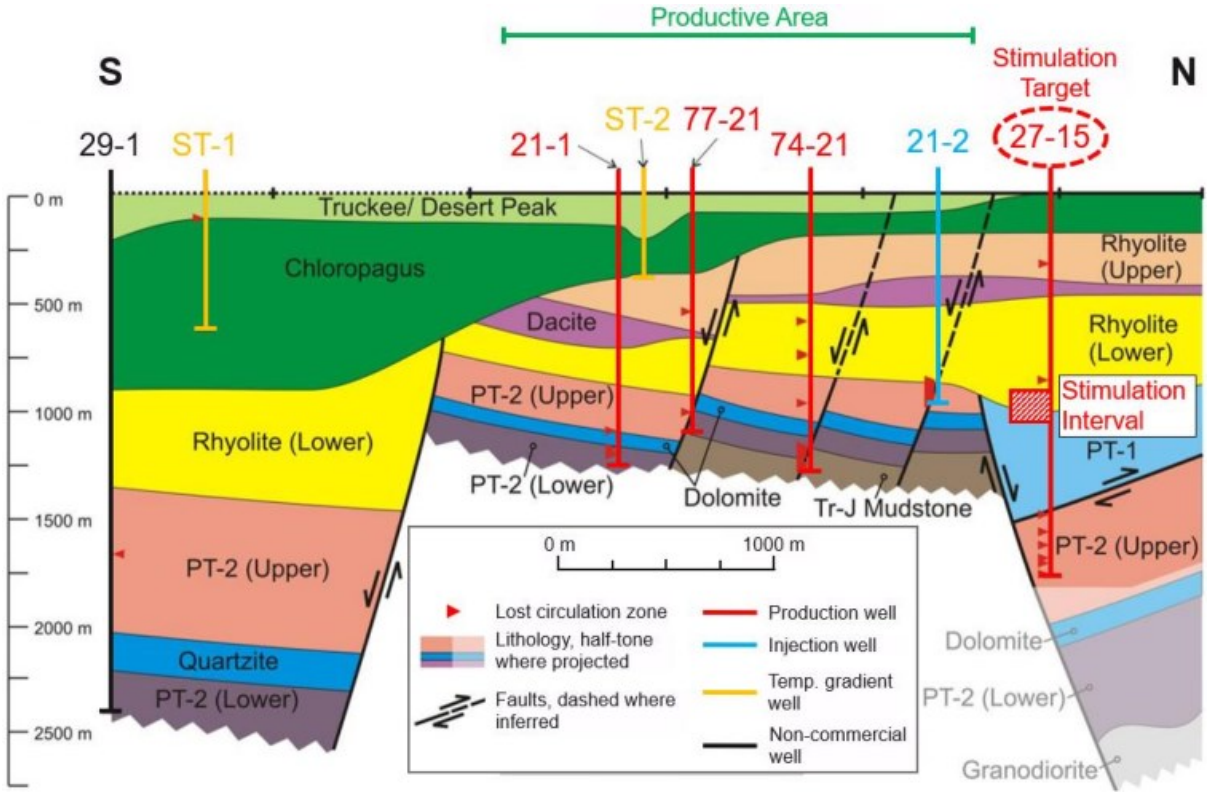

Figure 37: South-North Geological Cross Section Through Desert Peak Geothermal Field, Nevada and Well 27-15 as the Stimulation Target (Chabora, et al., 2012).

The well stimulation at Desert Peak involved a comprehensive multi-phase approach to enhance injectivity and permeability. This approach included shearing stimulation, matrix acidizing stimulation, and hydraulic fracturing, each contributing to the overall improvement of the well's performance. The operation and result of each stimulation stage (Akerley, et al., 2021; Chabora, et al., 2012) is summarized as follows:

1. **Stage #1 (shearing)**: this phase aimed to enhance permeability by promoting shear displacement along pre-existing fractures. This method involved low-pressure injection at fluid pressures below the least horizontal principal stress (Shmin). The initial injection pressures started at 17.2 bar (250 psi) and were incrementally increased by 6.9 bar (100 psi), reaching a maximum of 44.8 bar (650 psi). Each injection step lasted approximately one week, with pressure fall-off observations and Pressure-Temperature-Spinner (PTS) surveys conducted between steps. The results indicated a significant increase in injectivity, achieving approximately 0.79 t/h/bar (0.24 gpm/psi). However, this value was still below the threshold for commercial viability. The stimulation progress was primarily realized early in the process, suggesting that a shorter duration with higher pressures might have been equally effective and more efficient in terms of operational time and resources.
2. **Stage #2 (matrix acidizing)**: following the shearing phase, the chemical stimulation aimed to dissolve mineral precipitates and open partially sealed fractures to enhance injectivity. This phase consisted of a two-stage chemical treatment. In the first stage, 45,000 to 60,000 gallons of a 2-4% chelating acidic sodium sulfophthalate (SPA) solution were injected, followed by water displacement and a 48-hour reaction period. The second stage involved the injection of 12,000 gallons of a mixture of 12% hydrochloric acid (HCl) and 3% hydrofluoric acid (HF), followed by water displacement. The results showed temporary increases in injectivity to about 0.25 t/h/bar (0.076 gpm/psi), but the process led to wellbore instability. A subsequent wireline survey revealed that debris had filled the lower part of the well, necessitating a wellbore clean-out. This phase highlighted the need for controlled hydraulic fracturing to achieve more substantial and lasting permeability enhancements.
3. **Stage #3 (hydraulic fracturing)**: this final phase aimed to achieve substantial permeability improvements by injecting at high pressures and rates. This phase included two sub-phases: a medium flow-rate phase and a high flow-rate phase, as shown in Figure 38. During the medium flow-rate phase, the injection rate was fixed at 500 gpm using spent brine from the power plant. This resulted in an increase in injectivity to 1.86 t/h/bar (0.56 gpm/psi) and the detection of 33 microearthquake (MEQ) events (0.1-0.76 Mw). The high flow-rate phase saw the injection rate increase from 575 gpm to 725 gpm, achieving a maximum injectivity of 2.61 t/h/bar (0.79 gpm/psi), which is equivalent to a 60-fold

increase in injectivity from the pre-stimulation level, thus significantly enhancing the hydraulic connectivity between wells. The permanent gains in permeability were attributed to self-propping shear failure. Additionally, during the high injection rate phase, the gross output of the Desert Peak power plant temporarily increased by approximately 1.5 MW.

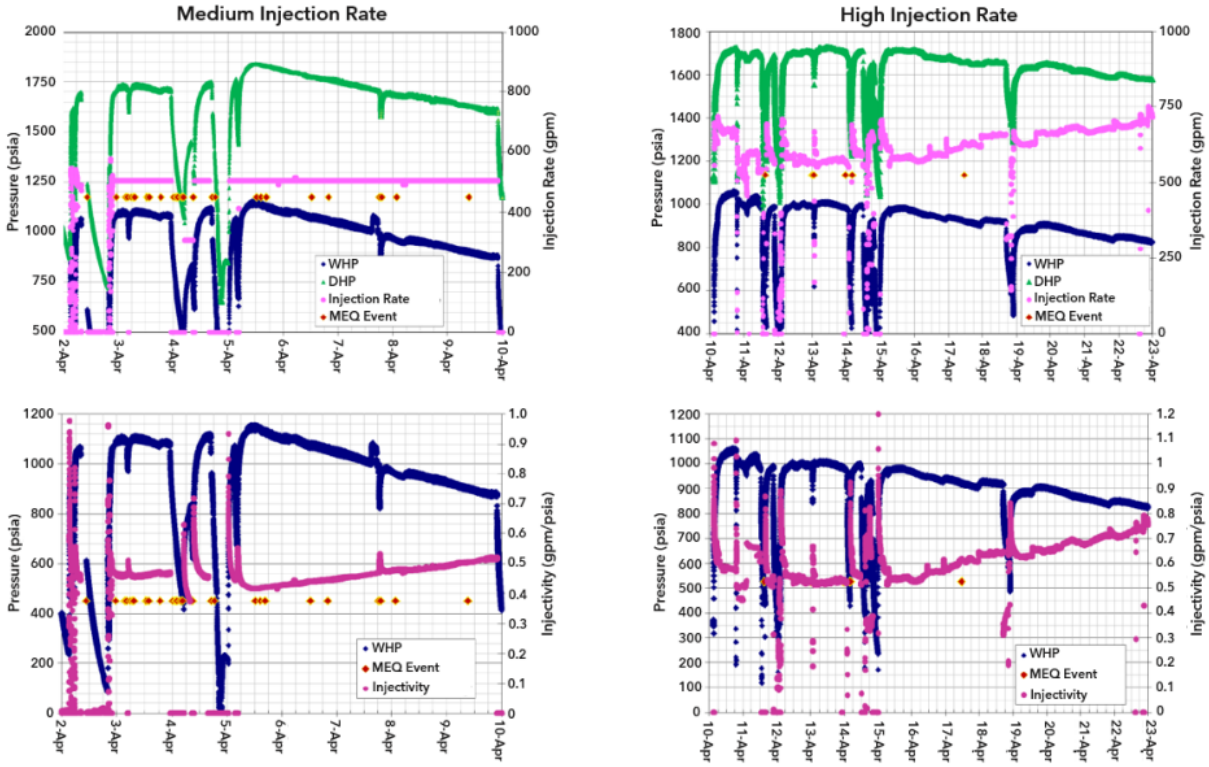

Figure 38: Measured Wellhead Pressure, Downhole Pressure, Injection Rate, Injectivity, and MEQ Events During the Medium (Left) and High (Right) Hydraulic Stimulation Injection Rates in the Desert Peak, Nevada (Chabora, et al., 2012).

These comprehensive well stimulation operations at Desert Peak collectively led to significant improvements in well injectivity and reservoir connectivity. Unfortunately, the post-stimulation permeability still fell short of the commercial permeability threshold of 5 t/h/bar. Nevertheles, the well stimulation at Desert Peak provided valuable insights and paved the way for future enhancements in geothermal stimulation projects.

3.3.2 Case Study #2: Brady's Hot Springs, Nevada (Shearing, Hydro-Shearing, and Pulsed Stimulation)

The Brady's geothermal field, situated approximately 50 kilometers northeast of Reno, Nevada, within the Hot Springs Mountains and Carson Sink, features a complex geological setting characterized by a Mesozoic metamorphic and plutonic basement overlaid with Cenozoic volcanic and sedimentary sequences. The primary geothermal reservoir, located between 600 and 1500 meters below the surface, lies within Oligocene ash-flow tuffs and Miocene lava flows (Akerley, et al., 2021). The Brady's Fault Zone, a prominent NNE-striking fault system, plays a crucial role in the field's geothermal activity, facilitating hydrothermal circulation. Well 15-12 ST1, which encountered high temperatures but low permeability, was selected for stimulation to enhance its hydraulic connectivity to more productive areas of the reservoir (Drakos & Akerley, 2015).

The 15-12 ST-1 well stimulation at Brady's involved a comprehensive multi-phase approach to enhance injectivity and permeability. This approach included shearing stimulation, hydro-shearing stimulation, and pulsed injection, each contributing to the overall improvement of the well's performance. The operation and result of each stimulation stage (Akerley, et al., 2021; Drakos & Akerley, 2015) is summarized as follows:

1. **Stage #1 (shearing)**: during this stimulation stage, the average injection rate was approximately 378 gpm, with an average injectivity of around 0.79 t/h/bar (0.24 gpm/psi). No microearthquakes (MEQs) were detected during this stage. The fall-off analysis showed that the closure pressure was uncertain, estimated at about 1058 psia, and the flow regime after closure was not certain.
2. **Stage #2 (hydro-shearing)**: during this stage, the maximum injection rate reached 650 gpm, with an average injectivity of approximately 1.48 t/h/bar (0.45 gpm/psi). Similar to Stage #1, no MEQs were detected. The fall-off analysis indicated an instantaneous shut-in pressure (ISIP) of around 935 psia

WHP. There were signs of pressure-dependent leak-off, which could be due to natural fractures or dilated fissures. The after-closure response suggested a radial flow pattern.

3. **Stage #3 (pulsed injection)**: this stage involved a maximum injection rate of about 1,100 gpm, with an average injectivity of around 1.75 t/h/bar (0.53 gpm/psi). As a result, an injectivity increase of 11-fold from the pre-stimulation level at 0.15 t/h/bar was achieved yet the commercial permeability threshold of 5 t/h/bar had not been met. Nevertheless, no MEQs were detected during this stage either. The fall-off analysis revealed a closure pressure of approximately 890 psia WHP, which was close to the minimum horizontal stress from the step-rate test. Similar to Stage #2, there were indications of pressure-dependent leak-off, likely from natural fractures or dilated fissures, and the after-closure response indicated radial flow.

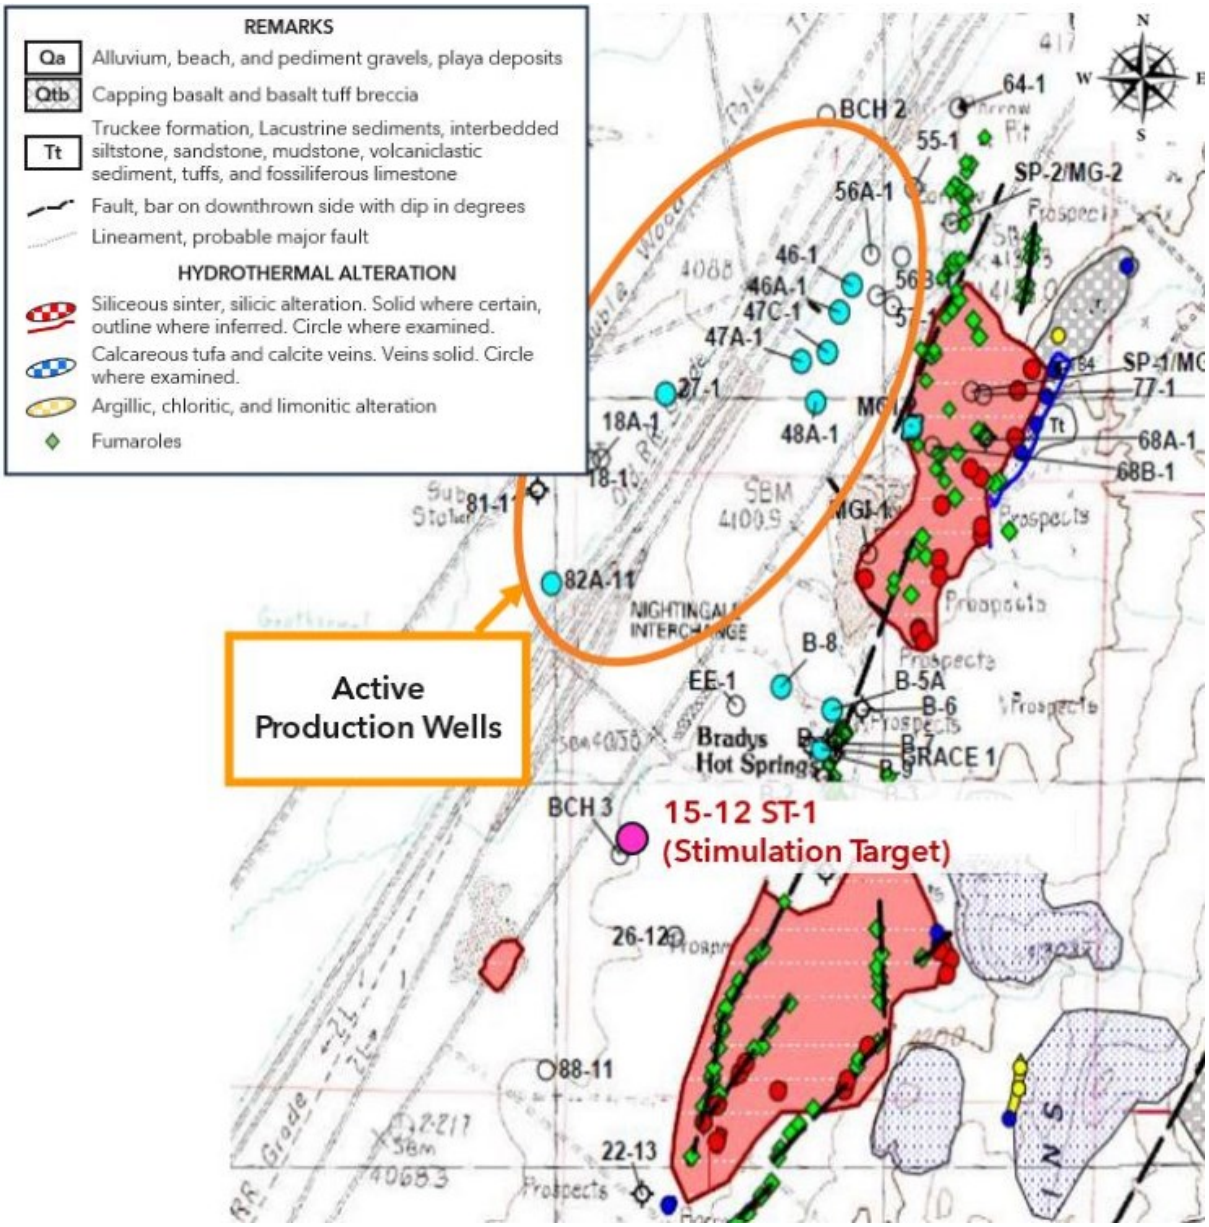

Figure 39: The Location of Well 15-12 ST-1 as the Stimulation Target in Brady's, Nevada (Drakos & Akerley, 2015).

3.3.3 Case Study #3: Raft River, Idaho (Thermal and Hydraulic Stimulation)

The Raft River geothermal field in Idaho is situated in a structurally complex terrain characterized by Cenozoic extension, Tertiary volcanism, and Precambrian rocks forming a metamorphic core complex. The field's geological setting includes approximately 1,524 meters of discontinuous Quaternary and Tertiary volcaniclastic and volcanic rocks overlying Precambrian basement rocks, primarily consisting of schist, quartzite, and quartz monzonite. The target formation for stimulation is the Elba Quartzite in the Precambrian basement, where fluid exits through a fracture zone at a depth of approximately 1,567 meters TVD. Well RRG-9 ST1 was selected for

stimulation due to its geologically strategic location within the Raft River field to target the Elba Quartzite formation effectively. From 2012 to 2014, this well underwent multiple stimulation campaigns, including hydraulic and thermal fracturing, with the main goals of developing and demonstrating practical, cost-effective EGS techniques and improving hydraulic communication between the well and the primary reservoir fracture networks. The location of RRG-9 ST1 in the field is shown in Figure 40.

The RRG-9 ST1 well stimulation at Raft River involved a combination of thermal and hydraulic fracturing techniques to enhance the permeability and injectivity of the geothermal reservoir. The operation and result of each stimulation stage (Xing, et al., 2024; Bradford, et al., 2015) is summarized as follows with the injectivity improvements is shown in Figure 41:

1. **Stage #1 (thermal fracturing)**: it began in June 2013 with low-rate stimulation using injectate from the geothermal plant at an average rate of 9.8 t/h (163 gpm), 34°C, and a wellhead pressure of 19.3 bar. This phase continued until late August 2013, at which point wellhead pressures were increased to 37.2 bar at an average rate of 32 t/h (534 Lpm). From September 12th to September 24th, 2013, cold water with an average surface temperature of approximately 12°C was injected to maximize thermal stress. This phase was followed by the resumption of warmer plant water injection on September 25th, 2013, which continued into 2014. The thermal fracturing managed to increase the well's injectivity from initially 0.49 t/h/bar (0.08 Lpm/kPa) to 1.5 t/h/bar (0.25 Lpm/kPa), equivalent to a 3-fold increase in injectivity.
2. **Stage #2 (hydraulic fracturing)**: it was conducted to further enhance permeability through high-pressure injection. This phase began in April 2014 by injecting cold water at 45°C at the rate of 71.76 t/h (1,196 Lpm) anf wellhead pressures of 17.93 bar. Furthermore, more than 20 microearthquakes (> 1 Mw) were recorded during the hydraulic fracturing phase. The modified Hall plot analysis showed that the hydraulic fracturing successfully increased fracture conductivity and/or a decreasing skin factor around the wellbore with the injectivity index rising significantly to 5.52 t/h/bara (0.9 Lpm/kPa) by December 2014, equivalent to an 11-fold increase in injectivity from the pre-stimulation level. The post-stimulation II has surpassed the commercial permeability threshold of 5 t/h/bar, hence can be utilized as a commercial production well.

Despite Indonesia not having optimally developed low-medium temperature resources like those in the U.S., the country has notable experience with EGS well stimulations in high-temperature geothermal fields. The application of EGS techniques s in Indonesia has been primarily focused on optimizing the productivity of these high-temperature resources. As summarized in Table 10, various well EGS stimulation techniques such as thermal fracturing and hydraulic fracturing have been employed with varying degrees of success across different geothermal fields. These efforts highlight Indonesia's potential to enhance geothermal production through EGS technologies, which can lay the foundational knowledge and provide lessons learned for future EGS applications in low-medium temperature geothermal fields.

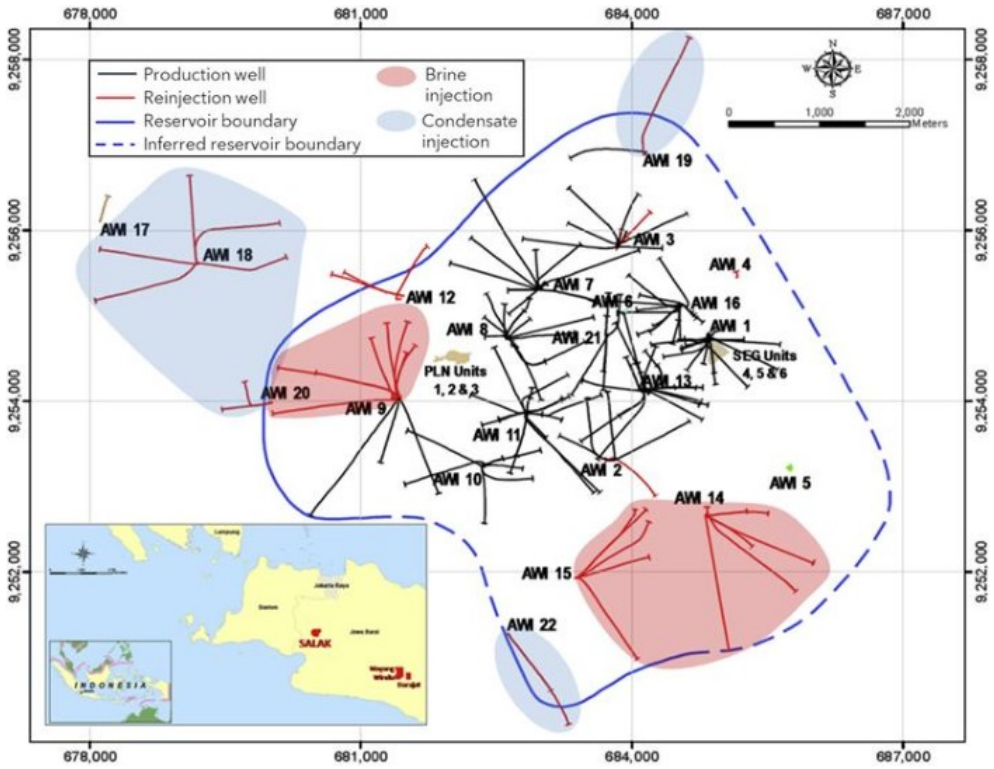

Figure 42: Well Trajectory at the Salak Geothermal Field, West Java (Golla, et al., 2020).

3.3.4 Indonesia's Experience #1: Salak, West Java (Thermal and Hydraulic Stimulation)

The Salak geothermal field is characterized by a high-temperature, water-dominated reservoir with temperatures exceeding 325°C and low-to-moderate non-condensable gas content (Stimac, et al., 2008). The reservoir is divided into four production cells (West, Central, East, and Far East) based on pressure measurements and the distribution of permeable zones identified in wells (Golla, et al., 2020). The primary fluid flow is controlled by northeast-trending surface and subsurface structures, contributing to the geothermal system's efficiency. Since the start of commercial production in 1994, the field has faced challenges such as injection breakthrough, wellbore scaling, and the influx of non-condensable gases, necessitating a series of well stimulation programs in 2005 to improve injectivity and sustain production levels (Pasikki, et al., 2010). Figure 42 shows the well trajectory within and around the reservoir boundary including the brine and condensate injection areas at the Salak geothermal field.

Two EGS wells stimulation techniques were impemented at the Salak geothermal field in 2005, namely thermal fracturing and hydraulic fracturing. The thermal fracturing was performed in addition to the subsequent bullhead acidizing at the AWI 11-15 and AWI 11-6OH wells. Meanwhile, the hydraulic fracturing was performed at the AWI 18-1 and AWI 20-1 wells. The II changes from those four wells due to the stimulations are displayed in Figure 43. Furthermore, the well stimulation operation and results at those wells (Pasikki, et al., 2010) are summarized as follows:

1. **AWI 11-5**: the well is first thermally stimulated by involving alternating injections of hot brine (165oC or 330°F) and cold condensate (38oC pr 100°F) at flow rates up to 892 t/h (2000 kph) for hot brine and 281 t/h (630 kph) for condensate. This was followed by a bullhead acid treatment using hydrochloric acid to address formation damage yet it failed to improve permeability due to low acid concentration and poor acid placement. The II increased from 3.95 t/h/bar (0.6 kph/psi) to 14.48 t/h/bar (2.2 kph/psi) over several cycles, indicating improved permeability. The injectivity improvement thus had met the commercial permeability threshold and the well was potential to be used as a production well.
2. **AWI 11-6OH**: similar to AWI 11-5, AWI 11-6OH first underwent thermal stimulation using hot brine and cold condensate. The II increased from 7.22 t/h/bar (1.1 kph/psi) to 14.45 t/h/bar (2.2 kph/psi) This process was followed by a slow acid stimulation (SAS) involving acidified cold water (HCl mixed with condensate) and later acidified hot water but it did not successfully improve the permeability further due to poor acid placement. Additionally, corrosion issues encountered during the acid treatment led to an early termination of the stimulation program.
3. **AWI 18-1**: the hydraulic stimulation at AWI 18-1 was conducted in two phases. The first phase involved continuous water injection using gravitational and positive displacement pumps, gradually increasing the injection rates. The second phase employed triplex pumps and a pressure cycling injection method. The injectivity significantly improved, with the II increasing by 180% from 2.96 t/h/bar (0.45 kph/psi) to 7.953 t/h/bar (1.21 kph/psi). Injection capacity increased tenfold, indicating successful stimulation and enhanced connectivity to fracture networks.
4. **AWI 20-1**: this multilateral well underwent hydraulic stimulation similar to AWI 18-1. Initial injectivity tests revealed low injectivities, leading to continuous and cycling injection operations with increasing condensate water rates. The post-stimulation II of 4.64 t/h/bar (0.7 kph/psi) was instead lower than the initial II of 5.2 t/h/bar (0.79 kph/psi). However, the injection flow rate at a given WHP was increased. Therefore, the improved injection performance was interpreted to be caused by the newly created connectivity to lower pressure fracture networks rather than enhanced permeability.

3.3.5 Indonesia's Experience #2: Wayang Windu, West Java (Hydraulic Stimulation)

The Wayang Windu geothermal field is characterized by a complex geological setting associated with the Sunda Volcanic Arc. The field features a transitional geothermal system with vapor-dominated and liquid-dominated zones, primarily hosted in andesitic volcanic rocks intruded by microdiorite-porphyry dikes (Mulyadi & Ashat, 2011). The northern part of the field, which provides over 90% of the steam production, consists of a vapor-dominated two-phase zone that overlies a deep liquid reservoir, as shown in Figure 44. In 2007, hydraulic fracturing was initiated as a well stimulation technique to address declining well productivity. This decision was informed by a micro earthquake (MEQ) survey conducted from May to July 2005, which provided detailed insights into the stress orientation and distribution within the field. The MEQ data indicated potential for hydraulic fracturing to enhance permeability and steam production by inducing fractures and improving fluid flow within the reservoir (Pizzocolo, et al., 2021; Mulyadi, 2010).

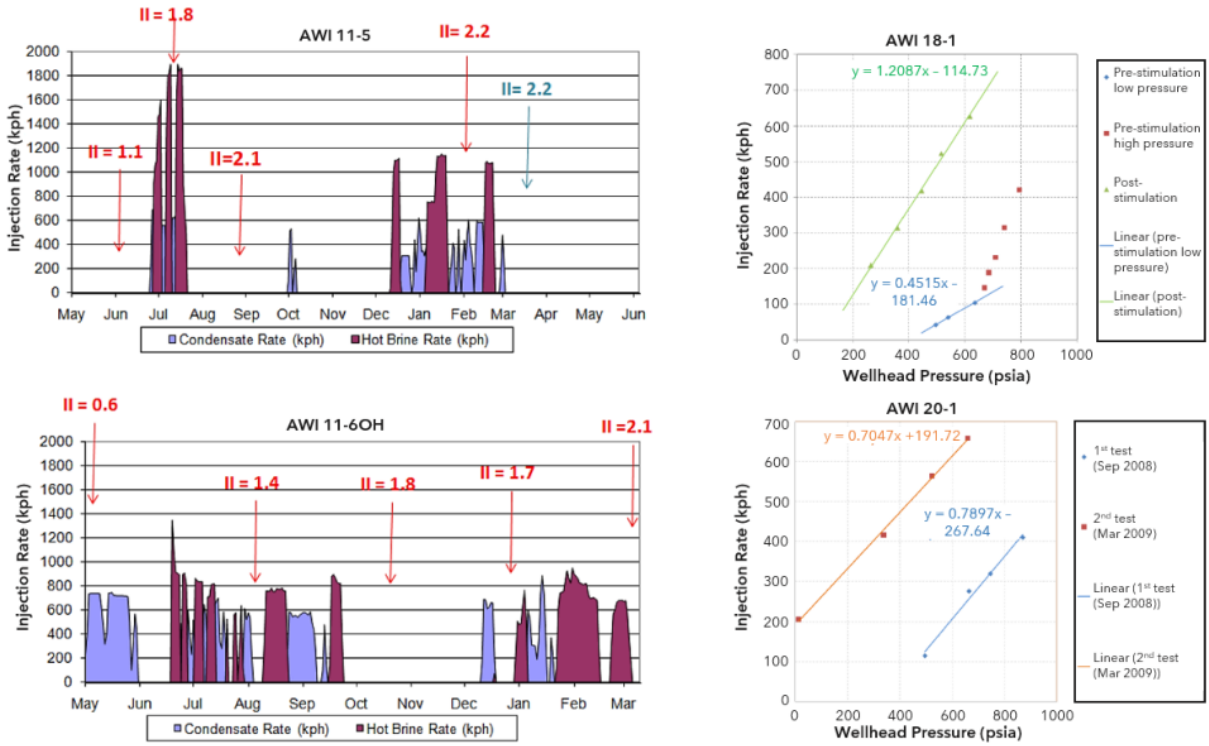

Figure 43: Injectivity Evolution During Thermal Fracturing (Left) and Hydraulic Fracturing (Right) at the Salak Geothermal Field, West Java (Pasikki, et al., 2010).

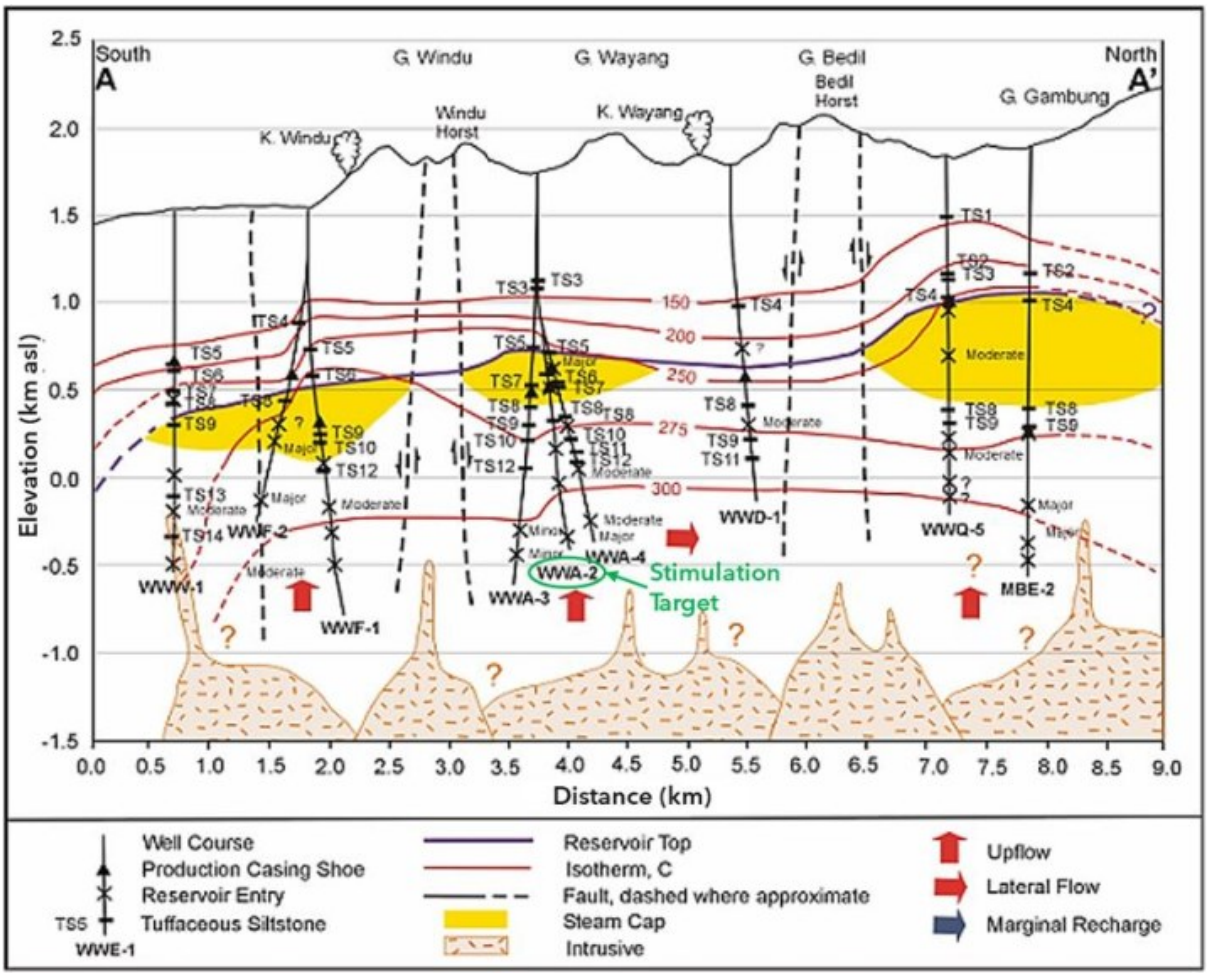

Figure 44: Conceptual Model of Wayang Windu Geothermal Field, West Java (Mulyadi & Ashat, 2011).

Four wells at Wayang Windu, namely WWQ-2, WWQ-3, WWQ-4, and WWA-2, were subjected to hydraulic fracturing techniques. The operations and results obtained from the hydraulic fracturing process applied to these wells, with a focus on their stimulation duration, initial and post-stimulation production, and specific observations (Mulyadi, 2010) are summarized as follows:

1. **WWQ-2**: hydraulic fracturing was performed at the WWQ-2 well with a stimulation duration of 60 hours. The bottomhole pressure (BHP) decreased from around 60 barg to a stable value after 3.5 hours, with fracture closure pressure observed at 47.6 barg during the fall-off test, as shown in Figure 45. The initial steam production was 14.4 t/h, which increased to 28.9 t/h post-stimulation, indicating a significant improvement in production and permeability. The well demonstrated an open fracture, which contributed to the increased productivity.
2. **WWQ-3**: the fracture closure pressure was noted at 51.2 barg after 1 hour during the fall-off test, as shown in Figure 45. Despite the presence of an open fracture, there was no observable improvement in production. This was attributed to the lower permeability of the well, which hindered the effectiveness of the hydraulic fracturing process.
3. **WWQ-4**: hydraulic fracturing failed to create an open fracture, and there were no improvements in production. The lack of fracture creation was due to the inability of the maximum injection rate to exceed the rock stress magnitude required for fracture initiation.
4. **WWA-2**: the hydraulic fracturing involved a stimulation duration of 22 hours. The initial steam production was 14.4 t/h, which increased to 21.8 t/h post-stimulation. The bottomhole pressure profile indicated successful fracture creation with improved permeability and production. The well showed an open fracture and demonstrated significant improvement in both production and permeability, similar to WWQ-2.

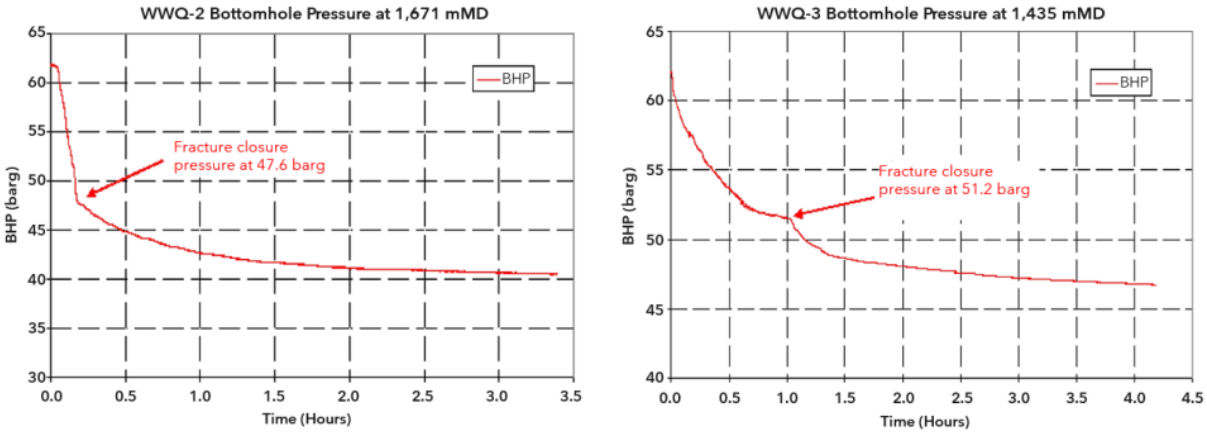

Figure 45: Bottomhole Pressure During the Fall-Off Test at WWQ-2 (Left) and WWQ-3 (Right) After Hydraulic Fracturing (Mulyadi, 2010).

The hydraulic fracturing operations at the Wayang Windu field yielded mixed results. Wells WWQ-2 and WWA-2 showed significant improvements in production and permeability due to the successful creation of open fractures. The fracture closure pressures observed at these wells were within the expected range, leading to enhanced steam production post-stimulation. However, wells WWQ-3 and WWQ-4 did not exhibit similar improvements. WWQ-3, despite having an open fracture, did not see production gains due to its lower permeability. WWQ-4 failed to create an open fracture, resulting in no improvement in production.

The study by (Pizzocolo, et al., 2021) further corroborates these mixed results by highlighting the technical and geological challenges associated with hydraulic fracturing in the Wayang Windu field. The long perforated liner and the dense natural fracture network in the wells pose significant obstacles to effective hydraulic fracturing. The study concludes that the Wayang Windu field is not suitable for hydraulic fracturing due to the following reasons:

1. **Long perforated liner**: the wells in the Wayang Windu field have long perforated liners, making it difficult to isolate short sections necessary for fracture location optimizations..
2. **High fluid leakoff rates**: the dense natural fracture network in the geothermal reservoir leads to high fluid leakoff rates, reducing the effectiveness of the hydraulic fracturing treatment. Hydraulic fracturing in Wayang Windu is also economically unviable due to he large volumes of fracture fluids and proppant required due to the high leakoff rates.
3. **Wellbore integrity issue**: significant variations in stress along the perforated sections increase the risk of wellbore integrity issues, such as plastic buckling and shear failure. Moreover, the absence of a

cemented annulus in the wells increases the likelihood of compromising wellbore integrity during hydraulic fracturing operations.

4. **Undesired fracture propagation pattern**: the induced fractures tend to propagate vertically to the clay cap zone, failing to penetrate the deeper parts of the reservoir that are crucial for improving connectivity with pre-existing fractures.

These factors compromise the economic feasibility and technical effectiveness of hydraulic fracturing, suggesting that alternative stimulation techniques, such as thermal and acid stimulations, may be more appropriate for this geothermal field.

3.3.6 Indonesia's Experience #3: Patuha, West Java (Hydraulic Stimulation)

The Patuha geothermal field is a volcano-hosted vapor-dominated geothermal system located in West Java, Indonesia, with high-temperature reservoirs ranging from 220°C to 260°C. The Patuha field's geological setting is influenced by the nearby volcanic activity of Mt. Patuha and other local volcanic structures such as Mt. Urug and Crater Putih. Surface manifestations like fumaroles and hot springs are indicative of the geothermal activity beneath (Ashat, et al., 2024). In the field, a geothermal power plant with an installed capacity of 55 MW was commissioned in 2014. However, the field has faced challenges such as declining steam production, prompting the need for well stimulation techniques like hydraulic fracturing to enhance permeability and sustain energy output (Lee, et al., 2023). Therefore, in 2022, a hydraulic stimulation was attempted at PPL-6, which eventually improved the productivity of the two nearby wells, namely PPL-2 and PPL-4, as shown in Figure 46.

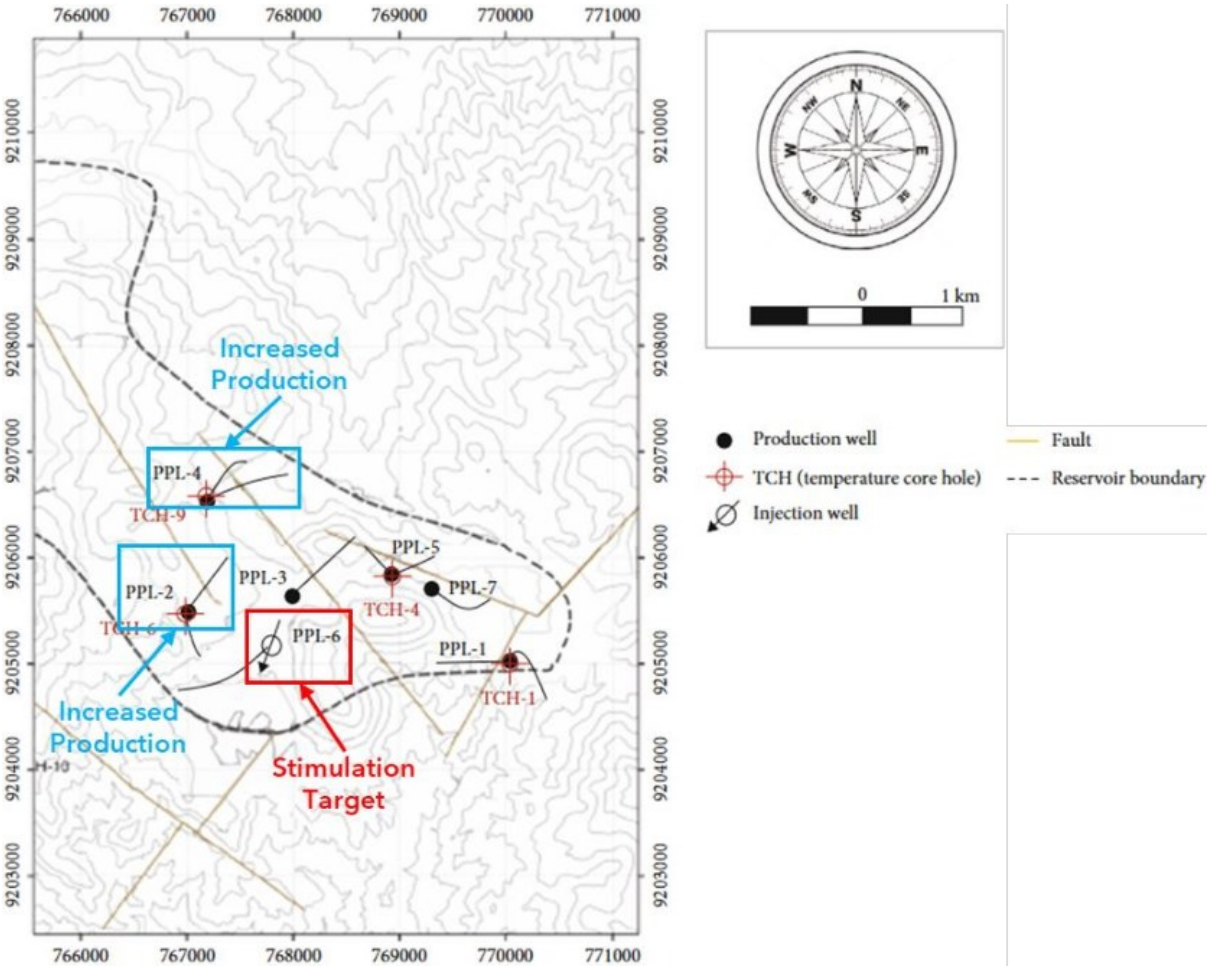

Figure 46: Well Trajectory and the Stimulated Wells at the Patuha Geothermal Field, West Java (Lee, et al., 2023).

The hydraulic fracturing process at PPL-6 involved the injection of 40,000 barrels of water through three distinct injection rate stages: step-up, plateau, and step-down. This operation was carefully monitored to assess its impact on reservoir pressure, temperature, and overall steam productivity. The measured injection rate and bottomhole pressure during each injection stage is shown in Figure 47. Furthermore, the observed injection behavior during each injections stage (Lee, et al., 2023) is summarized as follows:

1. **Step-up injection rate**: the water injection rate was gradually increased over a period of approximately 3.3 hours. The injection began at 3.18 m³/min (20 bbl/min) for the first 55 minutes, increased to 3.66 m³/min (23 bbl/min) for the next 90 minutes, and then to 4.93 m³/min (31 bbl/min) for the final 55 minutes. This phase was designed to carefully raise the bottom hole pressure and initiate fracture opening. The pressure response showed an initial sharp increase, indicating good permeability in the well, which accepted the injected water efficiently.
2. **Plateau constant rate injection**: water was injected at a constant rate of 4.13 m³/min (26 bbl/min) for 15 hours. During this period, the bottom hole pressure stabilized around 5.52 bar, with minor fluctuations, suggesting the reservoir's capacity to handle the sustained injection without significant disruption. The temperature profile indicated a slight decrease due to the cooler injected water, remaining below the saturation temperature, which was ideal for maintaining the liquid phase of the reservoir fluids.
3. **Step-down injection rate**: it involved gradually reducing the injection rate over 3.7 hours. The rates were decreased to 3.66 m³/min, 3.18 m³/min, 2.39 m³/min, 1.59 m³/min, and finally to 0.80 m³/min before stopping. This phase aimed to control the reactivation of steam inflow and prevent premature well reactivation. During this stage, fluctuations in pressure and temperature indicated phase changes as the steam and water mixed. The process required careful management to maintain stability and prevent excessive steam flow during the reduction of injection rates.

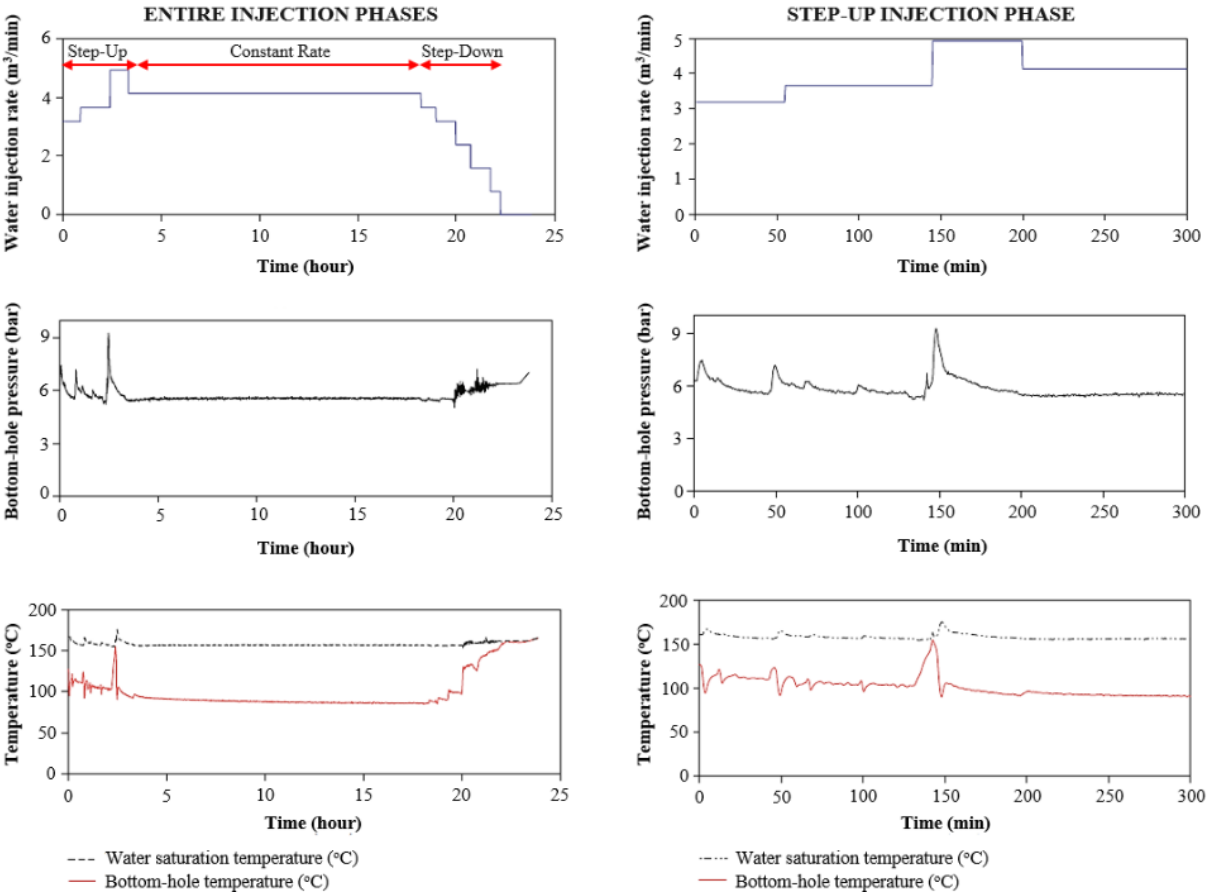

Figure 47: Measured Injection Rate and Bottomhole Pressure During the Three Injection Phases (Left) and During the Highlighted Step-Up Injection Phase (Right) During the PPL-6 Hydraulic Fracturing (Lee, et al., 2023).

The hydraulic stimulation at PPL-06 successfully increased the reservoir's permeability and steam production. The Hall plot analysis confirmed the formation was stimulated, with fractures opening after injecting approximately 4,000 barrels of water. This was evident as the Hall derivative tracked below the Hall integral, indicating reduced flow restriction, as shown in Figure 48. Furthermore, an increase in steam production was observed in the wells near to PPL-6, with PPL-2 showing a 9.6% increase from 46.7 t/h to 51.5 t/h and PPL-4 an 11.4% increase from 11.9 t/h to 13.2 t/h, as shown in Figure 48. Additionally, the overall power generation capacity of the Patuha field rose from 50.0 MWe to 56.3 MWe post-stimulation. This improvement was proportional to the volume of water injected, highlighting the efficiency of hydraulic stimulation in enhancing steam productivity in a vapor-dominated geothermalreservoir. However, the study emphasized the need for long-

term water injection to confirm the sustainability of these improvement effects and suggested further experimental analyses to optimize hydraulic fracturing designs (Lee, et al., 2023).

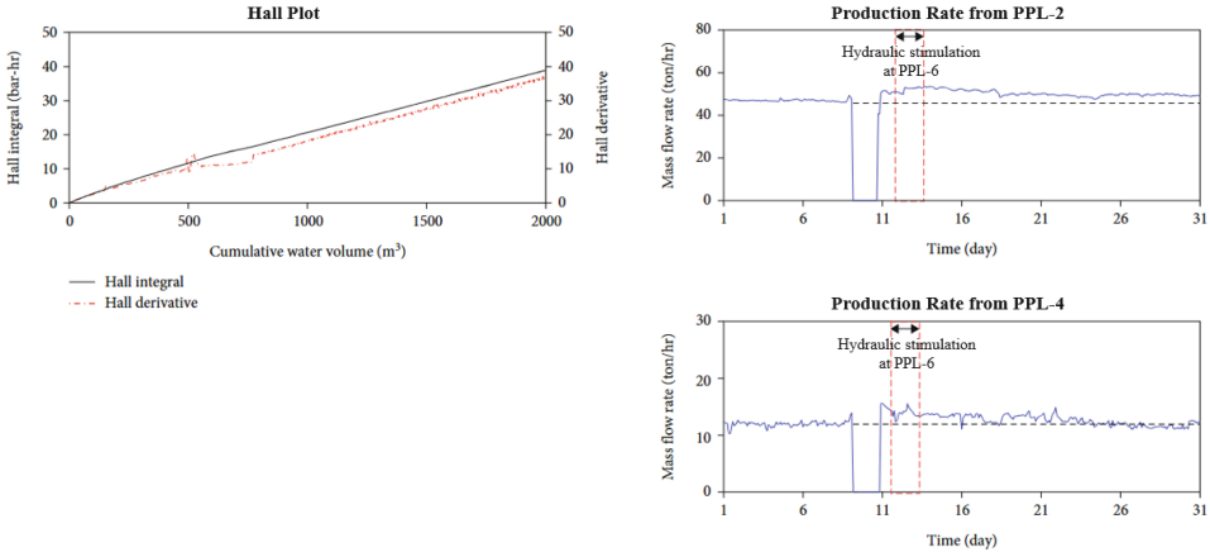

Figure 48: The Hall Plot (Left) and Production Rates at PPL-2 and PPL-4 (Right) In Response to the Hydraulic Stimulation at PPL-6 (Lee, et al., 2023).

Finally, the application of EGS in Indonesia's high-temperature geothermal fields, such as Salak, Wayang Windu, and Patuha, has provided valuable insights that can guide the optimization of low-medium temperature geothermal resources. The following lessons learned highlight key aspects that have proven crucial for the successful implementation of EGS technologies:

1. **Importance of selecting the appropriate stimulation technique**: the success of thermal stimulation in two wells and hydraulic stimulation in two other wells at the Salak field, combined with the increased steam production from hydraulic fracturing at Patuha, highlights the necessity of selecting the appropriate stimulation technique. However, the mixed results at Wayang Windu reveal that hydraulic stimulation may not be suitable for all fields due to factors such as geological setting, stress orientations, and fracture networks. These factors must be carefully evaluated to ensure the optimal selection of stimulation methods.
2. **Importance of detailed geological understanding**: the mixed results at Wayang Windu emphasize the necessity of a thorough geological understanding before applying hydraulic fracturing. Knowledge of stress orientations, fracture networks, and reservoir characteristics is crucial to predict the success of stimulation efforts accurately.
3. **Monitoring and adaptive management during stimulation operations**: continuous monitoring and adaptive management during stimulation operations, as practiced in all three fields, are essential to respond to real-time data and optimize stimulation parameters for better results.
4. **Importance of establishing a protocol to address EGS-induced seismicity**: Indonesia is highly tectonically active due to its location at the convergence of several major tectonic plates, including the Indo-Australian, Eurasian, Pacific plates. This positioning places Indonesia within both the Pacific Ring of Fire and the Alpide belt, leading to frequent and intense seismic and volcanic activity (Lu, et al., 2023; Hutchings & Mooney, 2021). The subduction of tectonic plates in this region generates significant volcanic and seismic activity, making Indonesia home to numerous active volcanoes. This geological setting necessitates the establishment of a protocol to address induced seismicity in EGS projects in Indonesia. The U.S. Department of Energy (DOE) launched an EGS-Induced Seismicity Protocol in 2012 to manage seismic risks and ensure public safety during EGS projects (U.S. DOE, 2012), driven by incidents like the magnitude 3.4 earthquake in Basel, Switzerland, in 2007 (Boyet, et al., 2023; Viganò, et al., 2021). (Kim, et al., 2018) proposed an EGS-induced seismicity protocol for the Pohang EGS project, Korea, by adopting U.S. DOE's protocol in response to the seismic events occurred in Pohang. The region is tectonically active, partly due to its proximity to the Yangsan fault, and there were more than 30 earthquakes recorded between 2005 and 2017 in Pohang (Kim, et al., 2018). These seismic events are interpreted to be caused by either natural, triggered, or EGS-induced mechanism (McGarr & Majer, 2023; Chang & Yoon, 2021). Similarly, Indonesia's EGS-induced seismicity protocol can be assembled by adopting the U.S. DOE's protocol and adjusting it into Indonesia's specific conditions. The U.S. DOE's procotol is comprised of seven steps summarized in Table 11.

These lessons emphasize the importance of carefully selecting and managing EGS techniques to improve geothermal production, especially in a tectonically-active region like Indonesia. Applying these insights can help unlock the potential of low-medium temperature geothermal resources, enhancing their permeability and optimizing the technical and economic feasibility of low-medium temperature geothermal resources in Indonesia.

3.4 Staging Development Using Modular Plants

Geothermal development projects can be performed using two approaches: 1) direct large-scale; or 2) staging. In the direct large-scale approach approach, as illustrated in Figure 49, development is performed in a single stage with a direct large-scale power plant installed capacity so that the Commercial Operation Date (COD) occurs only once. Developers who choose to use this approach generally aim to achieve:

1. **Lower CAPEX**: due to the economy of scale from the power plant capacity and the mobilization and demobilization of development drilling being carried out all at once.
2. **Higher revenue**: from the start of COD, developers immediately generate higher revenue due to the direct large-scale installed capacity since COD hence minimizing the value of revenue lost due to time value of money.

Table 11: Seven Protocol Steps Suggested by the U.S. DOE to Address EGS-Induced Seismicity (U.S. DOE, 2012).

Step	Description	Purpose	Recommended Approach
Step 1: Perform Preliminary Screening Evaluation	A rigorous initial screening to determine the overall feasibility of the EGS project and identify potential risks.	Evaluate the feasibility of an EGS project by assessing technical, socioeconomic, and financial risks. Identify potential show-stoppers and ensure public and regulatory acceptability.	Conduct a bounding analysis to categorize the likelihood of project approval. Review relevant laws, determine the radius of influence, identify potential impacts, and classify the overall risk.
Step 2: Implement and Outreach and Communication Program	Engage the community positively before and during project operations, addressing their concerns and demonstrating project benefits.	Ensure community acceptance by keeping public stakeholders informed and involved.	Develop and periodically update an outreach plan. Hold public meetings, site visits, and establish communication mechanisms to engage the community and stakeholders.
Step 3: Review and Select Criteria for Ground Vibration and Noise	Utilize existing criteria and standards to develop appropriate risk assessment criteria for EGS-induced seismicity.	Identify and evaluate existing standards and criteria for ground-borne noise and vibration impact assessment.	Assess existing conditions, review local ordinances, and evaluate criteria for building damage, human exposure, industrial activities, and ground-borne noise.
Step 4: Establish Local Seismic Monitoring	Continuous seismic monitoring throughout the project to ensure accurate data for operational decisions and mitigation strategies.	Gather baseline and operational seismic data to forecast and understand induced seismicity for mitigation and reservoir management.	Implement a comprehensive seismic monitoring program before and during project operations, ensuring data collection is unbiased.
Step 5: Quantify the Hazard from Natural and Induced Seismic Events	Compare natural and induced seismic hazards to understand the potential increase in hazard due to EGS activities.	Estimate the ground shaking hazard from natural and induced seismicity to assess potential damage or loss.	Perform Probabilistic Seismic Hazard Analysis (PSHA) and Deterministic Seismic Hazard Analysis (DSHA) for both natural and induced seismicity.
Step 6: Characterize the Risk of Induced Seismic Events	A higher resolution risk estimate for making informed decisions on project design and operations.	Develop a detailed estimate of the risk associated with the EGS project design, construction, and operation.	Conduct a rigorous risk assessment considering the variations in risk during future operations and evaluate alternative operational procedures.
Step 7: Develop Risk-Based Mitigation Plan	A proactive mitigation plan to address potential risks and ensure safe and effective EGS operations.	Create a mitigation plan based on the risk assessment to minimize negative impacts of induced seismicity.	Develop and implement mitigation strategies tailored to the specific risks identified in the risk assessment.

However, this approach presents the following drabwacks:

1. **Reservoir response uncertainty**: since the development is carried out directly with a large capacity, developers do not have the opportunity to evaluate reservoir response after COD. This leads to the risks of rapid reservoir decline and oversized power plant units, which can incur financial losses where actual generation levels are below the generation levels in the initial projected project value.

2. **Longer time to reach COD**: since the power plant capacity during COD is higher than in the staged development scheme, a higher steam power under wellhead is required. Therefore, more production and reinjection wells have to be drilled before COD, leading to a longer time to reach COD.

Meanwhile, in the staging development approach, as illustrated in Figure 50, the addition of installed capacity is carried out gradually through several CODs until finally reaching the desired total capacity. Developers who choose this approach generally aim to achieve:

1. **Earlier revenue generation**: because the power plant capacity at each COD is smaller compared to the direct large-scale scheme, the required steam power under the wellhead during COD is also reduced. Therefore, fewer production and reinjection wells need to be drilled before COD, resulting in an earlier COD and revenue generation.
2. **Reservoir sustainability**: because capacity expansion is done gradually, developers can evaluate reservoir response before deciding to increase installed capacity hence reducing the risks of reservoir overproduction.

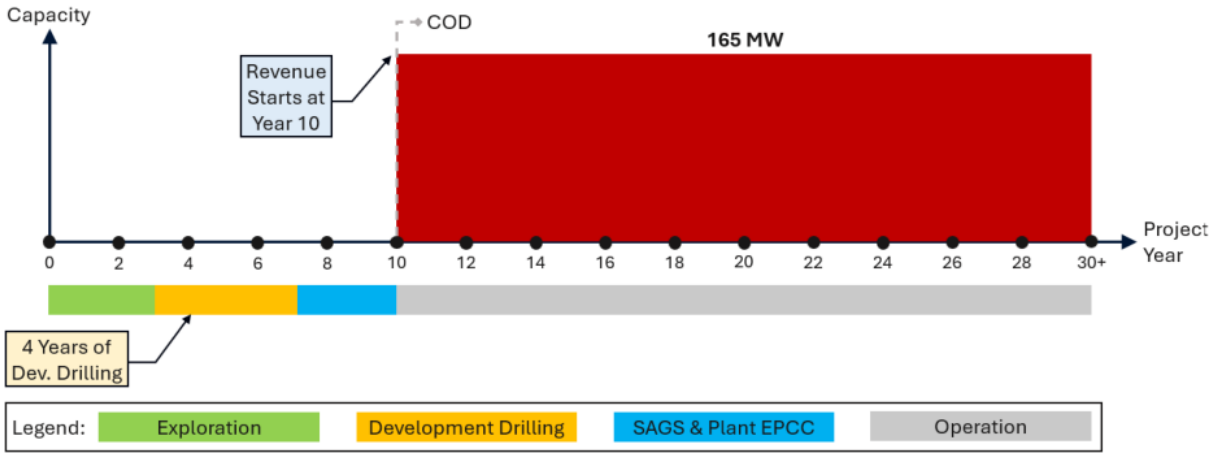

Figure 49: Direct Large-Scale Geothermal Power Plant Development Approach.

However, this approach presents the following drabwacks:

1. **Higher CAPEX**: due to the economy of scale from the power plant capacity and the mobilization and demobilization for the development drilling that are not performed at once, the CAPEX will be higher than the direct large-scale approach.
2. b: because the capacity of the power plant is added gradually, developers will lose more revenue due to the time value of money, altough the total power plant capacity will eventually be the same as the direct large-scale approach.

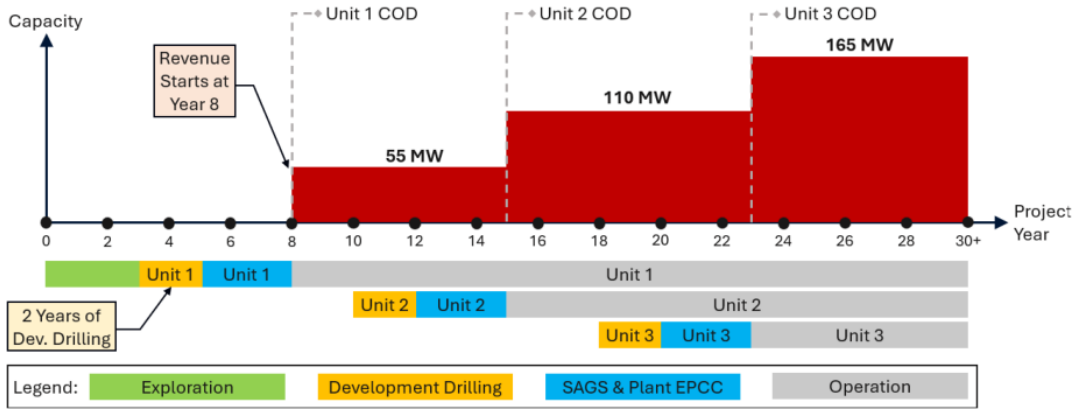

Figure 50: Staging Geothermal Power Plant Development Approach.

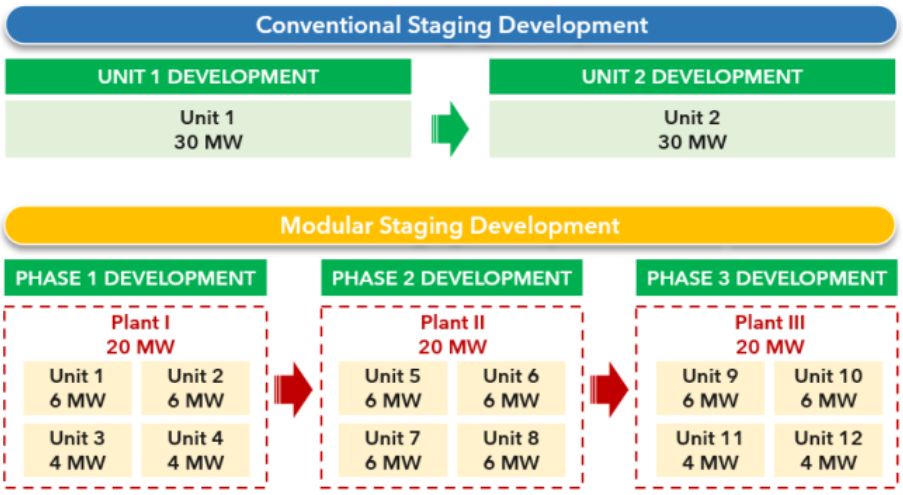

Figure 51: Staging Development Using Conventional Large Unit Plants (Top) and Modular Plants (Bottom).

3.4.1 Conventional and Modular Staging Development

Subsequently, the staging development approach can be classified further into the conventional staging and the modular staging development approach, as illustrated in Figure 51. The conventional staging development approach is straightforward, focusing on the sequential construction of large individual units, each representing a complete stage in the project's expansion. This method is linear, with each new unit signifying a substantial increase in overall capacity, typically employed in regions like Indonesia. In contrast, the modular staging development approach, commonly adopted in the United States, involves breaking down each phase into several smaller units within a single plant. This method allows for gradual and flexible scaling of the project. Each phase comprises multiple smaller units, which can be incrementally commissioned to match demand more closely and optimize resource use. This modular strategy facilitates phased investment and can adapt more dynamically to development needs and technological advancements.

In Indonesia, a conventional staging development approach is commonly used for geothermal power plant projects. Each stage of development is referred to as "Unit X," with the total capacity expressed as "[number of units] x [each unit's capacity]." By using the illustration in Figure 51 as an example, if Field ABC has two units of power plants, each with a 30 MW capacity, it is described as 2x30 MW. The development is staged into Unit 1 (30 MW) and Unit 2 (30 MW), facilitating a structured and phased approach to GPP capacity expansion. The conventional staging development offers the following advantages:

1. **Lower CAPEX**: the larger turbine unit capacity results in a cheaper unit plant CAPEX per megawatt of GPP installed capacity due to the economy of scale.
2. **Simpler operation & maintenance**: due to the less turbine units compared to the modular units, the plant's operation and maintenance are simpler and cheaper.

However, this approach may present the following disadvantages:

1. **Longer time to reach COD**: since each power plant unit possesses a larger capacity during COD compared to the smaller modular units, a higher steam power under wellhead is required. Therefore, more production and reinjection wells have to be drilled before COD, leading to a longer time to reach COD.
2. **Less flexibility during operation & maintenance**: if the turbine units need routine overhauls or unexpected shut-downs, the lost generation will be higher since a single turbine unit generates a larger capacity compared to a modular unit.

Meanwhile, in the United States, a modular staging development approach is commonly employed for power plant projects. Each stage of development is referred to as "Phase X." By using the illustration in Figure 51 as an example, in Field ABC, there are three plants: Plant I (20 MW), Plant II (20 MW), and Plant III (20 MW). Each plant consists of four units (turbines), with each unit having a capacity of 4 to 6 MW. This modular approach allows for flexible and scalable expansion of power generation capacity, enabling gradual increases in output as additional phases are developed and brought online. The conventional staging development offers the following advantages:

1. **Earlier revenue generation**: since modular units possess a smaller capacity compared to the conventional units, electricity generation and sales can be achieved after completing a single production

well drilling and a modular unit installation, which require significantly less time compared to drilling a large number of wells and constructing a larger plant.

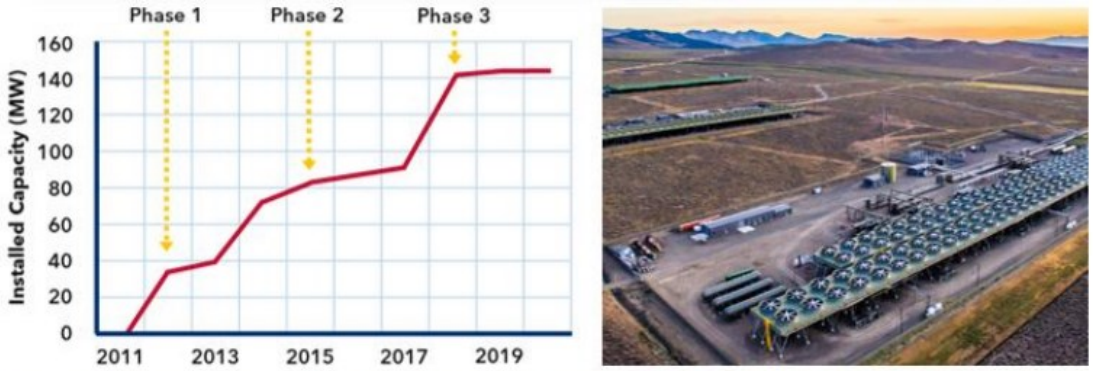
2. **Higher flexibility during operation & maintenance**: if the turbine units need routine overhauls or unexpected shut-downs, the lost generation will be smaller since the other turbine units can remain operational.

However, this approach may present the following disadvantages:

1. **Higher CAPEX**: due to the economy of scale from the power plant capacity and the mobilization and demobilization for the development drilling that are not performed at once, the CAPEX will be higher than the direct large-scale approach.
2. **Complex operation & maintenance**: since the plant has a large number of modular turbine units (more equipment involved), conducting operation & maintenance activities becomes more challenging and costly.

3.4.2 Experience in the U.S.: McGinness Hills and Steamboat, Nevada

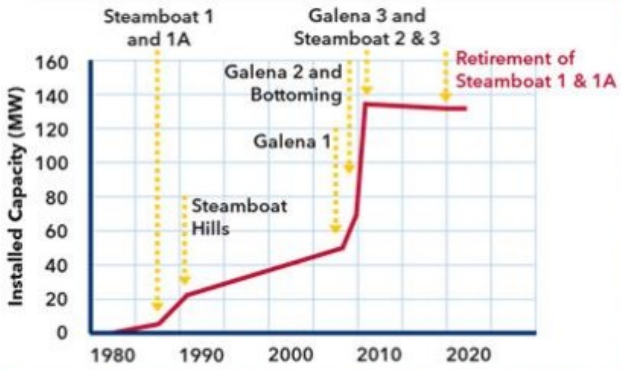
The McGinness Hills geothermal field has undergone three significant development stages (Robertson-Tait, et al., 2021; NREL, 2021). In 2012, the first phase was completed with the commissioning of three units, providing a capacity of 45 MW. This was followed by the second phase in 2015, which added another three units with the same capacity of 45 MW. The third phase, completed in 2018, introduced three more units, contributing an additional 48 MW. Altogether, the plant now operates nine units with a total installed capacity of 138 MW. Throughout these phases, the monitoring of reservoir response to development was crucial to ensure the sustainability of the resource during capacity expansions. It facilitated the updating of the conceptual model and the calibration of the numerical model, which guided the strategic expansion of the plant, ensuring sustainable and efficient development (Ormat, 2022). The historical development of McGinness Hills GPP is summarized in Figure 52.



GPP Name	No. of Units	Capacity (MW)	COD Year
McGinness Hills 1	3	45	2012
McGinness Hills 2	3	45	2015
McGinness Hills 3	3	48	2018
Total	**9**	**138**	

Figure 52: McGinness Hills GPP Development History (Ormat, 2024; Robertson-Tait, et al., 2021; NREL, 2021).

Similarly, the Steamboat geothermal field has experienced a series of developments since its initial commissioning (Robertson-Tait, et al., 2021; NREL, 2021). Steamboat 1, the earliest installation in 1985, had the highest number of units, with seven turbines, contributing a modest 2 MW. That same year, Steamboat 1A added two more units, providing an additional 2.4 MW. In 1988, Steamboat Hills was developed with a single unit producing 16.3 MW. The early 2000s saw significant expansions, starting with Galena 1 and Galena 2 in 2006 and 2007, each adding 30 MW and 13.5 MW respectively. Additionally, the Steamboat Hills Bottoming plant added 5.5 MW in 2007. The trend of expansion continued with Galena 3 in 2008, which introduced another 30 MW, followed by Steamboat 2 and Steamboat 3, each adding two units with capacities of 18.2 MW in 2008. Over time, certain units were retired, notably Steamboat 1 and 1A, to optimize the overall capacity, which now stands at approximately 131.7 MW spread across 19 units. The historical development of Steamboat GPP is summarized in Figure 53.



GPP Name	No. of Units	Capacity (MW)	COD Year
Steamboat 1	7	2	1985
Steamboat 1A	2	2.4	1985
Steamboat Hills	1	16.3	1988
Galena 1	2	30	2006
Galena 2	1	13.5	2007
Steamboat Hills Bottoming	1	5.5	2007
Galena 3	1	30	2008
Steamboat 2	2	18.2	2008
Steamboat 3	2	18.2	2008
Total	**19**	**131.7**	

Figure 53: Steamboat GPP Development History (Ormat, 2024; Robertson-Tait, et al., 2021; NREL, 2021).

4. CONCLUSION AND PATHFORWARD

The techno-economic optimization initiatives derived from the U.S. experience with low-medium temperature geothermal fields, combined with insights from Indonesia's high-temperature geothermal fields, provide a strategic pathway to enhance the economic attractiveness of low-medium temperature geothermal development in Indonesia. Currently, the development of these resources in Indonesia is sub-optimal compared to their potential and the advancements seen in high-temperature resources. By implementing advanced downhole pump technologies, such as electric submersible pumps (ESPs), and focusing on the development of shallower outflow zones, Indonesia can significantly reduce the levelized cost of electricity (LCOE). These strategies, along with lessons learned from successful high-temperature projects in Indonesia, such as well stimulation techniques and outflow zone optimization, can help mitigate the high initial costs and operational challenges typically associated with low-medium temperature fields.

Most future exploration pipeline projects (according to RUPTL 2021-2030) will be dominated by low-medium temperature resources. However, despite the availability and commercial success of technologies like binary plants, downhole pumps, and in-field enhanced geothermal systems (EGS) in the U.S. for over 40 years, Indonesia faces significant challenges. The lack of technological know-how and experience, coupled with hesitation to adopt these "new" technologies compared to the conventional high-temperature methods commonly used in Indonesia, hinders the development of low-medium temperature resources. Additionally, geological challenges such as deeper resources, lower permeability, and distinct host rock types (softer sedimentary rocks in the U.S. versus harder volcanic rocks in Indonesia) further complicate drilling operations and the discovery of commercial permeability, necessitating EGS stimulation in some cases.

To overcome these challenges and accelerate the development of Indonesia's vast low-medium temperature geothermal potential, the following steps are recommended:

1. **Resource Characterization**: Conduct detailed studies to characterize the resource depth and permeability of unexplored low-medium temperature geothermal fields. This will help identify resources that are technically and economically feasible to develop.
2. **Technology Transfer**: Enhance technology transfer from U.S. experts through technical training programs or business partnerships, such as joint ventures with experienced U.S. geothermal developers, including the induced seismicity mitigation for EGS projects.

3. **Adopt Best Practices**: Implement global best practices and foster technological innovation to create a more favorable investment climate and improve project bankability.
4. **Collaborative Efforts**: Encourage collaboration between the government, industry stakeholders, and international partners to drive advancements and achieve efficient, cost-effective development of low-medium temperature geothermal fields.

By adopting these optimization practices, Indonesia can diversify its energy portfolio, enhance energy security, and support sustainable economic growth. This collaborative approach will be crucial in realizing these advancements and achieving a more efficient and cost-effective low-medium temperature geothermal field development in Indonesia.

Empowering Coffee Farmers: A Strategic CSR Approach for Climate Resilience and Market Positioning at Supreme Energy Rantau Dedap

Andri Muhamad Affandi and M. Pradikta F. R

Anwar Muhammad Foundation (AMF)

andri.affandi@amf.or.id, mohammad.pradikta@amf.or.id

Keywords: Climate Change Adaptability, Market Positioning, Livelihood Improvement Program (LIP), Post-Harvest Coffee Processing, Inclusive Financing, Aggregator Scheme

ABSTRACT

The Corporate Social Responsibility (CSR) initiative by Supreme Energy Rantau Dedap (SERD), in collaboration with the Anwar Muhammad Foundation (AMF) and other stakeholders, aims to enhance climate change adaptability and strengthen market positioning for coffee farmers in the SERD geothermal project area. This area encompasses the Lahat District, Muara Enim District, and Pagar Alam City in South Sumatra Province.

In developing this CSR program plan, the sustainability of the Livelihood Improvement Program (LIP) which has been implemented in 2019-2022 targeted 131 Project Affected Peoples (PAP), was taken into consideration. These PAP are divided into five Joint Business Groups (KUBE) located in two main villages, Tunggul Bute Village in Lahat District and Segamit Village in Muara Enim District. The LIP intervention aimed to strengthen six household livelihood assets of the PAP, namely human resources, natural resources, physical resources, financial resources, social resources, and intellectual resources. Evaluation results showed that the program successfully increased the PAP's income by 75% compared to their initial conditions, with the main source of income for the majority of PAP (approximately 90%) being coffee farming. Therefore, the primary target of CSR is coffee farmers, both those included in the PAP and other community members within the SERD geothermal project area.

The main problems faced by coffee farmers in the project area are: 1) unpredictable weather conditions affecting the quality and quantity of coffee harvests; 2) lack of skills and knowledge about good coffee farming practices; 3) lack of skills and knowledge about good post-harvest coffee processing; 4) limited access to capital for coffee farmers; and 5) low selling prices and limited market access. The implementation of the CSR program is expected to address these problems and ultimately improve the welfare of coffee farmers.

The scope of CSR activities for the 2023-2024 period includes data validation activities for 131 PAP, facilitation of coffee farmer institutional development, technical support for post-harvest coffee, support for coffee drying and storage infrastructure, facilitation of inclusive financing for coffee farmers through the Islamic Blended Finance (IBF) scheme, and facilitation of coffee marketing using the aggregator scheme. This period's CSR implementation is focuses on about 30 coffee farmers who belong to the Gunung Patah Farmer Group in Segamit Village. This is a new group formed by coffee farmers in the village and includes both PAP and non-PAP households.

The next stage of the CSR program intervention aims to increase coffee productivity, promote sustainable agroforestry practices, and improve market access for coffee products for the 2024-2025 timeframe The target beneficiaries of the CSR program in this period are approximately 250 coffee farmers. In order to improve market access, initial efforts have been made to open cooperation opportunities with the Swiss Import Promotion Programme (SIPPO) and local buyer partners. Some plans to carry out this cooperation will be implemented gradually and will be added to the CSR program for the 2024-2025 period.

1. INTRODUCTION

In South Sumatra Province, coffee farmers face significant challenges related to financial inclusion and climate change (Schroth, G., et al. 2015). The limited access to financial services exacerbates their vulnerability to climate-related impacts, resulting in suboptimal coffee production and market interactions. Supreme Energy Rantau Dedap (SERD) recognizes the need to address these challenges through a strategic Corporate Social Responsibility (CSR) approach aimed at empowering coffee farmers to achieve climate resilience and improve their market positioning.

1.1 Background

Coffee farmers in South Sumatra, particularly in remote areas, struggle with limited access to financial institutions. This lack of financial inclusion, coupled with the adverse effects of climate change, hampers their ability to invest in necessary adaptations, such as post-harvest processing improvements and sustainable farming practices (Sarvina, Y., et al. 2023). The region's coffee production is heavily impacted by changing rainfall patterns, which

can lead to decreased crop quality and yield (Schroth, G., et al. 2015). Additionally, the exploitation by intermediaries, or 'toke,' further diminishes farmers' income, creating an unsustainable market environment.

In developing this CSR program plan, it is also in the context of the sustainability of the Livelihood Improvement Program (LIP) which has been implemented from 2019 to 2022, directed towards 131 Project Affected Peoples (PAP). These PAP are divided into five Joint Business Groups (KUBE) located in two main villages, Tunggul Bute Village in Lahat District and Segamit Village in Muara Enim District. The LIP intervention aimed to strengthen six household livelihood assets of the PAP, namely human resources, natural resources, physical resources, financial resources, social resources, and intellectual resources. Evaluation results showed that the program successfully increased the PAP's income by 75% compared to their initial conditions, with the main source of income for the majority of PAP (approximately 90%) being coffee farming. Therefore, the primary target of CSR is coffee farmers, both those included in the PAP and other community members broadly in the SERD geothermal project area

1.2 Context and Objectives

The main problems faced by coffee farmers in the project area include unpredictable weather conditions affecting the quality and quantity of coffee harvests, lack of skills and knowledge about good coffee farming practices, lack of skills and knowledge about good post-harvest coffee processing, limited access to capital for coffee farmers, and low selling prices and limited market access.

The implementation of the CSR program is expected to provide solutions to these problems and ultimately improve the welfare of coffee farmers. The scope of CSR activities for the 2023-2024 period includes data validation activities for 131 PAP, facilitation of coffee farmer institutional development, technical support for post-harvest coffee, support for coffee drying and storage infrastructure, facilitation of inclusive financing for coffee farmers with the Islamic Blended Finance (IBF) scheme, and facilitation of coffee marketing with the aggregator scheme. The CSR implementation in this period focuses on about 30 coffee farmers who are members of the Gunung Patah Farmer Group in Segamit Village. This group is a new group formed based on the initiative of coffee farmers in the village, consisting of PAP and non-PAP households.

In the next stage for the 2024-2025 period, the target of the CSR program intervention is to increase coffee productivity, promote sustainable agroforestry practices, and improve market access for coffee products. The target beneficiaries of the CSR program in this period are approximately 250 coffee farmers. In order to improve market access, initial efforts have been made to open cooperation opportunities with the Swiss Import Promotion Programme (SIPPO) and local buyer partners. Some plans to realise this cooperation will be implemented gradually and will become part of the CSR program for the 2024-2025 period.

SERD's CSR program aims to enhance the livelihood of coffee farmers by addressing these critical issues. The primary objectives are:

1. Strengthening the farmers' capacity to adapt to climate change.
2. Improving their market positioning to ensure fair trade practices and sustainable income.

2. STRATEGIC FRAMEWORK

To achieve these objectives, SERD has adopted a comprehensive approach, incorporating the Sustainable Livelihoods Framework and the AMF Co-Transformative Enterprise Development (C-TED) model.

2.1 Sustainable Framework

The framework focuses on designing strategies to optimise available capital and assets in response to vulnerabilities (Krantz, L. 2001). A thorough analysis of assets and vulnerability factors is at the core of this approach (Serrat, O. 2017). Six Capitals of Sustainable Livelihood Framework:

1. Financial Capital: Enhancing farmers' access to inclusive financial services to support business development and climate-resilient practices.
2. Manufactured Capital: Providing necessary infrastructure and equipment for improved coffee processing and production.
3. Intellectual Capital: Building farmers' knowledge and skills through training and capacity-building initiatives.
4. Human Capital: Empowering farmers with competencies and motivation to innovate and improve their farming practices.
5. Social Capital: Strengthening community networks and stakeholder relationships to foster collective action and information sharing.
6. Natural Capital: Promoting sustainable use of natural resources to ensure long-term productivity and environmental conservation.

2.2 AMF Co-Transformative Enterprise Development (C-TED)

The framework is designed to foster collaborative growth between parties through mutual learning, mutual support, and co-innovation among local enterprises (Shen, W., et al 2022). This approach leverages collective strengths to address common challenges, promoting sustainable social and economic development (Liddle, J. 2018). Collaboration between public, private, and nonprofit sectors such as AMF is essential for social enterprises to address complex social challenges and foster innovation (Qi, L., et al 2024). Key components include Co-Create, Co-Execute, and Co-Operate, creating a dynamic ecosystem that benefits the entire community by:

1. Co-Create: Collaboratively generating innovative ideas and market-based solutions tailored to the farmers' needs.
2. Co-Execute: Implementing these solutions through inclusive partnerships and effective management practices.
3. Co-Operate: Ensuring continuous improvement and sustainability of the initiatives through iterative processes and stakeholder engagement.

3. KEY ACTIVITIES AND OUTCOMES

The CSR program encompasses several strategic initiatives aimed at addressing the climate and market challenges faced by coffee farmers. Program addresses factors necessary for farmers to face potential challenges presented by climate change and market challenges. According to (Wright, D. R., et al. 2024) these initiatives collectively aim to create a sustainable and prosperous future for coffee farming communities in South Sumatra Province, those strategies including:

Financial Inclusion Initiatives:

1. Facilitating access to microloans and other financial services to enable farmers to invest in necessary adaptations and improvements.
2. Providing financial literacy training to enhance farmers' ability to manage their finances effectively.

Climate Resilience Measures:

1. Supporting the installation of climate-resilient infrastructure, such as solar panels for post-harvest processing.
2. Promoting sustainable farming practices that improve soil health and water management.

Market Positioning and Fair Trade:

1. Establishing fair trade partnerships to ensure farmers receive equitable prices for their coffee.
2. Creating a cooperative model to aggregate coffee production, thereby enhancing bargaining power and market access.

Capacity Building:

1. Conducting training programs on best farming practices, quality control, and business management.
2. Facilitating knowledge exchange and collaboration among farmers to foster innovation and continuous improvement.

Environmental Conservation:

1. Implementing measures to protect and restore natural ecosystems, ensuring the sustainability of coffee production.
2. Promoting agroforestry and other practices that enhance biodiversity and ecosystem services.

These initiatives collectively aim to address the multifaceted challenges faced by coffee farmers in the SERD geothermal project area, ensuring their economic sustainability and environmental stewardship (Wright, D. R., et al. 2024). By providing financial tools, enhancing climate resilience, improving market access, building capacity, and conserving the environment, the CSR program seeks to create a sustainable and prosperous future for the coffee farming communities in South Sumatra Province.

The CSR program focuses on enhancing the capabilities of coffee farmers and strengthening agricultural markets through the 6 capital approach, stakeholder mapping, mentorship, and monitoring. Additional activities supporting the CSR program include the construction of a greenhouse (Dome) and storage warehouse, participation in the IIGCE, collaboration with the ADB mission, presenting at the Serelo CSR Award, and holding collaborative discussions with RIGSIS and the Directorate General of New, Renewable Energy, and Energy Conservation (EBTKE) of the Ministry of Energy and Mineral Resources (ESDM). The execution and outcomes of these activities are detailed below.

Figure 1: Training and Assistance in Post-Harvest Coffee Processing.

Figure 2: Coffee Farmers in Post-Harvest Coffee Processing Training.

Figure 3: Coffee Farmers in Post-Harvest Coffee Processing Training.

The first site visit took place from August 28-31, 2023, aiming to identify and analyze the conditions of coffee farmers to form the basis for the CSR program planning. Activities included sustainable livelihood surveys through in-depth interviews and discussions with various stakeholders. The agenda encompassed socializing the CSR program with KUBE members and coffee farmers in Tunggul Bute and Segamit villages, conducting questionnaires and FGDs, observing coffee plantations, and surveying potential locations for the greenhouse and storage warehouse. Key findings indicated financial unpreparedness among farmers due to dependency on harvest

income, unstable coffee prices, and reliance on middlemen for farming capital. The visit also identified the roles of local government and potential land for development in Talang Pisang.

The second site visit, held from November 15-19, 2023, focused on post-harvest training for coffee farmers and the presentation of post-harvest processing facilities. Activities included coordinating the training with the Gunung Patah Farmers Group, observing potential construction sites for post-harvest facilities, and conducting training sessions on both dry (natural) and wet (full wash) coffee processing methods. The training involved 25 participants from the Gunung Patah Farmers Group and featured discussions on facility development plans. Concurrently, the AMF team discussed the CSR program implementation and community empowerment criteria with the EBTKE team during their visit.

4. CROSS-CUTTING INITIATIVE

The CSR program is aligned with the International Finance Corporation (IFC) Environmental and Social Standards (ESS) Framework 2017 and the Sustainable Development Goals (SDGs) of Indonesia. It focuses on:

1. ESS1 - Assessment and Management of Environmental and Social Risks and Impacts: Ensuring comprehensive risk assessments and management plans to mitigate environmental and social impacts.
2. ESS6 - Biodiversity Conservation and Sustainable Management of Living Natural Resources: Promoting practices that support biodiversity conservation and sustainable use of natural resources.
3. ESS10 - Stakeholder Engagement and Information Disclosure: Maintaining transparent and inclusive stakeholder engagement throughout the program implementation.

The Corporate Social Responsibility (CSR) program in the SERD geothermal project area aligns with the International Finance Corporation (IFC) Environmental and Social Standards (ESS) Framework 2017 and Indonesia's Sustainable Development Goals (SDGs). It prioritises comprehensive risk assessments, biodiversity conservation, stakeholder engagement, and transparent information disclosure to address environmental and social challenges

The CSR initiatives also contribute to several SDGs, including:

1. Goal 1: Ending poverty by enhancing the economic resilience of coffee farmers.
2. Goal 5: Achieving gender equality by empowering women farmers.
3. Goal 8: Promoting sustained, inclusive, and sustainable economic growth.
4. Goal 13: Taking urgent action to combat climate change and its impacts.
5. Goal 15: Protecting, restoring, and promoting sustainable use of terrestrial ecosystems.

5. CONCLUSIONS

The strategic CSR approach of Supreme Energy Rantau Dedap aims to empower coffee farmers by addressing the dual challenges of climate change and market positioning. Through financial inclusion, capacity building, sustainable practices, and fair trade initiatives, the program seeks to enhance the resilience and livelihood of coffee farmers. By aligning with international standards and contributing to global sustainability goals, SERD demonstrates its commitment to fostering a sustainable and equitable coffee industry in South Sumatra.

Keywords: Waste Heat Recovery, Geothermal brine, Spiral Heat Exchanger, Direct use, Dieng field

ABSTRACT

Most of the liquid dominated geothermal fields, such as Dieng, produce a significant quantity of hot brine that exits the separator. They still have enough pressure and temperature to be utilized to optimize the geothermal resource. However, most geothermal brines contain silica that may deposit in the brine pipelines and other equipment. The presence of silica deposition will afftect the operation and maintenance scenario including costs. The main component of a Waste Heat Recovery System is the heat exchanger. Since the main consideration of the study is the formation of deposited silica scale in the heat exchanger, the selection of heat exchanger type is crucial, hence the Spiral Heat Exchanger was chosen for ease of maintenance. The objective of this study is to evaluate the effectiveness of the designed heat transfer to extract heat from geothermal brines to the surface water to be utilized further, such as for water and space heating. This technology can be applied in locations like Dieng since hotels and homestays continue to use gas as their primary energy source, which is costly. The research project adopts analytical and computational studies using Ansys Fluent. From the given brine data and selected heat exchanger, the calculation indicated that the dimensions of the heat exchanger consist of a shell diameter of 563 mm, a spiral diameter of 543 mm and the number of spiral rotations of 10. Variations in mass flow rates of 0.25 kg/s, 0.5 kg/s, 1 kg/s, 1.4 kg/s, 2 kg/s, and 3 kg/s resulted in effectiveness values of 80.0%, 76.5%, 72.1%, 68.9%, 66.2% and 64%, respectively. The mass flow rate affects the total heat transfer rate, effectiveness, and pressure drop in the heat exchanger.

1. INTRODUCTION

One of the main concerns for most geothermal developers is to optimize their resources. It can be started from the very upstream subsurface side, i.e., monitoring reservoir performances to the downstream power plant side, such as utilizing “waste” brine leaving the separator. It is fortunate that most of geothermal systems in Indonesia are categorized as high enthalpy water dominated systems, so that they produce brines on the surface with large amount. Recently, many developers are utilizing this brine for electricity generation using Organic Rankine Cycle (ORC) binary power plant for additional power output. Hence, the power plant efficiency and revenue in the end will increase.

However, from the social point of view, the developers or companies have a mission that they are not only as business entities but also as social institutions, namely Corporate Social Responsibility (CSR) program. CSR program is not only in the form of charity but also empowering the community surrounding their working areas with their resource. One of the advantages by involving community directly or indirectly related to geothermal resource within their areas, it will help geothermal industry to promote geothermal also as their opportunity to get better live economically and environmentally. Hence, better acceptance for geothermal energy by the community or public can be achieved.

Dieng has been known as a tourist destination area where currently it does not need promotions to increase the level of tourist arrivals, both domestic and overseas. The required current situation is how to make tourists feel at home and comfortable staying longer in Dieng. One of the problems in Dieng is that it is very cold especially at night. Therefore, the facilities that are most needed are hot water for bathing and space heating in homestays. At present, in Dieng Kulon there are about 350 homestays, while overall in the Dieng area, which includes 7 villages, there are around 1500 homestays. Currently, to meet the need for hot water, all homestays use LPG as an energy source and only around 2% of homestays have installed space heating facilities. Meanwhile, Dieng is well known as one of the geothermal energy producers, which it can be utilized for this purpose. The benefits of using this energy are that apart from the wider use of green and clean energy from the environmental point of view, it is also expected that it will reduce the operational costs from economical consideration.

Meanwhile, in Dieng area there is an electricity producer company, namely PT. Geo Dipa Energi (Persero) which has operated the geothermal power plant for almost 20 years. In their operation, there is brine which still has sufficient heat with a ranging temperature of 160°C - 180°C. Considering this potential, it would be very beneficial if this brine is optimized by extracting this heat energy, including for bathing and space heating. However, since the implementation of this project involves many stake holders, all of them must be aware that all aspects of its development including partnership, social responsibility, business, and the final target is that the acceptance of geothermal energy by the community become crucial issues that must be handled. Another important activity that must be prepared is the preliminary design of the technology of the heat recovery from the technical point of view, particularly for Dieng.

2. PROPOSED TECHNOLOGY

2.1 Proposed System Configuration and Process

In this study, hotter geothermal brine leaving the separator is used to heat the colder surface ground water that will be utilized for some purposes, for example for bathing and/ or space heating as illustrated in Figure 1. To extract the heat from the brine, heat exchanger technology is used with ground water as the heat carrier medium for further utilization. The heated ground water is circulated through a closed piping system which is equipped with a flow rate, temperature and pressure measurement and control system, so that the performance of the waste heat recovery system can be achieved and operational safety is maintained. However, one of the problems faced in the utilization of brine from PT Geo Dipa Energi is the possibility of silica scaling deposition. For this reason, it is necessary to anticipate by preventive or corrective methods. The preventive method is carried out by adding inhibitors to prevent scaling with the consequence of additional operational costs. Meanwhile, the corrective method is carried out by designing equipment that are relatively easy to maintain. The colder brine leaving the heat exchanger then is transported to cooling pond or reinjection well.

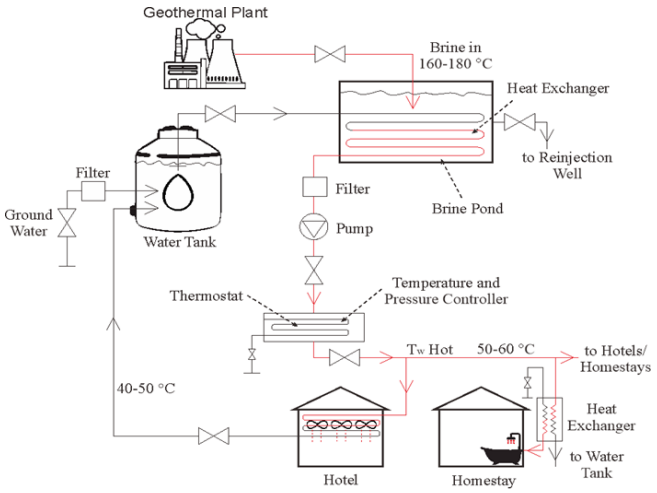

Figure 1: The proposed installation of waste heat recovery from geothermal brine for bathing and space heating.

2.2 Proposed Spiral Plate Heat Exchanger

In this study, we focus on the design and analysis of the proposed heat exchanger since it becomes the main and crucial component, especially in Dieng case. From the technical point of view, the main consideration of designing heat exchanger for heat recovery from brine in Dieng is its high potency of silica scaling formation inside the heat exchanger. For this reason, Spiral Plate Heat Exchanger (SPHE) is adopted since its easy maintenance. SPHE is a type of heat exchangers that use a spiral design to transfer heat between two fluids. It consists of two concentric spiral flow channels, one for each fluid, with the fluid flowing in the opposite direction. The channel is sealed and connects to a port on the cover, and its design optimizes effectiveness of transfer of heat and space. It also making it easier for manual cleaning. SPHE is very suitable for geothermal brine which tends to cause deposition due to high silica content. Due to its single channel geometry and continuously curved, this design creates high flow turbulence with high shear stress which reduces the risk of fouling. Channel geometry sole also creates a scrubbing effect that helps cleaning accumulation of deposits as they form. This effect will ensure that it remains high value of heat transfer that occurs in the heat exchanger. Figure 2 represents the proposed Spiral Plate Heat Exchanger.

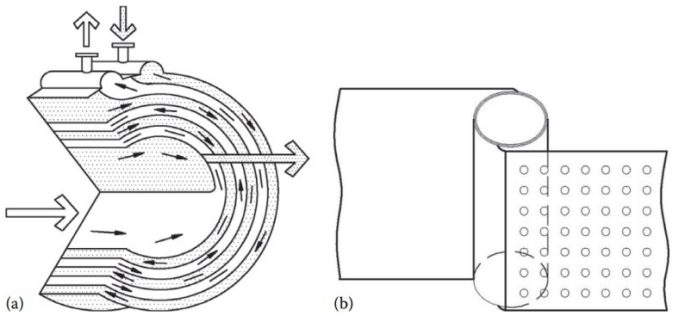

Figure 2: The schematic diagram of proposed Spiral Plate Heat Exchanger (a) unit and (b) two-plate design (with studs or plain). (Thulukkanam, 2013).

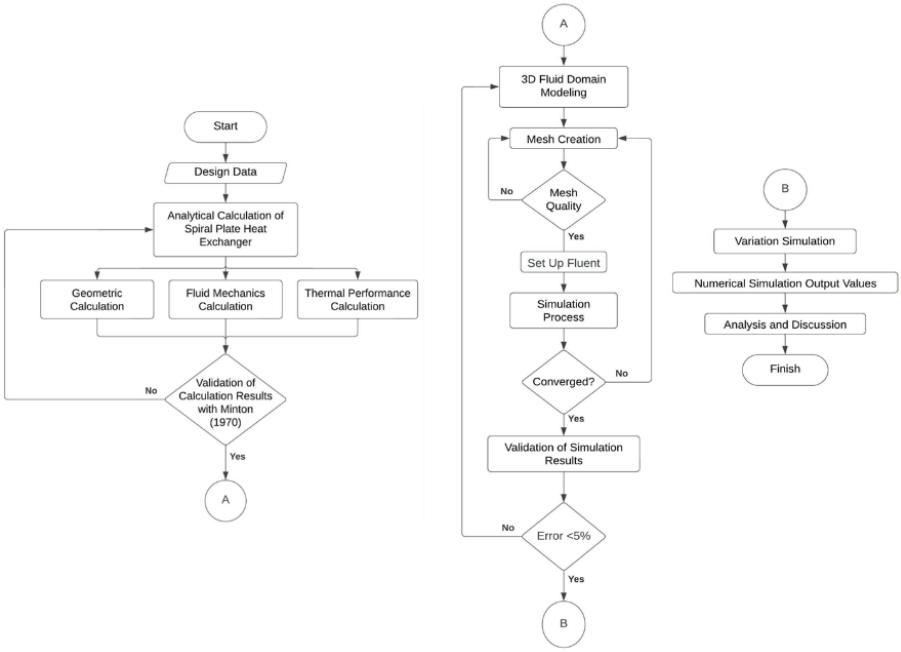

Figure 3: The flow chart of research steps and analysis.

3. METHODOLOGY

Both analytical and numerical methods are used for designing and evaluating the heat recovery system, particularly for the heat exchanger component as illustrated in Figure 3. Analytical method is adopted to design the geometry and dimension of heat exchanger, while the numerical (simulation) method is useful for understanding the physical phenomenon of the fluids from fluid mechanics and heat transfer point of views. We can also compare both results for validation of the calculation and the simulation at the same time.

3.1 Input Parameters

Input parameters for fluid and heat exchanger materials are presented in Table 1 and Table 2, respectively. In this study, the design of spiral plate heat exchanger is based on one proposed by Minton (1970).

Table 1: Input of fluid properties.

Properties	Value	Unit
Cold fluid inlet temperature ($T_{cold,in}$)	10	[°C]
Hot fluid inlet temperature ($T_{hot,in}$)	160	[°C]
Density (ρ)	998.2	[kg/m^3]
Specific heat (c_p)	4182	[J/kg K]
Thermal conductivity (k)	0.6	[W/m K]
Dinamic viscosity (μ)	0.001003	[kg/m s]

Table 2: Input of stainless-steel heat exchanger plate properties.

Properties	Value	Unit
Density (ρ)	8030	[kg/m^3]
Specific heat (c_p)	502.48	[J/kg K]
Thermal conductivity (k)	173073	[W/m K]

3.2 Analytical Approach

Analytical calculation refers to the basic governing heat transfer equation as well as the empirical equation introduced by Minton (1970). Furthermore, the basic dimensions of the spiral and plate dimensions follow the calculation results proposed by Shirazi et al. (2020) since it has the best thermal effectiveness. Then variations in the mass flow rate are carried out at the inlet of the two fluids, namely 0.25 kg/s, 0.5 kg/s, 1kg/s, 1.4 kg/s, 2kg/s, and 3 kg/s. With these six data variations, the values of the outlet temperature, pressure drop, total heat transfer rate and thermal effectiveness of the heat exchanger can be calculated using the log mean temperature difference (LMTD) method.

3.2.1 Geometrical Calculation

Geometrical calculations are the design basis for the size of the heat exchanger. In this study, only one type of geometrical design was used and then variations in the fluid mass flow rate were given. The plate sizes and basic geometries used in heat exchangers are presented in Table 3 that is proposed by Shirazi et al. (2020). These values are adopted with the consideration that this geometry is used for validation purpose with numerical study.

Table 3: Geometry of basic dimensions of proposed heat exchanger (Shirazi et al., 2020).

Properties	Value	Unit
Spiral inner diameter (D_i)	0.2032	[m]
Plate length (L)	11.55	[m]
Plate width (H)	0.5334	[m]
Plate thickness (x)	0.003175	[m]
Gap between plates for cold fluid (b_c)	0.00595	[m]
Gap between plates for hot fluid (b_h)	0.00476	[m]

By using the equations adopted from Dongwu (2003), Núñez et al. (2007) and Minton (1970) the parameters of spiral rotation, hydraulic diameter, outer diameter, free flow area, and heat transfer area can be obtained. These parameters are depicted in Table 4, while the calculated dimensions are illustrated in Figure 4.

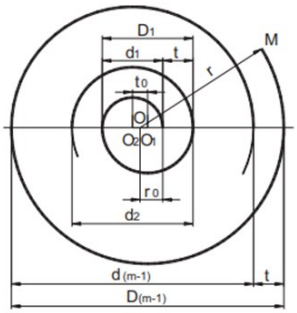

Figure 4: Schematic diagram of semi-circled spiral (Dongwu, 2003).

Table 4: Calculated parameters of proposed heat exchanger.

Parameters		Value	Unit
Spiral rotation (N)		10	[-]
Hydraulic diameter (L)	Cold fluid	0.0118	[m]
	Hot fluid	0.00944	[m]
Outer diameter (D_s)		0.5417	[m]
Free flow area (A_f)	Cold fluid	0.00317	[m]
	Hot fluid	0.00254	[m^2]
Heat transfer area (A)		12.3215	[m^2]

3.2.2 Thermofluids Calculation

Thermofluids parameters are affected by the fluid output from the heat exchanger. In this study, there are several variations in the mass flow rate to study its effects on thermofluids parameters. To give an overview the thermofluids design parameters, a mass flow rate value of 0.5 kg/s is used for cold fluids and hot fluids to demonstrate its effects. The values of the fluid properties used in the heat exchanger are presented in Table 1 while the calculated fluid mechanics parameters are listed in Table 5, while for thermal performances are presented in Table 6.

Table 5: Calculated fluid mechanics parameters for a given mass flow rate of 0.5 kg/s.

Parameters		Value	Unit
Reynolds number (Re)	Cold fluid	1848	[-]
	Hot fluid	1852	[-]
Critical Reynolds number (Re_{cr})	Cold fluid	5872	[-]
	Hot fluid	5471	[-]
Average velocity (V_f)	Cold fluid	0.158	[m/s]
	Hot fluid	0.197	[m/s]
Prandtl number (Pr)		6.99	[-]
Nusselt number (Nu)	Cold fluid	22.805	[-]
	Hot fluid	22.768	[-]
Pressure drop (ΔP)	Cold fluid	1807.3	[Pa]
	Hot fluid	2521.8	[Pa]

Table 6: Calculated thermal performances for a given mass flow rate of 0.5 kg/s.

Parameters		Value	Unit
Heat transfer coefficient (h)	Cold fluid	1160.77	[W/m^2 K]
	Hot fluid	1450.13	[W/m^2 K]
Total heat transfer coefficient (U)		576.52	[W/m^2 K]
Heat capacity rate ratio (C)		-1	[-]
Number of Transfer Units (NTU)		3.397	[-]
Temperature Difference Correction Factor (F_T)		0.962	[-]
Thermal effectiveness per Rotation (ε)		72.2	[%]
Total thermal effectiveness (ε_{tot})		76.5	[%]
Fluid outlet temperature (T_{out})	Cold fluid	124.86	[°C]
	Hot fluid	45.14	[°C]
Logarithmic Mean Temperature Difference (ΔT_{LM})		35.14	[K]
Total heat transfer rate (Q)		240.2	[kW]
Maximum total heat tranfer rate (Q_{max})		313.6	[kW]

3.2.3 Summary of Analytical Calculation

Analytical calculations were carried out on geometry, fluid mechanics and thermal performance by varying the independent variable mass flow rate at the heat exchanger inlet for both fluids. The calculated variations in mass flow rate are 0.25 kg/s, 0.5 kg/s, 1 kg/s, 1.4 kg/s, 2 kg/s, and 3 kg/s. The expected output from the calculation includes the outlet temperature and pressure drop of the cold fluid and hot fluid, the total heat transfer rate and the thermal effectiveness of the heat exchanger. A summary of the results of SPHE analytical calculations is presented in Table 7.

Table 7. Summary of analytical calculations for mass flow rate variation at the inlet.

Outputs	Inlet Mass Flow Rate [kg/s]					
	0.25	0.5	1	1.4	2	3
Flow Type	Laminar	Laminar	Laminar	Laminar	Turbulent	Turbulent
Re	925.29	1850.58	3701.16	5181.63	7402.33	11103.49
ΔP_{cold} [kPa]	1.194	1.807	2.793	3.481	16.075	33.087
ΔP_{hot} [kPa]	1.678	2.522	3.864	4.791	27.657	56.689
$T_{c,out}$ [°C]	130.1	124.9	118.2	114.3	109.5	103.1
$T_{h,out}$ [°C]	40	45.2	51.9	55.8	60.6	67.0
Q [kW]	125.48	240.17	452.42	610.24	831.51	1167.52
ε_{tot} [%]	80.0	76.6	72.2	69.5	66.3	62.1

3.3 Numerical Simulation Approach

From the analytical calculation described in Section 3.1 and the relevant data, the numerical simulation using Computational Fluid Dynamics (CFD) with Ansys 2023 R1to study the physical phenomenon of the fluids and the performance of the SPHE was carried out. The steps of numerical simulation are depicted in Figure 3, while in term of CFD the main activities consist of pre-processing, solving and post-processing (ANSYS, 2017).

3.3.1 Pre-Processing

In this sub-process, a three-dimensional geometry was created from two spiral plates as the basic geometry of the spiral plate heat exchanger. Then, the spiral plate geometry was transferred into .itp format to Ansys SpaceClaim to continue the 3D model creation process, namely creating the fluid domain as shown in Figure 5, the inter-fluid partition plate and the spiral plate heat exchanger cover. The next activities following this model creation included mesh independence test, and mesh arrangement that is illustrated in Figure 6.

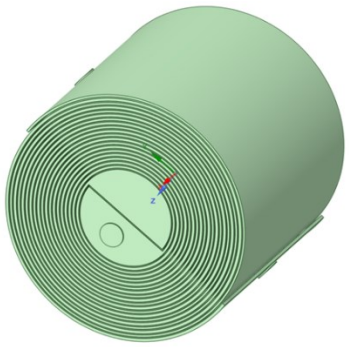

Figure 5: Fluid domain of 3D model of spiral plate heat exchanger.

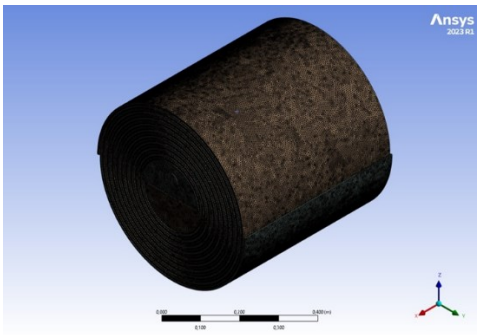

Figure 6: Result of fluid domain meshing of spiral plate heat exchanger.

3.3.2 Solving

This process was peformed in the set-up menu in Ansys Fluent that consisted of general set-up (steady or transient), model simulation (energy, viscous model, k-epsilon model, near-wall treatment), material of fluids (density, specific heat, thermal conductivity, viscosity), plate material (density, specific heat, thermal conductivity), cell zone conditions (water-liquid, stainless-steel), inlet-outlet boundary conditions (mass flow rate, turbulence specification, turbulent intensity, hydraulic diameter, temperature, thermal conditions), mesh interfaces (coupled wall), solution method (pressure velocity coupling, spatial discretization), solution controls (under-relaxation factors), initialization methods (hybrid inisialization), running (iteration calculation).

3.3.3 Post-Processing

After the solving process is carried out, the results of the simulation will be obtained. The simulation results can be visualized using Ansys CFD-Post software. In this study, the simulation results include temperature distribution, pressure distribution and flow field in the spiral plate heat exchanger.

4. RESULTS AND DISCUSSION

4.1 Validation

Simulated results were validated with analytical calculation on the spiral plate heat exchanger design that was made in the Ansys software. The validation stage was carried out based on simulations with fluid properties by Shirazi et al. (2020) compared with the results of analytical calculations. The properties of cold and hot fluids are shown in Table 8, while validation results are presented in Table 9.

Table 8: Properties of cold and hot fluids (Shirazi et al., 2020).

Properties	Cold Fluid	Hot Fluid
Mass Flow Rate [kg/s]	0.7465	0.7843
Inlet Temperature [°C]	60	200
Density [kg/m^3]	843	843
Specific Heat [J/kg K]	2763.288	2972.628
Thermal Conductivity [W/m K]	0.32339	0.34789
Dynamic Viscosity [kg/m s]	0.008	0.00335

Table 9: Validation result for SPHE simulation.

Output	Analytic	Simulation	Deviation [%]
Cold Fluid Outlet Temperature [°C]	150.46	154.06	2.4
Hot Fluid Outlet Temperature [°C]	120.25	119.06	0.99
Total Heat Transfer Rate [kW]	186.283	192.0	2.87
Total Thermal Effectiveness [%]	64.50	66.35	2.87

The difference between the analytical calculation and the simulation results shows a small deviation value and is within the deviation tolerance criteria. This shows that the simulation results are quite accurate and can describe the actual conditions of the spiral plate heat exchanger. Thus, the simulation process can be continued for simulations with variations in mass flow rate with water-liquid fluid properties.

4.2 Simulated Results

4.2.1 Contours for Main Parameters

After the simulations on the validation data that had been carried out, pictures of the temperature distribution contour, pressure distribution contour and streamline that occur in the heat exchanger were obtained as shown in Figure 7.

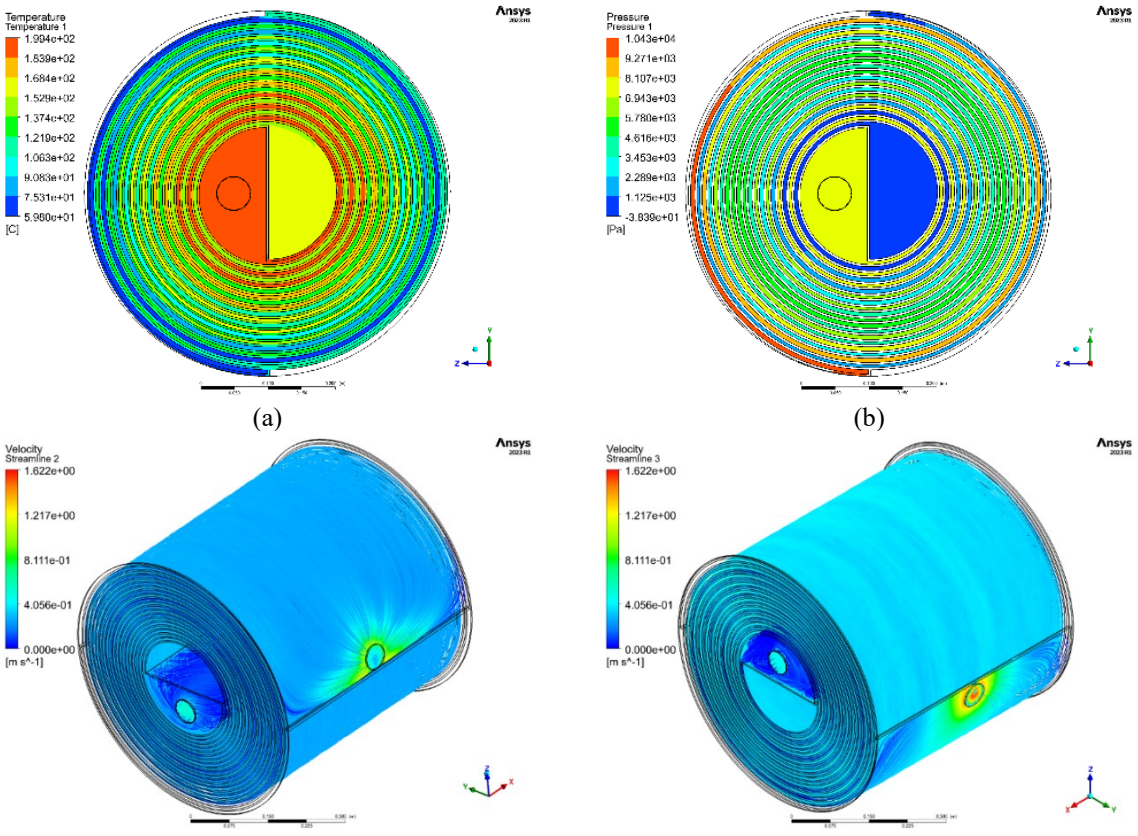

Figure 7: Main parameter contours: (a) temperature, (b) pressure, (c) cold streamline fluid, (c) hot streamline fluid.

The temperature distribution contour in Figure 7 (a) is taken from SPHE in the YZ Plane with a value of X = 0 m. It can be recognized the different color gradients in each fluid due to heat transfer between fluids, resulting in the

temperature of the stainless-steel plate changing, influenced by the temperature of the fluid. Based on the results of simulation data, the average temperature of the stainless-steel plate is 135.89°C. The pressure distribution contour in Figure 7 (b) is taken from SPHE in the YZ Plane with a value of X = 0 m. In can be noted the different color gradients in each fluid that represents pressure distribution gradient to consider the maximum pressure drop allowed in the SPHE. In the simulation, the outlet pressure value is determined by a gauge pressure of zero, so that the largest pressure will occur at the SPHE inlet section. Figure 7 (c) and (d) show the streamlines for cold and hot fluids, respectively. The average speed of hot fluid flow is faster than cold fluid, namely 0.303 m/s for hot fluid and 0.237 m/s for cold fluid, so the hot fluid is lighter than cold fluid. The maximum speed occurs at the outlet of both fluids, namely 0.95 m/s for the hot fluid and 0.485 m/s for the cold fluid.

4.2.2 Effects of Mass Flow Rate

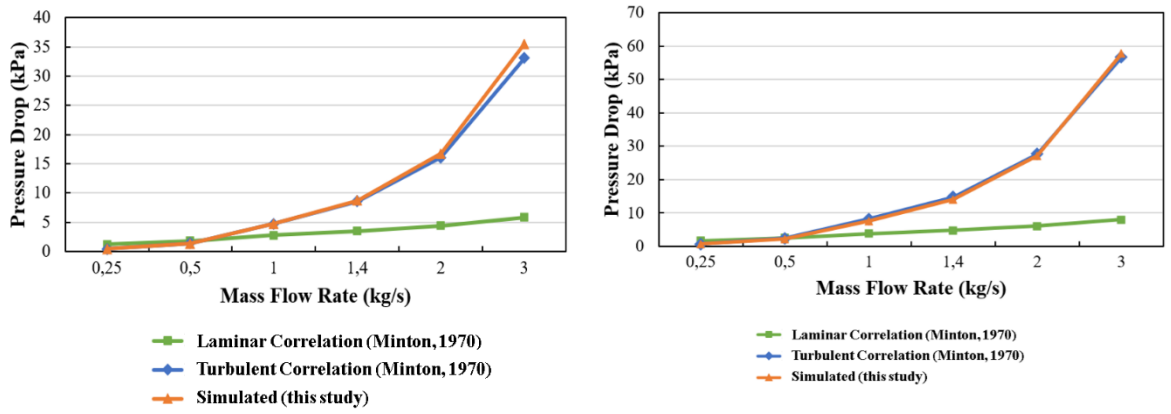
After validation of the spiral plate heat exchanger simulation results was carried out, the heat exchanger simulation variations were continued with six different mass flow rates, i.e., 0.25 kg/s, 0.5 kg/s, 1 kg/s, 1.4 kg/s, 2 kg/s, and 3 kg/s to evaluate the differences in performance among these variations. No geometric changes were made to this variation of the simulation. Data on the properties of the water-liquid fluid and stainless-steel plates used in the Ansys Fluent software are in accordance with Tables 1 and 2. The results of simulation is depicted in Table 10.

Table 10: Summary of simulated results for different mass flow rates at the inlet.

Outputs	Mas Flow Rates at Inlet [kg/s]					
	0.25	**0.5**	**1**	**1.4**	**2**	**3**
$T_{cold,out}$ [°C]	134.43	131.49	126.71	122.57	120.01	113.36
$T_{hot,out}$ [°C]	36.33	40.72	46.47	49.36	54.18	59.78
ΔP_{cold} [kPa]	0.414	1.362	4.717	8.706	16.751	35.507
ΔP_{hot} [kPa]	0.669	2.169	7.586	14.023	27.122	57.762
Q [kW]	130.74	254.39	489.62	668.57	922.35	1313.99
ε_{tot} [%]	83.37	81.11	78.06	76.13	73.52	69.83
$T_{plate,avg}$ [°C]	78.56	79.52	79.65	78.97	80.06	79.76

4.2.3 Pressure Drop

The comparison between analytical calculation and simulation for pressure drops of the cold and hot fluids is shown in Figure 8.



(a) (b)

Figure 8: Pressure drops in the fluids: (a) cold fluid, (b) hot fluid.

From Figures 8 (a) dan (b), it can be noted the higher the mass flow rate value, the higher the pressure drop value. Based on the results of analytical calculations, when the fluid speed reaches the critical Reynolds number, the laminar fluid flow will experience turbulence, causing a very high increase in pressure drop. Therefore, for spiral plate heat exchangers, the recommended mass flow rate value is below 1.4 kg/s with a Reynolds number below its critical value, because the type of flow is laminar which has a pressure drop below 10 kPa as recommended by Minton (1970). This will indirectly reduce heat exchanger manufacturing and maintenance costs. However, the pressure drops simulation results show a large percentage deviation from the results of analytical calculations for fluids with laminar flow. The reason for the difference is because the Ansys Fluent software with the standard viscous k-epsilon model can only determine that the flow acting on the spiral plate heat exchanger is turbulent, where the software uses a general calculation formula, whereas in the SPHE analytical calculation formula

presented by Minton (1970). There is an empirical pressure drop formula which is influenced by the value of the Reynolds number and its critical value of the fluid. It is proven that the trend of differences between simulation results and analytical calculation results is in line for cold and hot fluids, with an average error of only 4.53%.

4.2.4 Outlet Temperatures

The comparison between analytical calculation and simulation for outlet temperatures of the cold and hot fluids is shown in Figure 9.

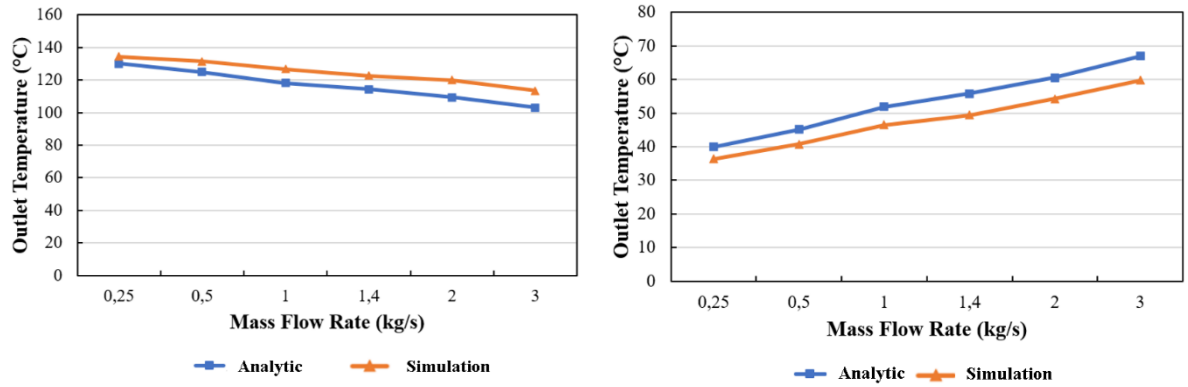


Figure 9: Outlet temperatures of the fluids: (a) cold fluid, (b) hot fluid.

From Figures 9 (a) and (b) it can be seen that variations in mass flow rate will affect cold fluids and hot fluids. The higher the mass flow rate, the cold fluid outlet temperature decreases, while the temperature of the hot fluid increases. This change trend is in line with the results of analytical calculations and simulations for both fluids, with an average error of 8.75%. External factors from fluid properties, such as fouling and scaling at a certain temperature will affect the selection of the appropriate mass flow rate.

4.2.5 Total Heat Transfer Rate and Total Thermal Effectiveness

Figure 10 shows the results of analytical calculations with simulation results for the total heat transfer rate and total thermal effectiveness with variations in the inlet mass flow rates.

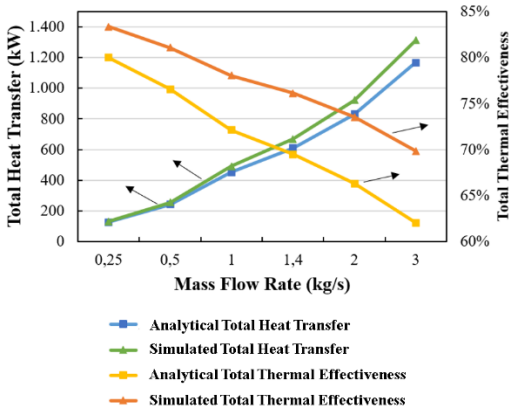

Figure 10: Total heat transfer and total thermal effectiveness for different mass flow rates.

From Figure 10, it can be observed that the mass flow rate greatly affects the total heat transfer rate that occurs in the heat exchanger. The higher the mass flow rate, the greater the total heat transfer rate. However, because a high mass flow rate causes a greater pressure drop, it will affect the total thermal effectiveness of the heat exchanger which decreases. It can also be noted that the analytical results and simulation results produce the same trend, with an average error of 8.57%.

5. CONCLUSIONS

From the discussion described in the previous sections, some of the important findings can be summarized as follows,

- Spiral Plate Heat Exchanger (SPHE) was adopted in this preliminary design study since its easy maintenance as the main consideration.
- The effect of mass flow rate on output results, an increase in mass flow rate will

    - lower the cold fluid outlet temperature, and increase the hot fluid outlet temperature,
    - increase the pressure drop and become more significant above a mass flow rate of 1.4 kg/s,
    - increase the total heat transfer rate and reduce thermal effectiveness.
- Thermal effectiveness of simulation results for mass flow rates of 0.25 kg/s, 0.5 kg/s, 1 kg/s, 1.4 kg/s, 2 kg/s, and 3 kg/s are 83.37%, 81.11%, 78.05%, 76.13%, 73.52%, and 69.82%, respectively.

ACKNOWLEDGEMENT

This research is funded by the Departement of Mechanical and Industrial Engineering, Faculty of Engineering, Universitas Gadjah Mada under the contract number of 1542901/UN1/FTK.1/III/PT/2024.

ABSTRACT

Given the importance of improving data quality to accelerate Indonesia's geothermal development in achieving Net Zero emissions, it is essential for current geothermal professionals to possess comprehensive geothermal literacy, technical expertise, industry insights, and sustainability awareness, combined with proficiency in the latest technology to optimize data value and mitigate risks. However, the accessibility of educational programs to thoroughly accommodate such criteria, particularly for undergraduates aiming for careers in the geothermal industry is unavailable. Furthermore, the gap between undergraduate students' knowledge and the geothermal industry's needs remains a challenge for the education sector. Studithermal, a learning program initiated by PT. Anugerah Indonesia Lima (AILIMA) in collaboration with Indonesia's Ministry of Education, Culture, Research, and Technology (MoECRT), is an innovative effort that aims to address this issue. It offers a comprehensive learning pathway via JIWA Cloud Computing System that combines advanced technology in collaborative data management, analytics, modeling, and machine learning with fundamentals and real-world experience in the industry to shape the future leaders of energy.

1. INTRODUCTION

1.1 Background

Geothermal energy presents a compelling solution for the global transition to clean energy. Indonesia, a country rich in geothermal potential, recognizes its strategic importance in achieving its Net Zero emissions goals. At the same time, geothermal can significantly contribute to a clean energy future alongside other renewables. However, the geothermal sector faces challenges related to data quality and the technical expertise of professionals. Improving data quality is crucial for developing and operating geothermal projects. Practicing data collection, entry, and governance by experts working together is essential in almost all work areas so it can be analyzed thoroughly for decision-making (Sidqi et al., 2024). Equally important is the quality of the human resources. A skilled workforce is essential for efficient geothermal development and operation. Therefore, investing in geothermal education is crucial for creating a competent workforce and unlocking Indonesia's full geothermal potential. By enhancing the skills of future workers, productivity in this sector is expected to increase.

Despite the recognized importance of geothermal energy, the lack of educational programs in local communities related to geothermal projects is one of the biggest challenges because it causes community resistance to this project in various regions (Umam et al., 2018). Moreover, no comprehensive educational programs are specifically designed for undergraduates aspiring to enter the geothermal industry. At the university level, undergraduate students still need to be provided with specific studies in geothermal energy. Those who pursue engineering studies such as geoscience or energy encounter geothermal topics in only one or two courses, which is insufficient to gain a complete understanding of geothermal literature and practices. While master's degree programs that offer comprehensive studies in geothermal science do exist, they may not be accessible to everyone to pursue further education at that level due to cost or individual circumstances.

Meanwhile, the reality is that the industry urgently needs a workforce. Increasing the geothermal workforce in Indonesia shows that the average workforce needs are around three people for every MW generated. Thus, with an average increase of 150 MW per year, 450 workers are needed per year. This increase should be the concern of the government and stakeholders in preparing this workforce (Umam et al., 2020). The workforce requirements include geologists, geophysicists, geochemists, reservoir engineers, production engineers, drilling engineers, project engineers, power plant engineers, drillers, technicians, and other skilled personnel. This calculation is for both the exploration phase and the operation and maintenance phase. Education plays a crucial role in meeting these needs, particularly at the university level. In Indonesia, the engineering majors that study renewable energy in the geothermal field are primarily mechanical engineering, chemical engineering, physical engineering, electrical engineering, petroleum engineering, geological engineering (geology), geophysics (geophysical

engineering), and energy conversion techniques (Umam et al., 2021). This gap hinders the development of a skilled workforce capable of addressing the challenges within the geothermal sector. To support geothermal development in Indonesia, geothermal-related courses must be integrated into the university curriculum, particularly in geology, geophysics, mining, petroleum, mechanical, or chemical engineering (Saptadji, 2010). It would be even better if undergraduate students in science, technology, engineering, and mathematics (STEM) programs could be introduced to geothermal science to increase their understanding and reduce the gap between graduates'knowledge and the practical needs of employers in the geothermal sector.

1.2 Objectives

The primary goal of the Studithermal program is to bridge the gap between academic knowledge and the practical needs of the geothermal industry. This program aims to develop a comprehensive learning pathway that equips undergraduates with the necessary geothermal literacy, technical expertise, industry insights, and sustainability awareness. To advance technological training, such as collaborative data management and machine learning, the program integrates advanced technology with fundamental education to enhance data management, analytics, and modeling skills using JIWA Cloud Computing System (Prabata et al., 2021), developed by PT. Anugerah Indonesia Lima (AILIMA). The specific objectives include:

- Improving geothermal literacy among students through a robust curriculum.
- Enhancing technical skills related to geothermal data management and analysis.
- Providing industry insights and real-world experience through collaborations with industry partners.
- Fostering sustainability awareness and the application of advanced technologies in geothermal projects.

By fostering a new generation of geothermal professionals equipped with advanced technical skills and industry insights, Studithermal aims to significantly contribute to Indonesia's goal of achieving Net Zero emissions through sustainable geothermal energy development and shape the future leaders of energy.

2. STUDITHERMAL

2.1 Program Design and Implementation

Studithermal is an intensive learning program designed to create synergy between understanding technology and practical applications in the geothermal industry. This program allows undergraduate students at universities in Indonesia under the Ministry of Education, Culture, Research, and Technology (MoECRT) to study outside their campus and earn up to 20 credits, equivalent to approximately ten subjects (assuming each subject is two credits) through the national curriculum policy called the Merdeka Belajar Kampus Merdeka (MBKM). This credit conversion is facilitated by the Ministry of Education, Culture, Research, and Technology (MoECRT) and participating universities where students are enrolled in the program, allowing students to apply their learning towards their degree requirements.

During the five months, students will have the opportunity to interact and learn with industry practitioners who will guide them and help bridge the gap between academic knowledge and industry needs. The program is conducted entirely online, allowing learners from various locations to participate and gain the same quality of education.

In the First batch, Studithermal takes on the learning topic of "Applied Data Management, Analysis, Modeling, and Machine Learning for Sustainable Geothermal Energy Development." This topic was chosen because it addresses the critical need for advanced technological training in the geothermal sector, ensuring that future professionals are equipped with the skills necessary to manage, analyze, and model geothermal data effectively. Furthermore, the integration of machine learning techniques enhances the ability to optimize geothermal energy development, contributing significantly to the sustainability and efficiency of geothermal projects. A capability assessment is conducted at the beginning to determine learners' prior knowledge and ensure the curriculum meets their current level of understanding.

2.2 Learning Module

The learning pathway is structured to enhance geothermal literacy, technical skills, and industry insights among undergraduate students. The First batch is from February 2024 to June 2024, The curriculum is divided into several key modules, each designed to cover a specific aspect of geothermal energy development.

The learning activities will focus on developing soft and hard skills through practical, real-world case studies in the industry, with hands-on project assignments for each module. The learning process is divided into 11 modules (shown in Figure 2). Each module includes hands-on project assignments, allowing students to apply theoretical knowledge to industry-relevant scenarios. The first ten modules serve as preparatory modules leading to the final module, the Final Project. These initial ten modules are designed to equip students with the foundational knowledge needed to complete the Final Project. Each learning material has been collaboratively developed with

Subject Matter Experts (SMEs) using extensive experience and competencies relevant to the studied topics. SMEs are practitioners actively working in the geothermal industry, bringing valuable real-world insights and expertise, with many having over a decade of in-depth experience. In the first batch, the contributed SMEs from both AILIMA and other prominent institutions and energy industries such as the Ministry of Energy and Mineral Resources Indonesia, Supreme Energy, Pertamina Geothermal Energy, Geo Dipa Energi, Medco Power Indonesia, Sumbawa Timur Mining, ENOWA, Pertamina Hulu Energi, ENI, Sarana Multi Infrastruktur, and more.

Figure 1: Learning Design of Studithermal.

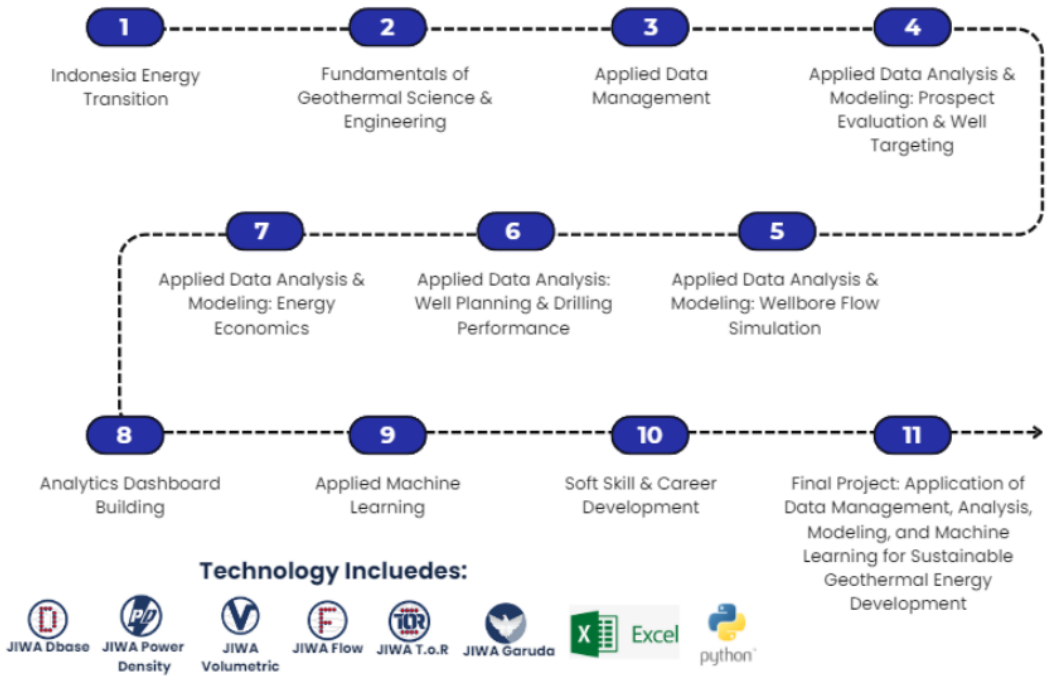

Figure 2: Curriculum Learning of Studithermal.

2.2.1 Technologies and tools

As a technology provider, particularly in the geothermal sector, AILIMA integrates specialized training into the curriculum for several of its technologies (JIWA Systems), as well as other relevant software. These technologies have already been used by various companies in the geothermal industry, making them essential skills for those beginning a career in this field. Throughout the program, students will leverage technologies, including:

2.2.2 Learning model

All learning activities in this program will be conducted fully online. The Learning Model will consist of synchronous sessions, where participants engage in real-time interaction with SMEs, mentors, and peers, as well as asynchronous sessions, where participants can access materials and complete tasks at their own pace, delivered through the JIWA Learning as a Learning Management System (LMS) developed by AILIMA. This format allows

participants from various cities in Indonesia to join the program and collaborate. Participants will have the opportunity to collaborate with others from diverse backgrounds, including different majors, hometowns, and universities.

Table 1: Software & Application usage.

Software and Application	Description
JIWA Dbase	Integrated geothermal data management and analysis in cloud system from preliminary survey, detail 3G, drilling and well testing, to operation and maintenance (O&M)
JIWA Power Density	Analytics tool to estimate geothermal resources in the early exploration stage
JIWA Volumetric	Resource and reserve estimation tool
JIWA Flow	An Artificial Intelegence to perform detail wellbore analysis for well characterization, well capacity estimation and optimization
JIWA ToR	Top of Reservoir (ToR) uncertainties estimation in the exploration stage with the probabilistic approach
JIWA Garuda	Multipurpose Machine Learning for everyone without coding
Microsoft Excel / Spreadsheet	Application for computation, organization, analysis and storage of data in tabular form
Python	An interpreted, object-oriented, high-level programming language with dynamic semantics

2.3 Participant Selection

In the first batch, a rigorous selection process was conducted to identify 100 participants from a pool of 3,489 applicants. The selection criteria included academic performance, interest in geothermal energy, personal growth and potential for future contributions to the industry. Each prospective participant will undergo a selection process involving the verification of administrative documents to ensure compatibility with the program and several initial tests. Several parameters are considered: students must be at least in their 5th semester of undergraduate program, and their major should be related to the program or come from a Science, Technology, Engineering, and Mathematics (STEM) discipline.

Figure 3: Participant Selection Process.

The selected participants come from 39 different universities across Indonesia, including both public and private institutions. They come from various study backgrounds that meet the selection criteria, ensuring a diverse cohort to promote inclusivity and a broad exchange of ideas.

This diversity in academic disciplines fosters a multidisciplinary approach, essential for addressing the complex challenges of geothermal energy development.

2.4 Project Based Learning

Project Based Learning stimulates students to actively participate in learning to maximize understanding and critical thinking capacity (Zulyusri at el., 2023). During the learning process, participants are grouped into teams and assigned mentors from AILIMA, who are geothermal engineers, to assist with day-to-day learning. Additionally, the instruction is provided by geothermal practitioners from both AILIMA and external collaborators, referred to as Subject Matter Experts (SMEs). These mentors offer continuous guidance and support throughout the program, helping to bridge the gap between academic learning and practical industry requirements. Team collaboration fosters a cooperative learning environment, encouraging participants to collectively share knowledge and tackle challenges.

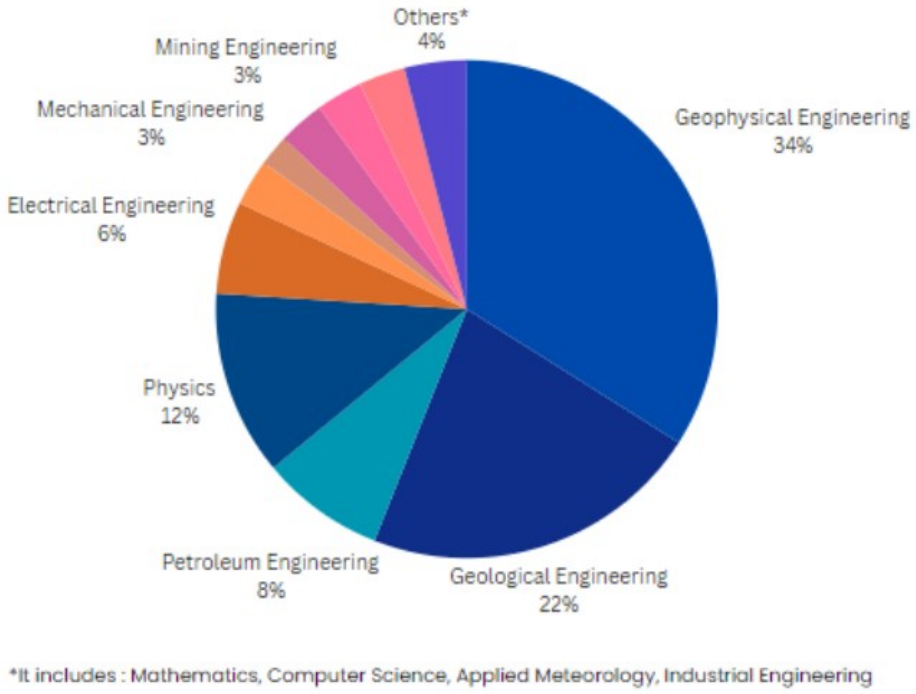

Figure 4: Pie Chart of Background Study Selected Participant batch 1.

This Approach allows participants to engage in individual hands-on project assignments related to each learning module, designed to reinforce theoretical knowledge through practical application. Towards the end of the program, participants collaborate on a final project focused on comprehensive geothermal prospect evaluation and proposing a sustainable development strategy. The project not only strengthens their technical knowledge but also cultivates key Skills: Digital Literacy, Citizenship, Working with Others, Problem-Solving & Decision Making, Self-Management, and Professionalism. The final project results are presented to a jury of experienced industry practitioners and AILIMA experts, showcasing the participants' analytical skills, collaborative problem-solving abilities, and innovative solutions. The judges evaluate the presentations based on technical accuracy, creativity, feasibility, and potential impact in the future development.

2.5 Knowledge and Skills Enhancement

Studithermal for batch 1 program concluded in June 2024, participants demonstrated significant improvements in several key competencies:

Table 2: Learning Outcomes of Studithermal.

Focus Areas	Learning Activities
Geothermal Literacy	Pre- and post-program assessments indicated a substantial increase in participants' understanding of geothermal energy principles, exploration techniques, and sustainability considerations
Technical Expertise	Practical assigments and project work led through hands-on project to enhance proficiency in data management, analysis, and modeling, as well as the application of machine learning techniques to geothermal data
Industry Insights	Collaboration with industry practioners was a critical component of the program's success. Mentorship and real-world case studies provided participants with invaluable industry insights and practical knowledge. This collaboration bridged the gap between academic learning and practical application, preparing participants for future careers in the geothemal industry

Moreover, participants who complete the program will possess extensive knowledge and skills essential for the geothermal industry, encompassing both technical and non-technical aspects critical in exploring and developing sustainable geothermal resources to support energy transition. Key roles covered included Geoscientist, Reservoir Engineer, Production Engineer, Drilling Engineer, Finance Analyst, and Project Engineer. Additionally, as digital talents, they can leverage their expertise and competencies in data analytics and machine learning. They can apply their skills as data analysts, data scientists, machine learning engineers, and/or similar roles to innovate new techniques for the geothermal industry, energy sector, or other domains.

3. GEOTHERMAL LEARNING AT AILIMA

AILIMA, as a leading learning provider focused on enhancing literacy in geothermal fields, currently offers a variety of learning programs for all audiences. The learning offerings are diverse and fullfield to participants' needs. AILIMA envisions a future where everyone has access to comprehensive, flexible, integrated, and job-relevant education in geothermal energy and technology. A systematic learning syllabus enables learners to study according to their needs, and access to learning is made easier through the JIWA Learning e-learning platform, allowing learners to study anytime and anywhere, thus ensuring that geothermal learning is accessible to everyone. There are plans to offer numerous courses with the hope of attracting even more participants to study geothermal sciences and energy, whether through the Studithermal program or other AILIMA learning initiatives.

4. SUMMARY AND RECOMMENDATION

The Studithermal program serves as a blueprint for future educational initiatives aimed at developing a skilled and knowledgeable workforce capable of advancing sustainable energy solutions. By integrating advanced technologies, practical industry experience, and comprehensive educational content, the program equipped participants with the skills and knowledge necessary to contribute to the sustainable development of geothermal energy. The collaboration with industry practitioners and the support from the MoECRT were instrumental in the program's success, providing participants with real-world insights and academic recognition. Through this initiative, AILIMA and MoECRT hope to significantly advance Indonesia's geothermal capabilities and support the country's ambition to achieve Net Zero emissions.

The success of the Studithermal program sets a precedent for future educational initiatives in the energy sector. The program's structure and methodology can be adapted and expanded to other areas of green and renewable energy, fostering a skilled workforce capable of driving sustainable development in Indonesia and beyond.

Keywords: Geothermal, high-temperature geothermal resource, low-temperature geothermal resource, medium-temperature geothermal resource, geothermal system, geothermal development strategies, Indonesia

ABSTRACT

Indonesia's geological landscape, predominantly shaped by subduction zone volcanoes, harbors high-temperature geothermal resources concentrated in areas such as Sumatra and Java. The study confirms that the majority of developed geothermal fields in Indonesia fall into the high-temperature category and are predominantly liquid-dominated. However, as Indonesia's government aims to tap into low to medium temperature resources in the future, challenges arise due to limited experience and success stories in this area. This necessitates innovative strategies and knowledge sharing to overcome obstacles in their future development. This study is part of our research to identify future geothermal projects in Indonesia and find the lessons learned and applicable feasible strategies for geothermal development in the country. The study is initiated by examining the current projection of geothermal energy development plans in Indonesia, tailored to the unique regional geological context. It underscores the considerable low-temperature geothermal prospects in the government's development plan, emphasizing the need for further study and exploration of low to moderate-temperature geothermal systems to build the necessary knowledge and strategies for successful development, including their discovery and utilization, is essential to unlocking the potential of these resources in Indonesia.

1. INTRODUCTION

The government of Indonesia is committed to support Net Zero Emission Target by 2060. One of its commitments is to increase the renewable energy capacity in the power generation mix, including geothermal energy. According to the Electricity Supply Plan of Indonesia (RUPTL), the utilization of Geothermal energy is expected to reach 5,799 MWe by 2030. As of mid-2024, the installed capacity in Indonesia is 2,418 MWe (ThinkGeoEnergy, 2024), leaving approximately 3,381 MWe needed to achieve the 2030 target.

Geothermal systems in Indonesia can be classified into low, medium, and high-temperature systems based on their temperatures. From an economic and feasibility perspective, high-temperature systems, particularly those associated with volcanic/magmatic systems, are still seen as the primary resource base for power generation in Indonesia. The most developed Indonesian geothermal fields, from the early 1980s to the present, fall into these 'volcanic-hosted' high-temperature systems (vide in Hochstein & Sudarman 2008 & 2015). The classification of reservoir temperature used in this study refers to the classification by Sanyal (2005). This classification is chosen because it has narrower temperature range compared to other classifications.

Nevertheless, to achieve the power generation mix and the net zero emission targets, low-medium temperature geothermal systems may need to be considered, especially since most high temperature systems in Indonesia have already been developed (e.g., Kamojang, Darajat, Dieng, Lahendong, etc). In fact, low to medium temperature systems offer more abundant prospects and are fairly distributed, as they do not necessarily have to be associated with volcanic setting (Wibowo, Hadi, & Risdianto, 2021; Putriyana L. , Daud, Saha, & Nasruddin, 2022). These resources can reach areas not located within volcanic regions, such as Kalimantan, parts of Sulawesi, and Papua.

Currently, low-medium temperature geothermal systems in Indonesia are still considered less attractive, partly due to their characteristics, which are not well understood. For example, the active thermal features (e.g., warm and hot springs) may not be as appealing as those in high temperature geothermal fields (e.g., fumarolic/solfataric steam discharge, boiling hot pool, etc). Additionally, some fields may lack surface thermal features, known as blind/hidden geothermal systems. Conventional exploration and extraction concepts used for high temperature system may not be fully applicable for these conditions, leading to very high resource risks and impacting their economic value. Therefore, understanding exploration and extraction strategies for low-medium temperature geothermal systems is critical to accelerate their development.

This study is part of our research to identify future geothermal projects in Indonesia and find the lessons learned and applicable feasible strategies for geothermal development in the country. The study is initiated by examining the current projection of geothermal energy development plans in Indonesia, tailored to the unique regional geological context. It underscores the considerable low-temperature geothermal prospects in the government's development plan, emphasizing the need for further study on low to medium temperature resources regarding their discovery and utilization.

2. GEOTHERMAL RESOURCES IN INDONESIA: REGIONAL SETTING

Indonesia is renowned for its abundant volcanic arcs, fault regimes, and sedimentary basins, all resulting from active tectonic processes. The subduction process has led to the formation of volcanic arcs extending from Sumatra to Nusa Tenggara and continuing to Sulawesi, endowing Indonesia with substantial geothermal energy resources. These regional settings play an important role to develop several geologic factors (i.e., topography, stress field, fault and fractures, lithology, etc.) which later controls several key parameters within the geothermal system such as permeability, reservoir characteristics and behaviour, fluid composition and flow, etc.

Additionally, fault regimes play a significant role in several geothermal fields, such as in Sumatra, where extensional regimes occur due to the influence of the Great Sumatran Fault (GSF). Similarly, in Sulawesi, several major regional faults, such as the Gorontalo graben zone and Palu-Koro fault zone, control several low-medium temperature geothermal prospects within the region.

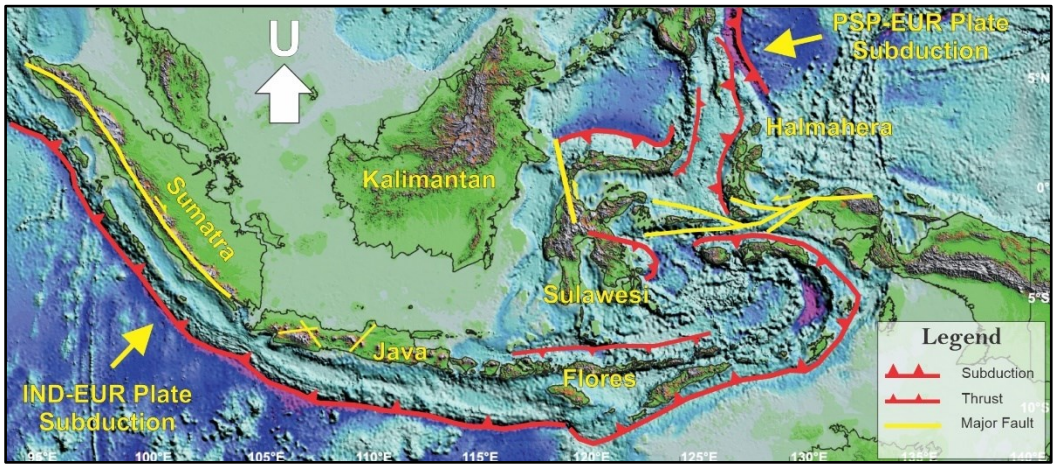

Figure 1: Major plate subduction zones and regional fault lines in Indonesia. IND-EUR: Indo-Australian Plate and Eurasian Plate. PSP-EUR: Philippine Sea Plate and Eurasian Plate (modified from Hall, 2009).

2.1 Tectonic setting

The present-day Indonesian archipelago has developed over a long period due to the region's complex plate tectonic setting (Hall, 2009). The archipelago is a product of several tectonic interactions, including the subduction of the Indo-Australian Plate (to the south and west) and the Philippine Plate (to the east) beneath the Eurasian Plate (to the north), as well as the subduction of the Pacific Plate (to the north) under the Indo-Australian Plate (to the south) along the northern margin of New Guinea Island. Figure 1 illustrates the Indonesian geological setting in relation to plate boundaries, highlighting regional fault lineaments across major islands resulting from these plate interactions. These tectonic movements have shaped Indonesia's geological features, including volcanic arcs, regional fault systems, and sedimentary basins.

Major geological features in Sumatra, such as the Barisan Mountain Range and the Great Sumatran Fault (GSF), are associated with the subducting Indo-Australian plate to the southwest. The Semangko Fault was an active fault in the mainland that divided the Sumatra Island, extending along the Bukit Barisan Mountains from Semangko Bay to Banda Aceh (McCaffrey, 2009). A large dextral fault of Sumatra Fault has active movement in Sumatra. The southern end of Sumatera Island cut by Semangko Fault (Siahaan, 2000; Gentana, et al., 2017) where the geothermal provenance with sufficient heat flow to power electricity generator was observed in the fault zone.

The volcanic arc in Sumatera is constructed on the continental crust, and the volcanoes sit on an uplifted pre-Tertiary basement terrane forming the Barisan Mountain Range (Simandjuntak & Barber, 1996). The region has experienced extension and subsidence, interpreted as a pull-apart basin formed by transtensional movement along the fault (Simandjuntak & Barber, 1996). This fault regime controls the occurrence of intrusions and volcanic activities within Sumatra (Hochstein & Sudarman, 1993; Simandjuntak & Barber, 1996). Several geothermal

fields, such as Namora I Langit and Silangkitang, are controlled by this regime, where the normal-fault boundary from pull-apart basins plays a crucial role as a fluid pathway, influencing reservoir structure and permeability (Hickman, et al., 2004; Muraoka, et al., 2010). Control of Neotectonic activity in Sumatra shows that there are various uplift and deformation processes in rocks, this causes variations in permeability which affects the distribution of manifestations in the prospect area (Gentana, et al., 2022).

In Java, the subduction of the Indo-Australian plate beneath the Eurasian plate to the south of the island has been occurring since the late Neogene (Sunda orogeny), forming geological features such as a forearc basin, a volcanic arc, Tertiary back-arc basins, and four main fault regimes across Java Island (Simandjuntak & Barber, 1996). This regime also controls several geothermal fields situated in Java. The major NW-SE oriented faults control West Java's volcanic arc and geothermal systems, such as Cisolok, Cilayu, and Cikundul. These faults act as a heat source and fluid pathway, as indicated by the alignment of volcanic edifices and surface thermal discharges (Purnomo & Pichler, 2014; Fauzi, et al., 2015). In Central Java, strike-slip faults with SW-NE and NW-SE trends significantly impact geological settings, resulting in subsidence, uplift, coastline indentation, and the shifting of the Quaternary volcanic arc (Satyana, 2007). The NW-SE lineament reflects some Quaternary volcanic chains in Central Java, such as Dieng-Sundoro-Sumbing and Telomoyo-Merapi-Merbabu. In Dieng, NW-SW trending faults are evident from the alignment of thermal manifestations, which are also spatially associated with the alignment of volcanic centers (Boedihardi, et al., 1991; Shalihin, et al., 2020). The depression between the Kendeng anticlinorium zone and the Southern Mountains (Pegunungan Selatan) in East Java controls the young volcanic arc within the area, which is favorable for developing volcano-hosted geothermal systems such as the Arjuno Welirang Volcanic Complex (van Bemmelen, 1949).

In Sulawesi, the tectonic setting is divided into four regions based on the lithotectonic province: (a) the Western and North Sulawesi Plutonic-Volcanic Arc; (b) the Central Sulawesi Metamorphic Belt; (c) the East Sulawesi Ophiolite Belt in the East Arm; and (d) the Banggai-Sula and Tukang-Besi continental fragments in the Southeast Arm (Soeria-Atmadja, et al., 1999; Baillie & Decker, 2022). The magmatic arc with Quaternary volcanoes is situated in the western and northern parts of Sulawesi, formed by the extensional tectonic movement of the Makassar Strait and the subduction of the Molucca Plate (Hartono, 1985; Zhang, et al., 2017). Geothermal prospects in the southern arm are more controlled by major faults; an example is the Bora Pulu geothermal field, primarily controlled by the Palu-Koro strike-slip fault (Abdullah, et al., 2020).

The Banda Arc in Eastern Indonesia is considered the product of the most recent continent collision in Indonesia. This arc is part of the Lesser Sunda-Banda Sector with double arc structures in the south and east (Von Der Borch, 1979). In the Lesser Sunda-Banda arc, Flores Island formed from the movement of the Pacific Block in the north and the subducting Australian continent in the south (Varekamp, et al., 1989; Muraoka, et al., 2005). Due to these tectonic movements, the geothermal system in the Bajawa Geothermal Field in Flores is controlled by lateral shear stress in the NNW-SSE trend (Muraoka, et al., 2005).

In Kalimantan, Sundaland extensional rifting in the Eocene age formed many thick sedimentary basins (Satyana, 1994). The rifting in Kalimantan led to the formation of numerous strike-slip and normal faults across the island. One regional strike-slip and normal fault is the Wonomulyo Fault, located in North Kalimantan. This fault system controls the fluid pathway of the Sajau geothermal prospect on the western side of the Tarakan Basin, while its geothermal fluid composition is influenced by intrusive rocks and the sedimentary basin environment (Kumalasari, et al., 2020).

2.2 Volcanism

Active plate tectonic interactions in Indonesia result in magmatic belts above the Benioff zone on the subducting plates. These features exist in active continental margins and island arcs across subduction lines (Hamilton W. , 1979). The magmatic belts bring magma to the surface, forming volcanic activities that host geothermal systems (Purnomo & Pichler, 2014). These areas are generally controlled by fault zones that serve as fluid pathways for surface manifestation discharges, with volcanic systems acting as the heat source (Hochstein & Sudarman, 2015).

Volcanism in Sumatra is controlled by the regional shear zone of the Sumatran Fault. Volcanic activities in Sumatra have an intermittent cycle, decreasing during the Eocene and becoming active again in the Late Miocene (Hochstein & Sudarman, 1993). Generally, geothermal prospects in Sumatra are located on the flank of volcanic edifices or pull-apart basins (Muraoka, et al., 2010). An example is the Sibayak geothermal field, situated within the Singkut Caldera, where geological structures controlled by volcanic activities enhance reservoir permeability (Atmojo, et al., 2000).

In Java, Tertiary magmatic activity occurred from the Late Eocene to Early Miocene and the Late Miocene to Late Pliocene, followed by Quaternary volcanism (Bellon et al., 1989 in Soeria-Atmadja et al., 1994). There are 17 volcano-hosted geothermal systems in Java, located on the Quaternary volcanic belt, with heat sources from intrusive rocks and magmatic activities (Purnomo & Pichler, 2014). One example is the Darajat geothermal field,

where the system is controlled by partially collapsed volcanic remnants, and the heat source is partial magma melt (Hadi, 2001).

Volcanic activity in the Banda Arc is associated with the subduction of the Indian-Australian plate towards the Eurasian plate, forming inner and outer volcanic arcs separated by the Savu forearc basin and Weber Deep (Bowin et al., 1977 in Von Der Borch, 1979). Geothermal prospects in the Eastern Banda Arc are linked to an active volcanic system formed by the mid-Tertiary collision of the Australian continent (Audley-Charles, 1975 in Nasution et al., 2002). An example is the Nage geothermal field, associated with the Inerie stratovolcano in the inner volcanic arc, notable for its high-volume manifestation discharge from magmatic sources (Nasution, et al., 2002).

The volcanic system in Kalimantan resulted from the subduction from Sumatra towards the Asiatic continent, emerging since the Cretaceous age (Katili, 1971). Late Cretaceous subduction in eastern Kalimantan led to mélange deposition associated with volcanic and granitic rocks in the southwest (Hartono, 1985). Currently, there is no active volcanism in Kalimantan. Most geothermal prospects are located in sedimentary basins and are less controlled by volcanism, categorized as low- to medium-temperature systems (Yushantarti, 2020).

Volcanism and plutonism in Sulawesi occurred with the subduction of the Molucca Slab. Late Quaternary volcanoes formed from the rifting in the Makassar Strait in western Sulawesi, extending to the northern arm of the Sangihe volcanic arc (Katili, 1971). This arc consists of Paleogene-Quaternary plutonic-volcanic rocks (Martosuwito, 2012). Unlike the southern arm, geothermal prospects in the northern arm are mainly controlled by Quaternary volcanism. The Lahendong geothermal system in northern Sulawesi is associated with Quaternary volcanic rocks, with its heat source from magma cooling beneath Mt. Lengkoan and Mt. Kasuratan (Siahaan, et al., 2005).

3. FUTURE GEOTHERMAL PROSPECTS IN INDONESIA

The Indonesian government has identified a list of fields for potential future geothermal development. These prospects are outlined in the National Electricity Supply Business Plan (RUPTL) 2021-2030 which can be categorized into three rankings (Figure 2):

- Rank 1: National Strategic Project (PSN) which already included in “Neraca Daya” or power grid so they supposedly become the most prioritized project to develop. There are about 37 projects included here that will supply about 1.5 GW power with expected COD year listed.
- Rank 2: project that also already included in power grid, but no specific fields are assigned. The supply power is around 710 MW.
- Rank 3: potential projects that are not included in power grid and has no expected COD year. There are 106 projects with total capacity of around 4.3 GW.

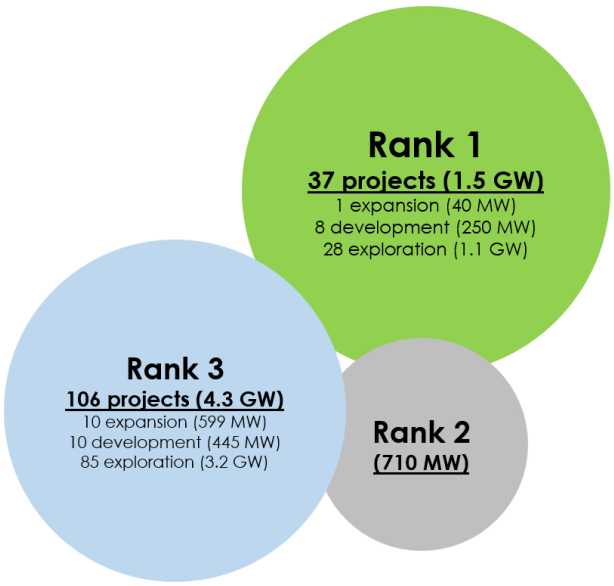

Figure 2: Priority distribution of Rank 1, Rank 2, and Rank 3 geothermal projects in RUPTL 2021-2030.

The geothermal fields listed in Ranking 1 are considered National Strategic Projects (PSN) and are included in the 'Neraca Daya' project list within the RUPTL 2021-2030. In contrast, the geothermal potential in Rank 2 is described as a general plan, which allocates one or several developers to supply a targeted quota of capacity by a specific year, without listing specific fields. Geothermal prospects in Ranking 3 have not yet been included in the 'Neraca Daya' and are currently not prioritized for immediate development, consisting of eighty fields. However, it is worth to note that geothermal prospects in Ranking 3 have considerable potential in low-medium temperature geothermal fields.

3.1 Rank 1 Indonesia's geothermal prospects in RUPTL 2021-2030

The geothermal fields listed in Ranking 1 are considered as National Strategic Projects and are included in the "Neraca Daya" project list in the RUPTL comprises twenty-three fields, mostly distributed along Sumatra, Java, Nusa Tenggara, and Maluku. Most of geothermal prospects listed here are often associated with arc volcanism linked to the subduction process of converging tectonic plates as seen in Tangkuban Perahu, Sungai Penuh, Ijen, Lawu, and Baturraden and others. The summary of these geothermal prospects characteristics categorized as Ranking 1 is presented in Table 1.

Based on their temperature, the fields listed in Rank 1 RUPTL 2021-2030 are predominantly categorized as high-temperature resources (14 of 22 fields). Most of them are in the exploration phase, such as Kepahiang, Rajabasa, Mount Sirung, while some fields have entered the development phase, including Ijen and Sungai Penuh. Additionally, some medium-temperature systems are also included in Rank 1, such as Danau Ranau, Cisolok, Baturaden, with a targeted production of about 350 MW much lower than the targeted production from the high temperature resource about ~1.1 GW.

Nevertheless, it is evident that medium to high-temperature resources still have a higher priority for future geothermal development in Indonesia (15 of 22 fields). However, it must be noted that temperature information from those listed fields still has some degrees of uncertainty as it derives from geochemical analyses, which may not fully represent the actual reservoir temperature in the subsurface. The distribution of the fields listed in rank 1 based on its temperature category are presented in Figure 3.

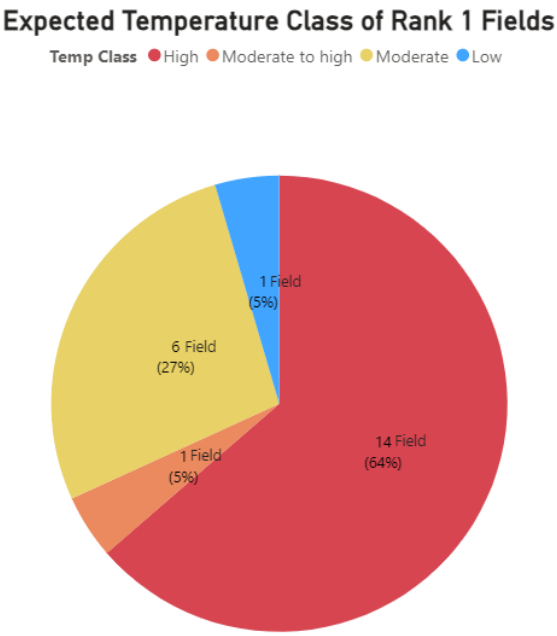

Figure 3: The distribution of the fields listed in rank 1 based on its interpreted reservoir temperature.

3.2 Rank 3 Indonesia's geothermal prospects in RUPTL 2021-2030

Unlike the fields listed in Ranking 1, the geothermal prospects listed in Ranking 3 have not yet been included in the 'Neraca Daya' and are currently not prioritized for immediate development, consisting of eighty fields. Based on their geological association, the fields listed in Rank 3 are more fairly distributed, situated in both magmatic and non-magmatic environments. The fields associated with volcanism generally share common characteristics with the currently developed geothermal fields. However, there are also fields situated in volcanic complexes without magmatic signatures (e.g., Candi Umbul-Telomoyo).

Table 1: Summary of geothermal fields characteristics categorized as Rank 1.

No	Geothermal field	Geologic factor	Reservoir temperature (°C)	Temperature category (Sanyal, 2005)	Reference(s)
1	Jaboi	Hybrid (young volcanism and fault systems)	327°C (gas geothermometry)	High	(Dwipa, et al., 2006; EBTKE, 2017; Nugraha & O'Sullivan, 2019)
2	Sungai Penuh	Subduction Young volcanism	250-280°C (gas geothermometry)	High	(Hochstein & Sudarman, 2008; Sukhyar, et al., 2010; Darma, 2016; EBTKE, 2017)
3	Danau Ranau	Subduction Young volcanism	200-220°C (Na-K-Mg)	Medium	(Afiat, et al., 2020; Idianto, et al., 2021; Rera, et al., 2021)
4	Hululais	Subduction Young volcanism	225-285°C (gas geothermometry from Kawah Biru and Kawah Hitam), >300°C (gas geothermometry from Kawah Belerang Atas)	High	(Kamah, et al., 2015; EBTKE, 2017; Nurseto, et al., 2021)
5	Kepahiang	Subduction Young volcanism	250°C (gas geothermometer fumarole of Kaba Crater)	High	(EBTKE, 2017; Nurdyanto, et al., 2019; Nurseto, et al., 2021)
6	Rajabasa	Subduction Young volcanism	260-265°C (Way Merak), 300-325°C (gas geothermometry)	High	(Darmawan, et al., 2015; EBTKE, 2017)
7	Rawa Danau	Subduction Young volcanism	260-270°C (gas geothermometry)	High	(EBTKE, 2017; Syah, et al., 2019; Sumotarto, et al., 2019)
8	Cibuni	Subduction Young volcanism	305°C	High	(Layman & Soemarinda, 2003)
9	Tangkuban Perahu	Subduction Young volcanism	200-285°C (Na-K geothermometry)	Medium to high	(Hochstein & Sudarman, 2015; Gaffar, 2018)
10	Cisolok-Cisukarame	Subduction Young volcanism	185-212ºC (Na-K geothermometry)	Medium	(Mandradewi & Herdianita, 2010; Sumartha, et al., 2020)
11	Tampomas	Subduction Young volcanism	187-208°C (Silica geothermometry) (Direktorat Jendral EBTKE, 2017), 160-175°C (silica geothermometry), 170 ± 10°C (Na/K geothermometry)	Low to Medium	(EBTKE, 2017; Permadi, et al., 2022)
12	Candradimuka	Subduction Young volcanism	250°C - 289°C (gas geothermometry)	High	(Bagaskara, et al., 2021)
13	Ungaran	Subduction Young volcanism	>300°C (gas geothermometry), Gradient temperature 10.4°C /100 m (thermal gradient well USL-1)	High	(Phuong, et al., 2012)

No	Geothermal field	Geologic factor	Reservoir temperature (°C)	Temperature category (Sanyal, 2005)	Reference(s)
14	Baturaden	Subduction Young volcanism	204-210°C (Na-K-Mg geothermometry)	Medium	(EBTKE, 2017; Harijoko & Juhri, 2017; Iswahyudi, et al., 2020)
15	Guci	Subduction Young volcanism	170-190°C (K-Na-Ca and Na-K-Mg geothemometry), 331-382°C (Na/K geothermometer) , 187-196°C (silica-enthalphy method)	Low to High	(Harijoko & Juhri, 2017; Iswahyudi, et al., 2020; Harijoko, et al., 2021)
16	Ijen	Subduction Young volcanism	250 - 300°C (in EBTKE, 2017)	High	(EBTKE, 2017; Daud, et al., 2019)
17	Telaga Ngebel	Subduction Young volcanism	250 - 260°C	High	(EBTKE, 2017; Yudiantoro, et al., 2020)
18	Bedugul	Subduction Young volcanism	280 - 320°C	High	(Darma, et al., 2010)
19	Tulehu	Hybrid (young volcanism and fault systems)	>230°C	High	(Daud, et al., 2022)
20	Atadei	Hybrid (young volcanism and fault systems)	~221°C (gas geothermometry)	Medium	(EBTKE, 2017; Prabata, 2018)
21	Oka Ile Ange	Subduction Young volcanism	148-173°C	Low	(Nugraha, et al., 2018; EBTKE, 2017)
22	Mount Sirung	Subduction Young volcanism	260°C (H2-CO2 gas geothermometry)	High	(EBTKE, 2017; Putriyana, et al., 2021)

The non-magmatic prospects listed in the Ranking 3 category are typically fault-controlled, with hydrology and resource distribution primarily confined by fault or fracture systems. Most of these prospects are located in Sumatra along the graben structure controlled by the GSF, such as Bonjol, Simisuh, Sumani, and Panti. In Sulawesi, the Palu-Koro fault zone also phosts several low-temperature geothermal prospects, including Bora Pulu, Marana, and Kadidia (EBTKE, 2017), while the Gorontalo graben zone hosts Suwawa and Pentadio prospects (Pasaribu, et al., 2023).

Some prospects are also associated with Tertiary volcanism, such as Cilayu and Ciseeng. According to the Geothermal Potential Book by EBTKE (2017), another type of geothermal resource in Indonesia is the hot sedimentary aquifer systems, exemplified by Sajau. However, this type of resource is not included in the RUPTL 2021-2030. A summary of geothermal prospects categorized as Ranking 3 is presented in Table 2.

Table 2: Summary of geothermal fields characteristics categorized as Rank 3.

Geologic Factor	Res. Temp. Classification (Sanyal, 2005)	Geothermal Field(s)	Reference

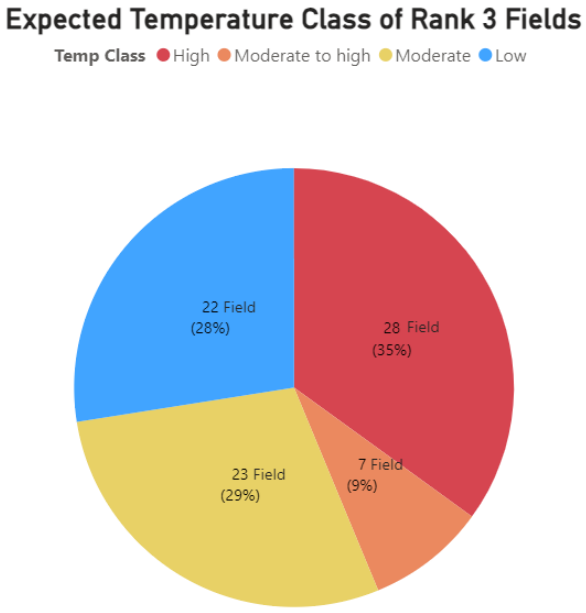

Figure 4: The distribution of the fields listed in rank 3 based on its interpreted reservoir temperature.

Slightly similar to the previously fields in Rank 1, several high-temperature fields are still included in Rank 3. However, a considerable amount of low to medium-temperature geothermal fields have already been included on this list (45 of 80 fields). It implies that after the fields listed in Rank 1 are already developed (which are mostly high temperature), the fields listed in this Rank 3 will become the next priority to be developed. Therefore, the

importance of further study on the exploration and utilization of the low-medium temperature systems in Indonesia should be initiated. The distribution of the fields listed in rank 3 based on its temperature category are presented in Figure 4.

4. RESOURCE CHARACTERISTICS OF FUTURE INDONESIA'S GEOTHERMAL PROSPECTS

4.1 Rank 1 Indonesia's geothermal prospects characteristics

Indonesia's geothermal prospects in Ranking 1 are predominantly influenced by arc volcanism associated with the subduction process. These areas are typically situated from the half-section to the active conduit-crater flanks of stratovolcanoes, exemplified by locations such as Tangkuban Perahu, Sungai Penuh, and Ijen (Danar & Syukar, 2010; Hochstein & Sudarman, Indonesian Volcanic Geothermal Systems, 2015; EBTKE, 2017), also within the crater such as Candradimuka prospect in Mt. Lawu (Bagaskara, et al., 2021). Meanwhile, prospects like Guci and Baturaden represent outflow systems from Mt. Slamet (Harijoko, et al., 2021), characterized by fumaroles and acidic hot springs in the upflow beneath the upper flank, with dilute chloride-bicarbonate discharges around the foothill as the outflow zone.

Developing geothermal resources in the magmatic environment requires consideration of the risk associated with acidic magmatic water, evident in fluid chemistry signatures. Several fields exhibit high non-condensable gas (NCG) content, such as Sungai Penuh with NCG around 0.5% and Bukit Daun reaching 6.83% near Kawah Belerang Atas (EBTKE, 2017). Lessons from developed geothermal fields in Indonesia like Lahendong, Dieng, and Sorik Marapi can inform strategies for managing high NCG contents in power plants.

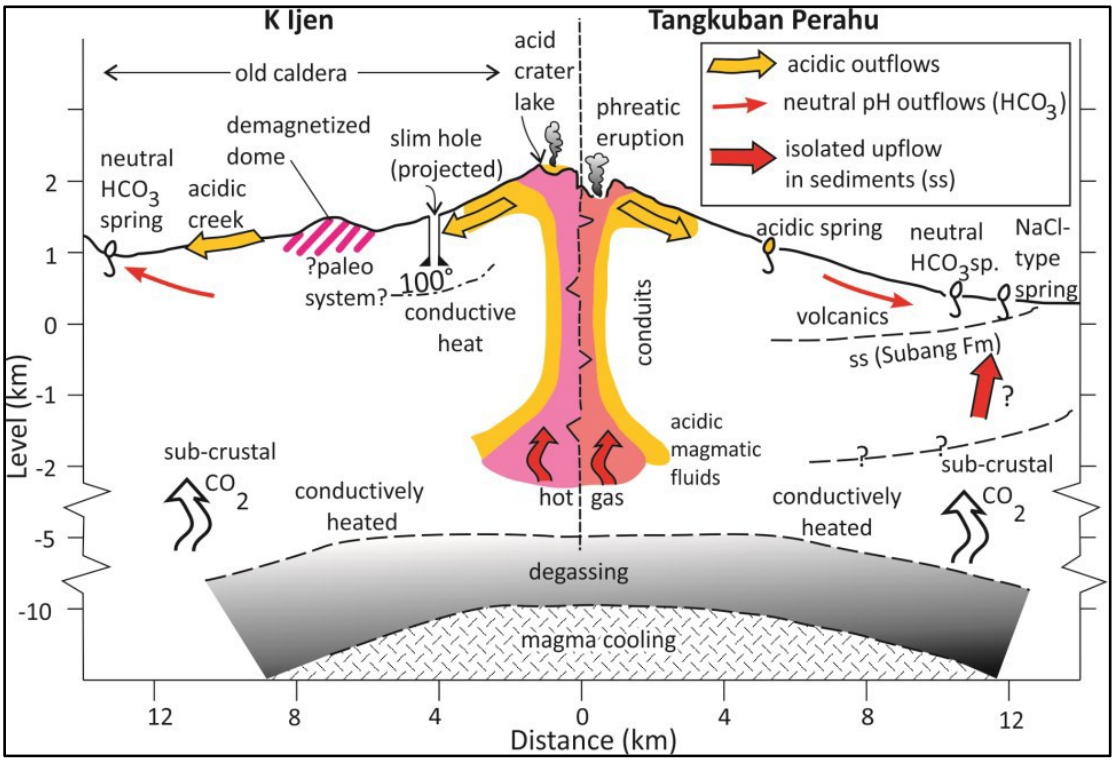

Figure 5: Illustration of volcanic-hosted geothermal systems at the Ijen and Tangkuban Perahu prospects typically associated with high-standing Quaternary volcanoes (conceptual model from Hochstein & Sudarman, 2015).

The absence of chloride hot springs and the prevalence of unequilibrated thermal manifestations—such as diluted and acidic condensate waters—in most prospects in this category limit the applicability of solute geothermometers. Gas geothermometers are often utilized for assessing reservoir temperatures (Hochstein & Sudarman, Indonesian Volcanic Geothermal Systems, 2015). Reservoir temperatures in Ranking 1 prospects generally range from moderate to high. Some intermediate to high temperature prospects, like Danau Ranau and Cisolok, indicate a cooling down process (Mandradewi & Herdianita, 2010; Rera, et al., 2021). The example of volcanic-hosted geothermal systems for some prospects in in Indonesia is illustrated in Figure 5.

Additionally, there are prospects in Indonesia that are expected to exhibit a hybrid nature, influenced by both magmatic activity and fault systems. For example, Jaboi on Weh Island is controlled by the Great Sumatran Fault (GSF), occurring within the graben zone formed by the stretching of faults like Leumo Matee (NNW-SSE) and

Ceunohot (NE-SW) as part of the GSF on the western side of Sumatra. Jaboi's heat source is likely associated with the Leumo Matee and Seumeureguh volcanoes; however, the occurrence of the Ceunohot fault likely controls the highest temperature zones in Jaboi. This is indicated by gradient thermal well data, which shows that wells situated closer to the fault tend to have higher temperature conditions than those located farther away (Dwipa, Widodo, Suhanto, & Kusnadi, 2006; Soetoyo & Widodo, 2010; Sumintadireja, Kasbani, & Suhanto, 2010; Nugraha & O'Sullivan, 2019). Conceptual model of Jaboi geothermal systems is presented in Figure 6.

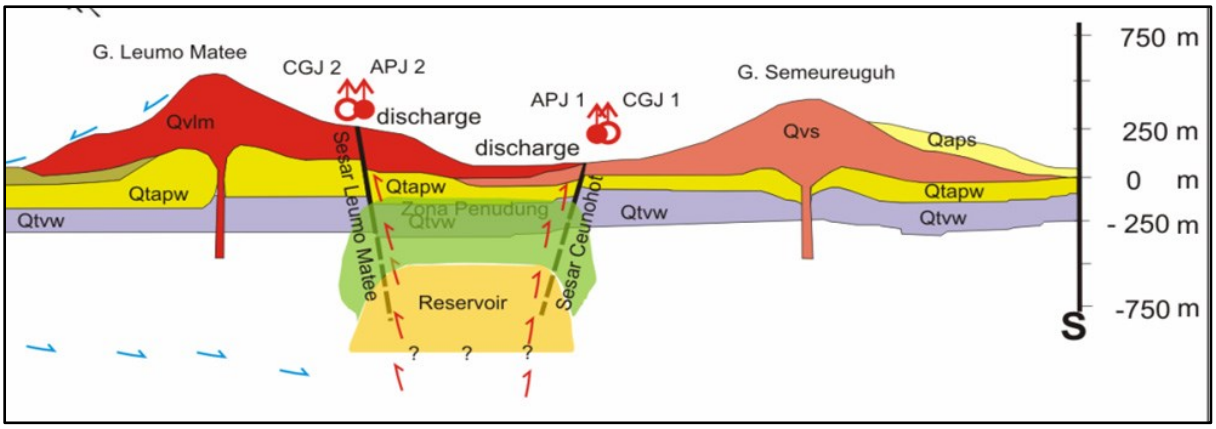

Figure 6: The Jaboi geothermal system might be categorized as a hybrid. Although Mount Leumo Matee and Seumeuregeu likely provide the heat sources, drilling data indicates that faults control the high-temperature zones within the system (conceptual model from Sumintadireja, et al., 2010).

Hybrid systems also might be seen for several prospects in Eastern Indunesia such as Tulehu (Molucca) and Atadei (East Nusa Tenggara). Tulehu, situated along NE-SW normal faults, is governed by Mt. Eriwekang as a potential heat source, supported by age dating indicating Quaternary eruptions around 413±6 kA (Daud et al., 2022). Na-Cl waters discharge along the northeastern shore and within the Tulehu peninsula, exemplified by undiluted geothermal liquid at Pulau Batulompa, characterized by high SiO2, K, and Li contents typical of deep, high-enthalpy geothermal reservoirs with temperature around 230°C (Marini & Susangkyono, 1999; Daud, et al., 2022). Meanwhile, Atadei, situated in the Watuwawer Caldera complex within the Quaternary Stratovolcano system comprising Mt. Ile Ape, Mt. Ile Werung, and Mt. Ile Hobal, relies on an intrusive magma chamber beneath Watuwawer Caldera as its heat source. This system is influenced by deep leakage along the Watuwawer and Lewo-Kebingan faults, allowing upwelling of hot geothermal fluid to Watuwawer Caldera and lateral flow through Mauraja Fault. Atadei is characterized by medium reservoir temperatures (Prabata, 2018).

4.2 Rank 3 Indonesia's geothermal prospects characteristics

Several geothermal prospects listed in Ranking 3 are influenced by magmatism associated with Quaternary stratovolcanoes. Thermal manifestations from magmatic influence include fumaroles (e.g., Seulawah Agam, Margabayur, Bukit Daun), solfataras (e.g., Bukit Daun), and sulfate hot springs (e.g., Tujuh Warna Crater in Bukit Daun). Some prospects lack gas or magmatic signatures, like Candi Umbul-Telomoyo, where thermal manifestations are primarily dilute chloride-bicarbonate springs (Hermawan, et al., 2012). Some of these prospects are expected to have high reservoir temperatures, including Seulawah Agam, Margabayur, Gede Pangrango, Papandayan and others. Additionally, some prospect exhibit medium to high temperature systems, such as Sekincau, Way Ratai, Mt. Ciremai, Jailolo, and Wae Sano. Hybrid systems are expected to occur in some low to medium geothermal prospects in Sumatra, including Simisuh, Bonjol, Sumani, and Panti.

Additionally, many of geothermal prospects in Rank 3 can be categorized as fault-controlled geothermal systems, where the heat source is unrelated to Quaternary magmatism, with hydrology systems and resource distribution primarily constrained by fault systems. In Central Sulawesi, prospects like Kadidia, Bora-Pulu, and Marana are influenced by the Palu-Koro sinistral strike-slip fault, creating graben zones with transtensional regimes (Figure 7). The heat source here is predicted to be deep Miocene to Pliocene granitic intrusions, with reservoir rocks comprising Pre-Tertiary to recent metamorphic and sedimentary rocks (EBTKE, 2017; Rachmatika, Haryanto, Hutabarat, Hermawan, & Mustofa, 2019). In Gorontalo, prospects like Suwawa, Pohuwato, and Pentadio are governed by the Gorontalo graben zone within the Limboto-Bone rift (Pasaribu, et al., 2023), featuring dyke systems beneath the graben zone as heat sources. In South Sulawesi, Bituang, Pincara, and Limbong are controlled by normal faults, heating through Tertiary volcanism (EBTKE, 2017). In Southeast Sulawesi, Lainea is influenced by the NW-SE Boro-boro fault, arising from the collision zone of the Australia Microcontinent, with fluids infiltrating through fault planes heated by metamorphism (EBTKE, 2017).

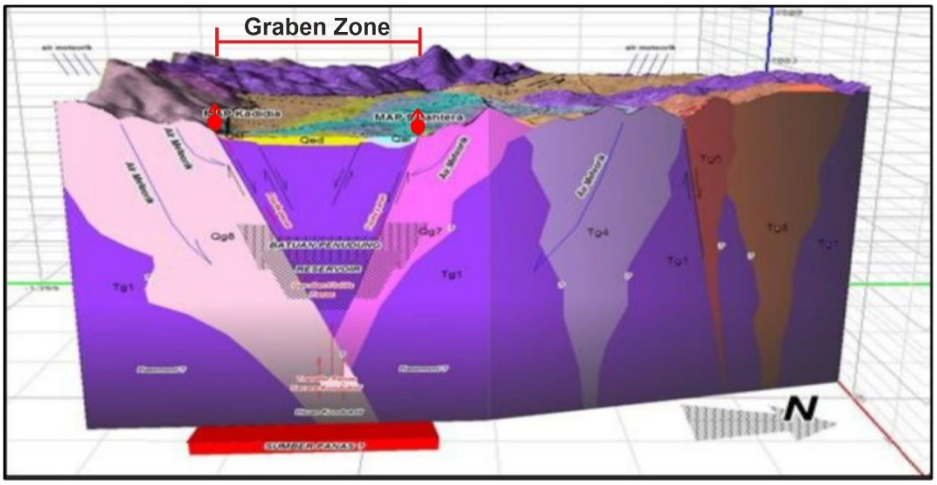

Figure 7: The Kadidia prospect in Sulawesi can be categorized as a fault-controlled system. This prospect is located within the graben zone created by the Palu-Koro fault systems. The faults allow deep fluid circulation within the graben, forming a geothermal system characterized by the presence of several warm springs in proximity of the faults (conceptual model was modified from EBTKE, 2017).

In Java, there are geothermal prospects associated with Tertiary volcanism such as Cilayu and Ciseeng, which are hosted by Middle Miocene diorite intrusions uplifted along fault planes, influencing thermal anomalies and fluid hydrology (Herdianita & Priadi, 2008; Azzam, et al., 2020). In the Moluccas, some geothermal prospects such as Tehoru and Badar Baru are interpreted to be influenced by metamorphic complexes (Siombone, 2022; Yushantarti & Hermawan, 2022). All of these Tertiary and metamorphic-influenced geothermal systems are interpreted to have low to medium temperature reservoirs.

5. CONCLUDING REMARKS AND PATH FORWARD

Currently, most of the developed geothermal fields in Indonesia are volcano-hosted high-temperature resources, providing abundant lessons learned for developing potential high-temperature resources in the future. However, it is worth noting that Indonesia also has considerable potential in low-temperature geothermal prospects, none of which have been developed yet.

High-temperature resources still have a higher priority for future geothermal development in Indonesia, as many high-temperature fields are listed in the RUPTL 2021-2030 as National Strategic Projects (Rank 1 category). However, a significant number of low to moderate-temperature geothermal fields are also listed, though with a lower priority (Rank 3 category). Despite their current low priority, many low to moderate-temperature resources are expected to be part of Indonesia's future development pipeline.

Geothermal developers and investors in Indonesia face challenges in developing low to moderate-temperature geothermal resources due to a lack of experience or success stories to draw from. This underscores the critical need for further study and exploration of these geothermal systems. Building the necessary knowledge and strategies for successful development, including their discovery and utilization, is essential to unlocking the potential of these resources in Indonesia.

To optimize geothermal development strategies in Indonesia, implementing development strategies, technologies, and utilization methods used in developed low to medium geothermal fields worldwide, such as those in the USA, Turkey, and other countries, could serve as an initial step to initiate development of low to medium geothermal prospects in Indonesia. This study represents our next path forward, building on the findings of our initial study.

To analyze comparable development strategies and practices that can be applied in the Indonesian context, it is crucial to acknowledge the unique characteristics of each geothermal field worldwide. Factors such as geologic conditions, fluid characteristics, and power generation technology selection can significantly influence geothermal development strategies. Therefore, categorizing similar geothermal fields into distinct categories and comparing fields within the same category offers the best methodology for analysis, considering the diverse factors that influence development strategies. This approach will guide our future research efforts in optimizing geothermal development strategies in Indonesia.

Keywords: Hot Sedimentary Aquifer, Midyan, Saudi Arabia, Low-medium Enthalpy, Geothermal

ABSTRACT

The hot sedimentary aquifer geothermal system is believed to be well-developed in the west coastal region of the Arabian Peninsula, particularly in the Midyan area, located in the northwestern part of the Kingdom of Saudi Arabia. Numerous efforts have been undertaken to conduct geoscientific exploration in this area, including geological mapping through remote sensing and ground-truthing activities, geophysical studies involving aeromagnetic surveys, regional gravity measurements, active seismic surveys, and the evaluation of pre-existing hydrocarbon exploratory wells. These efforts, involving the evaluation of combined public domain data and direct acquisition of field data, aim to assess the geothermal energy potential of the area.

The Midyan Basin exhibits elevated heat anomalies in the basin depocenter, primarily hosted in the pre-salt formation reservoir. This reservoir is intensely fractured due to the Red Sea rifting and the movement of the Gulf of Aqaba strike-slip fault. The heat source is interpreted to originate from the deep mantle, combined with radiogenic heat production from radioactive minerals in the granite basement. The presence of the salt formation also contributes to the elevated heat in this area, acting as a cap rock that seals hot water within the pre-salt reservoirs. The pre-salt formations, likely the Al Wajh, Burqan, or Magna formations, are interpreted to be the reservoir of the system, capped by the Mansiyah salt formation and intra-silt, mud, and claystone layers within each formation.

The next challenges in developing this energy source include drilling deep enough to prove the conceptual model while considering the potential of intersecting hydrocarbon prospective reservoirs and associated geohazards. Additionally, the hot water in the reservoir may not be sufficient for self-discharge to generate power, necessitating the use of downhole heat pumps to extract this energy. However, direct-use applications should also be considered for this energy source, given the high demand. These factors will significantly impact the economic viability of this geothermal prospect area.

1. INTRODUCTION

Geothermal resource province in Saudi Arabia particularly lies on the western coast and is associated with the Red Sea. The distinguished geothermal resource potential is commonly in accordance with volcanic fields (called Harrat) and was inferred by the presence of hot springs, specifically in Jizan and Al Lith. However, there are potential areas that might host the hot sedimentary aquifer system within the basin along the west coast, including in the Midyan area at the northwestern.

In Midyan area, however, there is no surface thermal manifestation identified. Despite the lack of surface manifestations, several studies have shown the presence of high heat flow in Midyan area (e.g., in Aboud, et al., 2023). This absence of surface indicators could be due to several factors: there may be no hydrothermal activity present, or the heat could be confined within a sedimentary basin, forming a confined aquifer. The latter condition is particularly relevant in the context of the Midyan region due to its subsurface geology condition.

In this paper, we present the results of our surface geoscientific investigations in the Midyan Area, providing insights into the geothermal characteristics of this region. We discuss the geological and geophysical data collected, analyze the potential for a hot sedimentary aquifer system, and propose further steps for geothermal exploration and development. By understanding the geothermal potential in this area, Saudi Arabia can diversify its energy portfolio and contribute to global efforts in sustainable energy utilization.

2. GEOLOGICAL SETTING

The Midyan basin (Figure 1) is geologically influenced by the development of the Red Sea Rifting and the Strike Slip movement of the Gulf of Aqaba. The Red Sea Rifting is part of the triple junction in the Afar region that spreads the Arabian Plate, Nubian Plate, and Somali Plate, then it creates the Red Sea Rift, Gulf of Aden Rift, and

Main Ethiopian Rift. The main Ethiopian rift is well known as the main heat provider of the geothermal system in the East Africa region.

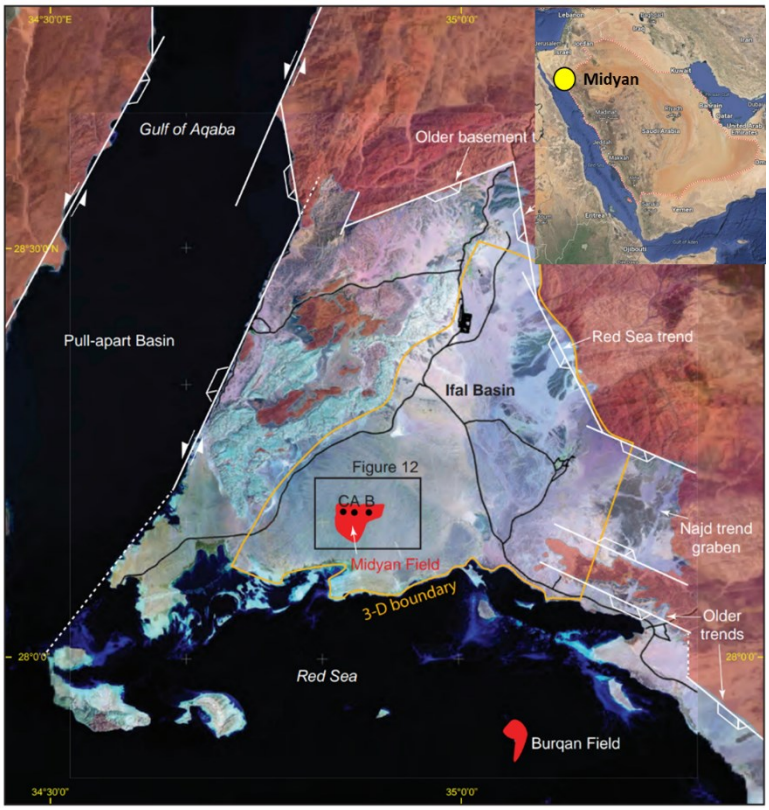

Figure 1: Tectonic framework of the Midyan Area (modified from Tubbs, 2014).

The Red Sea rift stretched out from the Afar region, at the south to the Gulf of Suez, towards the north. In the early stages of the rift, the Gulf of Suez was part of the Red Sea, sharing its geological history and structural patterns. The Red Sea basin features several zones of half-grabens that dip towards either the Arabian or African plates, with accommodation zones in between. These structures have been extensively studied in the Gulf of Suez and observed throughout the main Red Sea area.

2.1 The Red Sea Rift Development

The Red Sea Rift initiated 30-32 million years ago by the depression of the Afar plume, rifts the African-Arabian continental plate, and eventually developed into an oceanic rift. Prior to the beginning of the Red Sea Rift periods, the pre-Miocene formations existed with the Cretaceous formations being the oldest. These formations are thickest at the Gulf of Suez and become thinner towards the south, disappearing offshore and in outcrops in the northern areas of the Red Sea. Some Cretaceous outcrops are preserved within grabens along the Saudi western coast, extending towards the Yemen border.

- **Early Rift Stage (31-27 Ma)**

  During the early rift stage, characterized by normal extension, the entire 2,200 km long Red Sea opened simultaneously (Figure 2 left and Figure 2 right). At this time, the Early Oligocene deposits consisted of continental sands from the Al Wajh formation, present as continental red beds and lacustrine deposits up to 2200 meters thick. This period was followed by a marine incursion that deposited deep marine turbidites of the Burqan formation in tectonically active regions (Bosworth, et al., 2005).

- **Mid-Rift Stage**

  During 18-17.5 Ma, a significant environmental change occurred, marked by mid-clysmic unconformity during the Burqan sedimentary deposition. This event ended the deposition of the Maqna group, which showed low tectonic activity and basin-wide restriction (Figure 3 left and Figure 3 right), leading to the formation of regional anhydrite layers and the extensive Mansiyah halite (Bosworth, et al., 2005).

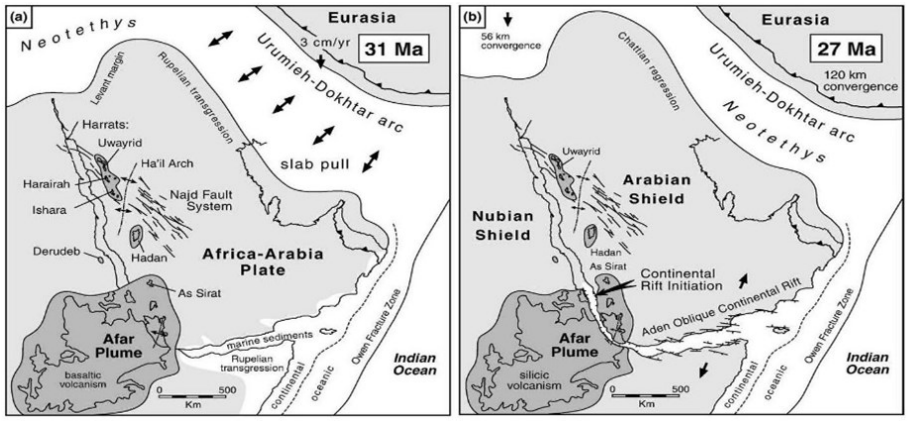

Figure 2: The early stage of the Red Sea rifting (Bosworth, et al., 2005).

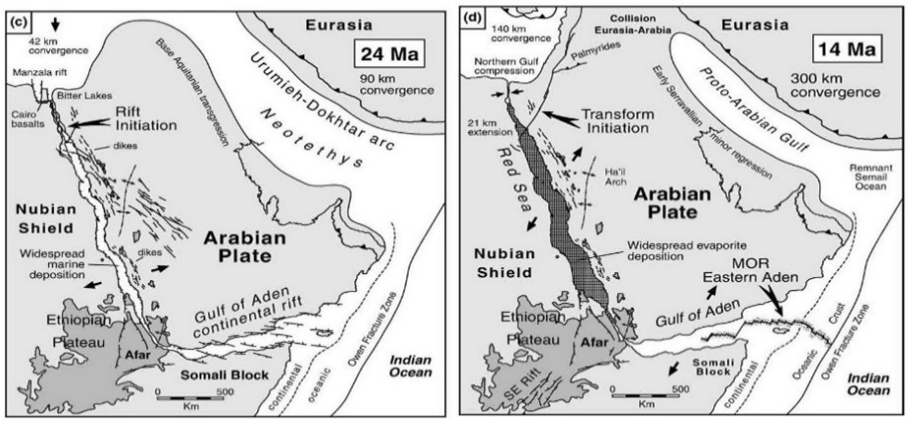

Figure 3: The mid-Clysmic unconformity occurred (Bosworth, et al., 2005).

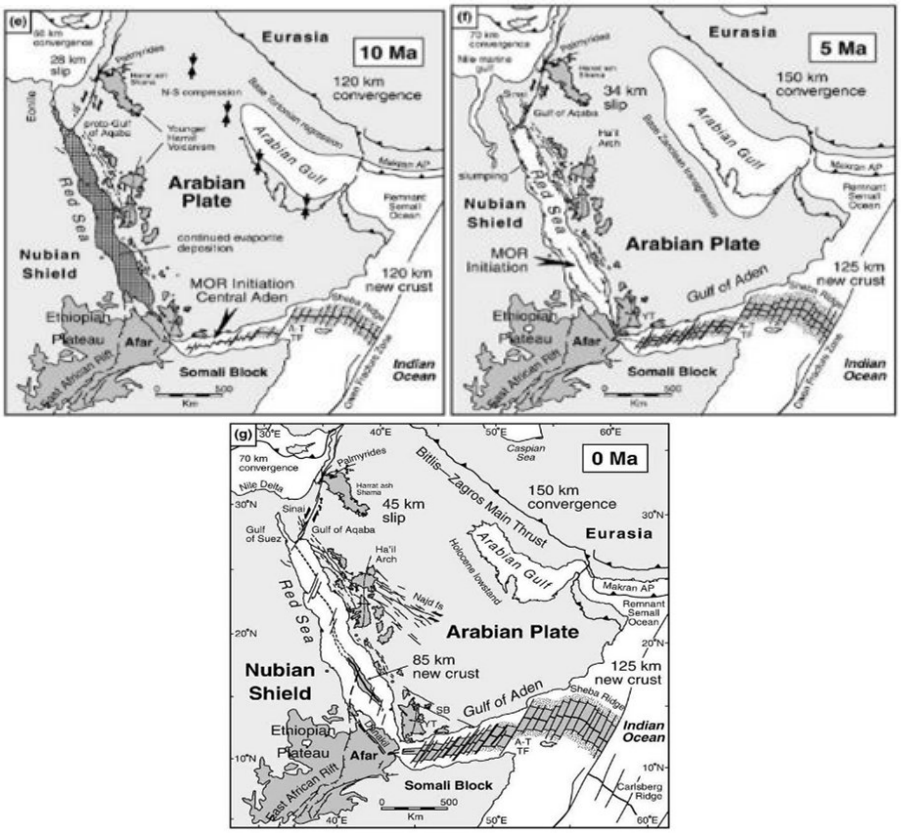

Figure 4: The late rift sequence and the opening of the Gulf of Aqaba (Bosworth, et al., 2005).

- **Late Rift Stage (14-12 Ma)**

  The Gulf of Aden rift evolved into an oceanic ridge with seafloor spreading. The collision between the Arabian and Eurasian plates rotated the Arabian plate counterclockwise, shifting the Red Sea to a rift-oblique extension (Figure 4 upper left, Figure 4 upper right, and Figure 4 bottom). This reactivated faults and caused strike-slip deformation, particularly in the northern Red Sea and the Midyan peninsula (Bosworth, et al., 2005).

2.2 The Gulf of Aqaba Opening

The counterclockwise rotation of the Arabian plate causes the opening of the Gulf of Aqaba, halting extension along the Gulf of Suez. This created strike-slip deformation across the basin, along the Gulf of Aqaba, and extended to the Dead Sea at the further north (Figure 5). This is also altering subsalt topography and causing the Mansiyah halite to move towards the center of the Red Sea. This process formed accommodation zones filled by the post-salt Ghawwas and Lisan formations.

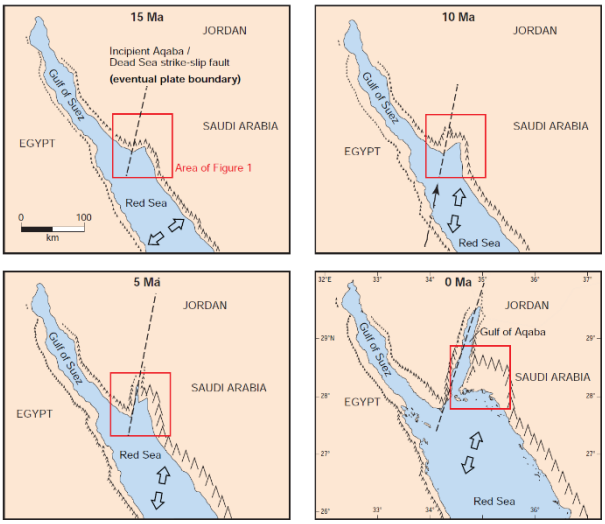

Figure 5: The opening of the Gulf of Aqaba (Tubbs, et al., 2014).

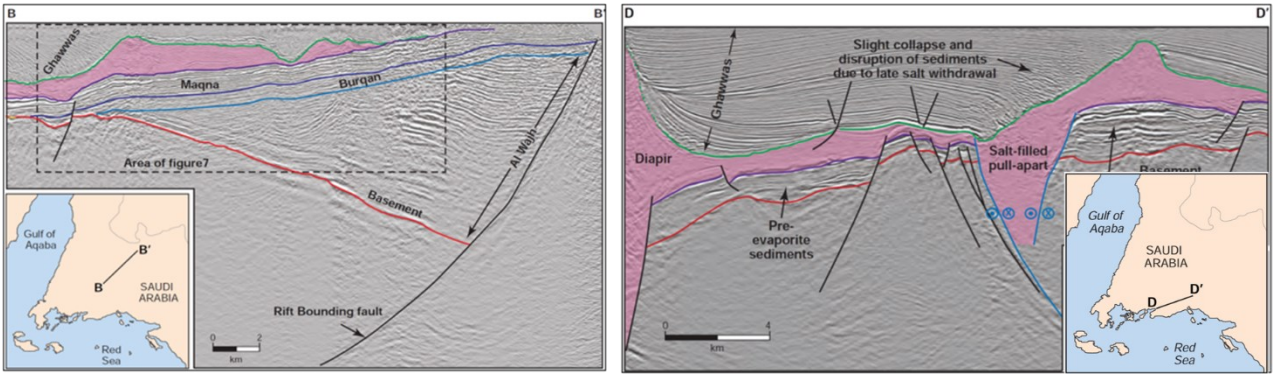

Figure 6: The Midyan basin structures (vertically exaggerated) described by Tubbs, et al. (2014)., Rift-basin structure is shown on the left side while pull-apart basin structure is shown on the right side.

3. MIDYAN BASIN MODEL AND STRATIGRAPHY LAYERS

The Basin model of Midyan area has been constructed comprehensively while doing hydrocarbon exploration by some parties. 2D and 3D seismic lines cover this area evenly and help to understand the basin structures, including the stratigraphic layers in it. Tubbs, et al. (2014), shows six seismic profiles and the interpretation across the area (Figure 6). Additionally, during the geothermal exploration, some other parties have added the 2D seismic lines to investigate the depocenter of the basin further where it is extended to Al Bad' at the north and Ras Shaik Humaid at the west.

The Midyan Basin is primarily characterized as a half-graben structure, formed due to extensional tectonics during the Miocene. The structural framework of the basin is defined by a series of normal faults, which are crucial for

the deposition and preservation of sedimentary layers. Additionally, the area is influenced by the strike-slip movement of the Gulf of Aqaba and the Dead Sea fault. This is evidenced by the presence of strike-slip faults observed in surface rock scarps and pull-apart structures within the region.

The basin fill comprises thick sequences of syn-rift siliciclastic rocks, which are primarily deposited during periods of tectonic activity. The pre-rift section comprised by **Neoproterozoic basement** that consists of commonly granitic, also metasediments, metavolcanics, and gabbro, with noticeable pockets of Cretaceous Adaffa Sandstones (Clark, 1987 in Tubbs, et al., 2014). The syn-rift section is comprised of Al Wajh formation, Burqan formation, Magna group, and Mansiyah formation. The post-rift section consists of Lisan group, Ghawwas formation, and post-Ghawwas formation (Beydoun, 1991; Hughes & Beydoun, 1992).

- **The Al Wajh formation** represents the earliest rift deposition of continental red beds that form sand wedges on top of the basement, generally within rotated half grabens. The Al Wajh sediment is expected to be composed of high porosity sandstone with the possibility of layers of tight facies in shales that were deposited along lacustrine beds in the basin.
- **The Burqan formation** signifies the first basin-wide marine incursion, marking the organized rift propagation across the Red Sea basin and its connection with global oceans. It consists of marine turbidites and is generally composed of interbedded sandstones and mudstones/shales, creating vertically stacked reservoir-seal pairs.
- During the formation of **the Maqna group**, rift kinematics started to slow down onshore, and there is evidence of basin-wide restrictions. The Maqna group comprises formations of siliciclastic/carbonate layers and anhydrite layers, resulting in vertically stacked reservoir-seal pairs, with the two anhydrite formations acting as seals.
- **The Mansiyah formation** is characterized by massive halite deposits, marking the peak of basin-wide restriction and a period of slow subsidence. This formation is correlated with the end of the active rift phase of the Red Sea faults and the activity along the Gulf of Aqaba strike-slip. The Mansiyah salt acts as the ultimate regional seal, capping the Maqna group, and is effective unless rift faults offset the base of the salt by more than the remaining salt thickness.
- Finally, **the Ghawwas formation** is a post-salt formation that is heavily influenced by salt evacuation, which controls both accommodation space and formation structures. This formation's characteristics are shaped by the dynamics of salt movement and the resultant geological features

4. GEOTHERMAL CONCEPTUAL MODEL

Currently, there are no geothermal drilling explorations conducted in the Midyan area to explore the subsurface parameters that were used to construct the geothermal conceptual model. Thus far, the conceptual model has been constructed by the surface geoscience data and the addition of the oil and gas wells data.

Extensive geoscience surveys have been conducted in the area, including comprehensive 2D and 3D seismic surveys. Regional magnetic data has been utilized to identify basement anomalies and determine the Curie depth. Additionally, regional gravity data from the Saudi Geological Survey has been used to enhance the interpretation of basement distribution and inferred faults. Surface geological mapping has also been performed to document the variety of lithologies, faults, and fractures. However, the absence of surface geothermal manifestations in the region makes the interpretation quite challenging.

The geothermal system in the Midyan area is identified as a hot sedimentary aquifer type. The critical resource parameters of this system include the temperature, permeability, reservoirs, and cap rocks. The primary heat source is thought to originate from deep below the region, linked to a thinning crust. Additionally, radiogenic heat from the decay of radioactive minerals in the granite basement contributes to the area's heat anomaly. Heat is conducted through the basement rock and ascends via faults and fractures, while convective heat transfer is likely present in the sedimentary layers. The temperature contour in Figure 7 does not accurately represent the actual heat distribution in the system, as it is influenced by the variety of lithologies and local fractures.

The heat convects through the sandstone reservoir of the pre-salt formation, potentially originating from the Al Wajh, Burqan, or Magna formations. These sandstone formations share similar characteristics, including porosity, permeability, and anomalous overpressure pores. The reservoir's thickness ranges from 1-2 km and can reach up to 4-5 km at the basin's depocenter. The reservoir is capped by siltstone and claystone within the formation and by the Mansiyah salt layer. However, while the salt layer effectively caps fluid movement, it does not impede heat transfer due to its excellent thermal conductivity.

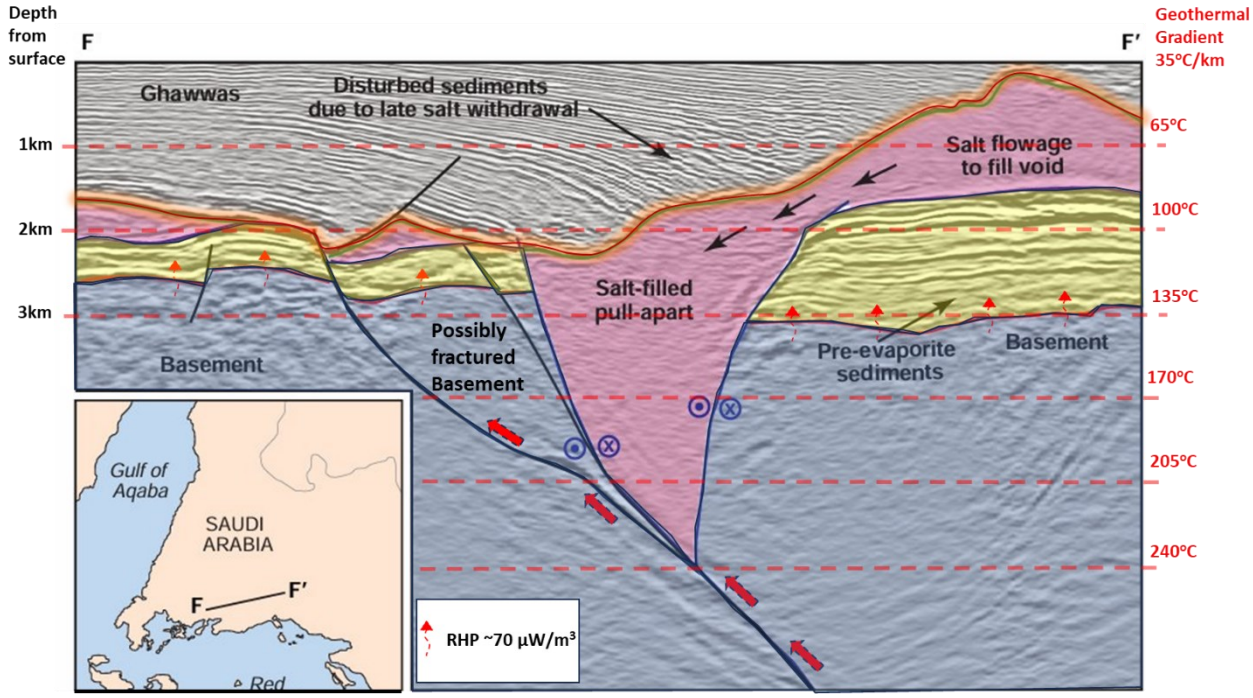

Figure 7: Proposed resource conceptual model in Midyan area (modified from Tubbs, et al., 2014). The geothermal gradient is inferred from the curie depth; The radiogenic heat production is analog from the closest surface granite analysis; Basement rocks are in dark gray, potential reservoir rocks in yellow, and the massive impermeable salt layer in pink.

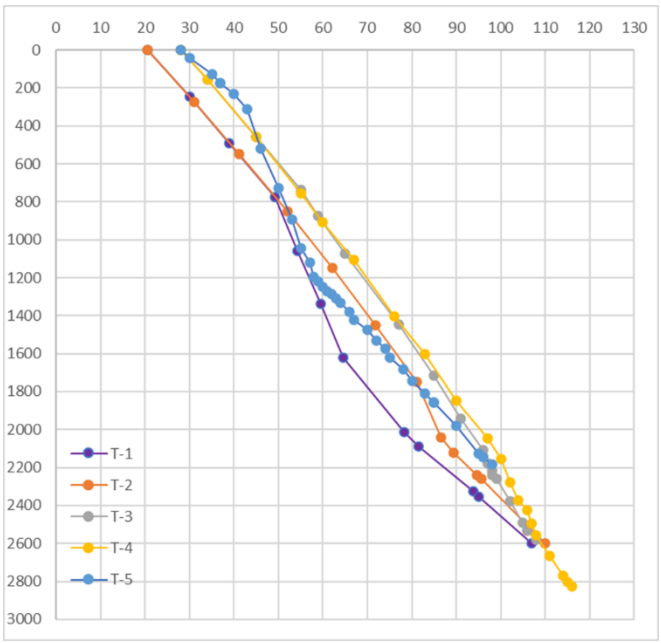

Figure 8: Temperature profile from several deep wells in the area.

4.1 Elevated Heat Anomaly

Heat exploration in the Midyan area is extremely challenging due to the absence of typical thermal signatures such as hot or warm springs, fumaroles, steaming ground, or altered ground that are usually found in conventional geothermal fields. The elevated heat in this region is theoretically interpreted from the regional geological setting associated with the thinning crust from the Red Sea rifting, which brings the hot mantle closer to the surface. This interpretation is supported by the curie temperature profile derived from regional magnetic data. Additionally, radioactive minerals from the granitic body bounding the basin could be a potential heat source for this system. The presence of a salt layer further aids in elevating heat along the body of the salt, allowing access to significant heat at shallower depths

4.1.1 Temperature Data from Deep Wells

There is limited subsurface data available in this area, sourced only from several deep wells (Figure 8). The quality of this data is uncertain, as the actual conditions of the wells are unknown. Additionally, the details regarding the measurement procedures, tool specifications, and the times at which measurements were taken are absent, making it impossible to conduct a data quality check. Furthermore, the locations of these wells are concealed to meet confidentiality protocols. From the deep wells, it is observed that the maximum temperature can reach 110°C at a depth of 2600 m, suggesting a temperature gradient of about 33-35°C/km for the deep formation.

4.1.2 Currie Point Depth

Curie temperature is a point at which magnetic minerals lose their magnetization due to high temperature (580ºC). It can be the bottom of the basement surface or the Moho surface (Aboud, et al., 2023). The curie point depth analysis was carried out by Aboud, et al. (2023) to image the subsurface of NEOM area, specifically the Midyan basin area. The data used in the analysis are collected worldwide from various magnetic surveys (ground, airborne, marine surveys) and compiled/merged into one magnetic model called World Digital Magnetic Anomaly Map (WDMAM). The result shows that the Curie point depth of the Midyan area is variously calculated at 12.9km to 15.4km at the promising area.

The curie point then can be used to calculate the regional temperature gradient of the area, considering the heat transfer mechanism is homogeneous to the surface. Simplified formula adapted to measure the geothermal gradient, Geothermal Gradient (GG) = 580ºC / Curie depth. The temperature gradient of the Midyan area is calculated at 37-44ºC/km at the promising area. To compare with the actual temperature data from the deep wells, at the depth of 3000m, it is calculated the temperature would be at 140-160ºC respectively with the average atmospheric temperature of 30ºC.

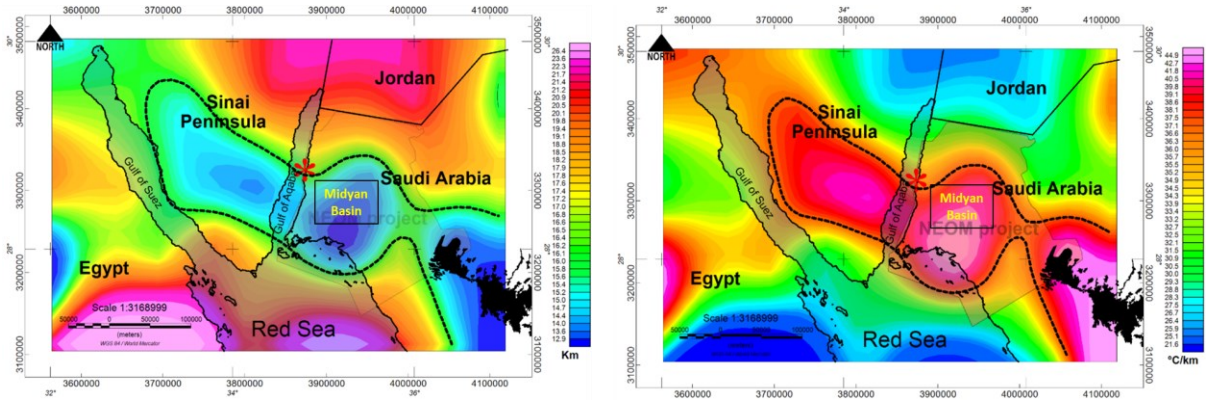

Figure 9: Currie depth map (left) and geothermal gradient map (right) from Aboud, et al. (2023).

4.1.3 Radiogenic Heat Source

Many studies have been conducted to assess the Radiogenic Heat Production (RHP) from the felsic plutonic rock within the Arabian Shield, particularly surrounding the Midyan area. Despite there being no sample directly taken from the subsurface basement of the Midyan area, the closest samples from Ghurayyah and the Gulf of Aqaba rocks could be the analog for the Midyan area (Figure 10). The amount of radioactive minerals is uniquely high, specifically in the veins of the rocks (see Table 1). During the radioactive decay, mass is converted to energy, and an important part of this energy is converted to heat. All natural radioactive isotopes generate heat to a certain extent but only the contributions of the decay series of 238U, 232Th, and the isotope 40K are geologically significant.

The same granite type is considered to exist as the basement of the Midyan basin. It appears in the seismic profiles that the basement spread evenly within the Midyan area with the top of the basement at 6 km at the depocenter, getting shallower towards the edge of the basin.

Table 1: Radioactive minerals from Felsic rocks taken from the surrounding Midyan area (modified from Harris & Marriner, 1980).

Sample	U (ppm)	Th (ppm)	K (wt%)	RHP (μW/m^3)
Ghurayyah Granite 1	104	625	2.59	70.2
Ghurayyah Granite 2	88	160	2.63	33.9
Gulf of Aqaba Granite (Vain)	363	590	1.65	134.2

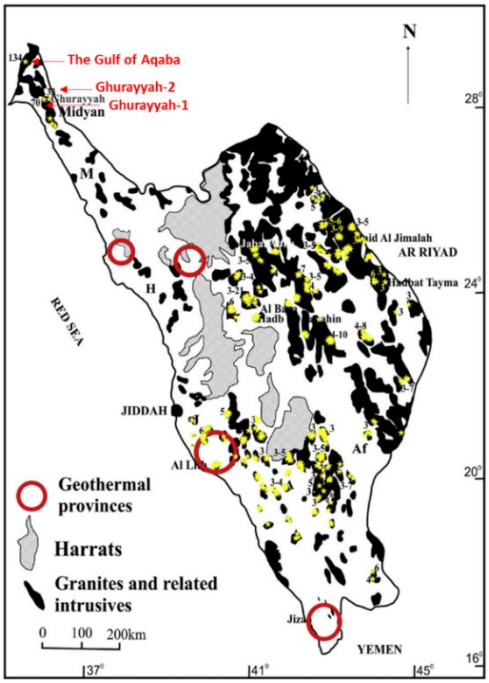

Figure 10: The location of Ghurayyah and The Gulf of Aqaba Granite samples (modified after Chandrasekharam, et al., 2015). The numbers indicate heat generated by the granites in µW/m3 calculated based on U, Th, and K values.

The radioactive heat production of granite rocks (RHP in μWm^{-3}) can be calculated by considering the heat generation constant (amount of heat released per gram U, Th and K per unit time) and from the uranium, thorium and potassium concentrations CU, CTh, CK present in rock (Cermak, Huckenholz, Rybach, & Schmid, 1982; Rybach, 1988 in Abbady & Al-Ghamdi, 2018):

$$RHP = \rho\,(9.52\,CU + 2.56\,CTh + 3.48\,CK)10^{-5} \quad (1)$$

where ρ is the bulk density of rock; Cu and CTh are in weight ppm; Ck is in weight %.

4.2 Salt Layer

The temperature gradient within sedimentary stacks in basin settings can be unusually high due to the increased thermal conductivity of salt layers. An analysis conducted in Eemshaven, Netherlands, reveals a temperature increase of between 17°C and 25°C at the same depth when comparing locations with normal stratigraphic salt thickness to those at the top of the salt structure (Daniilidis & Herber, 2017). Similarly, a study in the Pripyat Trough, Belarus, concludes that the highest heat flow density values, reaching up to 80-100 mW/m², occur at the crest of salt domes and caprocks, with a significant decrease at the base of the salt dome (Zui, et al., 2016). In the Midyan area, the presence of Mansiyah Salt locally affects the geothermal gradient and heat flow density within the basin. However, the proposed conceptual model does not yet reflect the final isothermal contour that accommodates the presence of the Mansiyah Salt.

Due to their high thermal conductivity, salt layers can act as efficient channels for heat, creating local positive thermal anomalies in the overburden of salt accumulations (Moeck & Breadsmore, 2014; Moeck, 2014). This unique property makes the areas above these formations are attractive targets for geothermal exploration, as the heat is channeled through the salt, creating a distinct temperature change in salt topography. Daniilidis & Herber (2017) demonstrated a 40% increase in energy extraction and a 25°C temperature rise within a salt formation in the north of the Netherlands, emphasizing the influence of salt thickness variations on heat gradients and thermal conductivity scenarios. Additionally, the geometric shape of salt domes affects heat accumulation, with narrower domes leading to less concentrated heat compared to elongated, conical structures (Daniilidis & Herber, 2017).

The presence of salt formations in the Midyan area can be identified through seismic line profiles published by Tubbs, et al. (2014). Modeling efforts of this salt formation are critical for geothermal resource modeling, as it influences heat flow direction within the reservoir. A study by Zui, et al. (2016) concludes that in the Pripyat field, Belarus, the salt layer controls heat flow density and direction. Additionally, the salt formation is impermeable; while it can conduct heat, it cannot allow fluid flow within the formation, thus acting as a cap rock for the underlying reservoirs. Understanding the Mansiyah Salt formation is essential for identifying where heat accumulates and how it is directed. This knowledge can help target resource areas, as it provides a substantial

amount of heat at both the top and bottom of the salt formation. By accessing this heat, drilling operations can avoid intersecting the salt formation, thereby reducing risks.

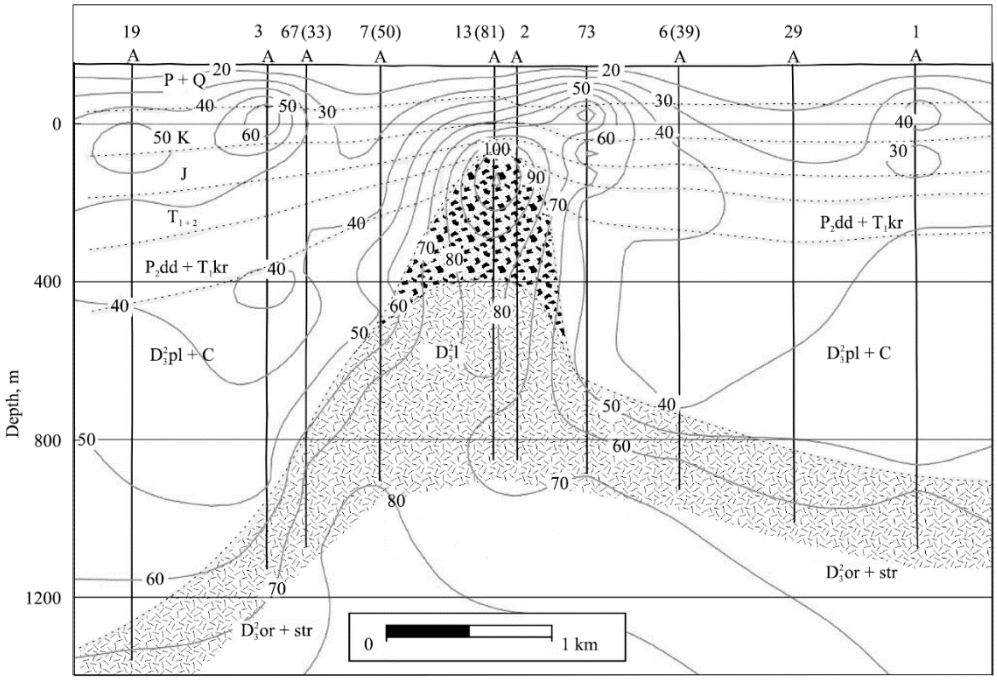

Figure 11:Salt dome profile versus heat flow in Pripyat Trough, Belarus (Zui, et al., 2016).

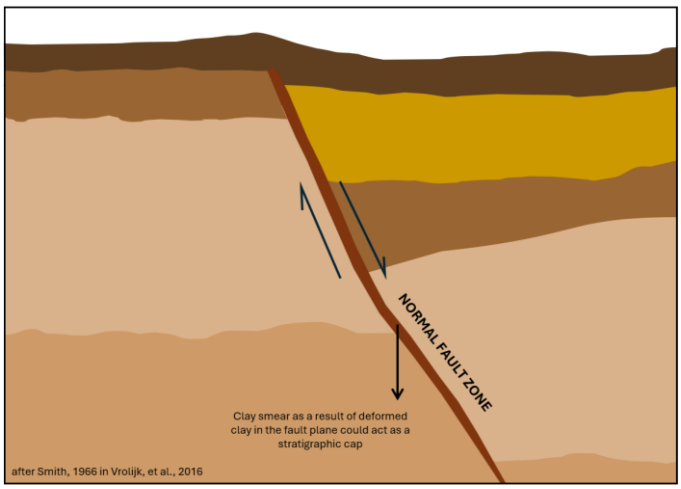

Figure 12: Illustration of clay smear concept (modified after Smith, 1966 in Vrolijk, et al., 2016).

4.3 Capping Mechanism

The presence of a clay cap, similar to that in conventional geothermal systems, is unlikely in the Midyan area. Instead, the impermeable rocks within the formation, originally deposited, are more likely to control the cap mechanism. This type of capping mechanism is akin to that found in hydrocarbon traps. For example:

- The red and green mudstones in the Al Wajh formation (Hughes & Johnson, 2005) potentially act as caps for the porous sandstones below.
- The calcareous mudstone of the Subayti member and the mud-dominated succession of the Nutaysh member of the Burqan formation (Hughes & Johnson, 2005).
- The deep marine mudstone of the Magna formation (Hughes & Johnson, 2005).

The tectonic evolution of this area has facilitated the development of stratigraphic caps, often combined with faults, which may be filled by clay (clay smear). Clay smears form in normal faults that deform layered sedimentary sequences, typically clastic sequences. They develop through mechanical processes alone and include the entire fault zone, from the most highly deformed clay to stratigraphically coherent fault lenses of shale. This

results in a lithologically and structurally heterogeneous fault zone, becoming significant once beds are completely offset from each other (Vrolijk, et al., 2016). Although no previous studies specifically address clay smears along the faults in the Midyan area, the area's stratigraphic layers and salt formations suggest the potential presence of this phenomenon.

Furthermore, the pre-salt reservoir rocks are significantly capped by the massive salt layer of the Mansiyah formation. This impermeable salt layer covers the entire Al Wajh, Burqan, and Magna reservoirs. However, due to its irregular distribution, variations in salt layer thickness are expected within the same area.

4.4 Reservoir Targets

The hot water reservoir in the Midyan area is influenced by the distribution of stratigraphic layers and is stored in porous sedimentary rocks and sharp formation contacts. Due to the presence of both permeable and impermeable strata, the water primarily moves laterally through the formations rather than vertically. The most promising formations for hosting hot water are the pre-salt formations, including the Al Wajh, Burqan, and Magna formations, as well as the contacts between these formations. Additionally, the bottom of the Ghawwas formation (post-salt) could also serve as a reservoir target, though the temperature there may be lower.

These promising formations are significantly influenced by the structural characteristics of the Midyan basin. The basin's prominent structures include the rift-bounding faults created by the Red Sea spreading and the pull-apart fault system caused by the Dead Sea strike-slip movement. These structures are believed to connect with the heat supply from below. The heat from the thinning crust moves upward primarily through conductive processes in the basement rock and convective processes along the faults. Reservoirs located closer to these faults can be expected to have higher temperatures. However, these faults are less likely to host large volumes of hot water. In addition, the basement contacts with the above formations are also expected to be permeable due to their sharp and disconformity nature. The heat generated from the decay of radioactive minerals in the basement moves upward and is primarily stored in these permeable basement contacts.

In summary, the reservoir and permeability targets of this hot sedimentary aquifer system include:

- **Top Basement Unconformity:** The top basement in the Red Sea, often heavily fractured and overlain by continental sands of the Al Wajh formation, offers significant reservoir potential.
- **Al Wajh Sands:** These sands, capped by an intra-Al Wajh facies seal or the Burqan formation seal, are another viable target.
- **Burqan Formation Sandstones:** These sandstones, capped by inter-formation seals, present promising reservoir prospects.
- **Maqna Group Reservoirs:** Capped by the anhydrites within the group or the Mansiyah salt, these reservoirs are attractive geothermal targets.
- **Bottom of Ghawwas Formation:** Located at the contact with the Mansiyah salt, this formation benefits from the salt's good thermal conductivity, efficiently transferring heat from below to above the salt layer. This allows access to the thermal properties without intersecting the salt layer, which is known to complicate drilling operations.
- **Major Rift-Bounding and Pull-Apart Faults:** These faults play a crucial role in heat distribution and can enhance the geothermal potential of adjacent reservoirs.

By understanding the distribution and movement of hot water in relation to both stratigraphic layers and structural features, we can better target potential reservoirs and optimize geothermal exploration efforts in the Midyan area.

5. UNCERTAINTY AND RECOMMENDATION

The proposed conceptual model requires validation due to its construction based on limited data. Although the geological framework of the area is extensively documented from numerous studies primarily targeting oil and gas exploration, the understanding of its geothermal potential remains inadequately explored. To maximize exploration efforts, a comprehensive approach involving detailed structural mapping, high-resolution 3D seismic surveys, advanced magnetic surveys (airborne or ground), precision gravity surveys, and ultimately, exploratory drilling is recommended.

The uncertainties inherent in the conceptual model are substantial and encompass several key parameters:

1. **Heat Source**: Despite the existence of temperature profiles from multiple wells in the area, the specific conditions of these wells are not fully understood, complicating the interpretation of temperature data. The curie depth inferred from regional magnetic data (Aboud, et al., 2023) does not necessarily represent the actual isotherm contour of the area, as it primarily indicates the depth of the demagnetized zone within the mantle. Furthermore, the radiogenic heat production calculated from surface granite samples

may not accurately reflect the characteristics of the Midyan basement, which could comprise Neoproterozoic granite with potentially diminished radioactive mineral content over time.

2. **Salt Layer**: The presence of the Mansiyah salt layer, as interpreted from 3D seismic profiles, necessitates corroboration through direct lithological sampling to ascertain the mineral composition and measure the thermal conductivity of the salt body. Detailed 3D modeling of the salt body is crucial for a more precise understanding of the geological and geothermal context of the area.
3. **Cap Rocks**: The potential cap rocks, including siltstone, mudstone, and claystone, cannot be precisely identified through current 3D seismic profiles, which lack the resolution to distinguish between sand and clay formations. These profiles rely on analogs from oil and gas exploration in the Suez and Sinai Peninsula. Additionally, the presence of smear clay along faults must be verified through direct exploration drilling.
4. **Reservoirs**: The pre-salt reservoirs, currently interpreted solely based on 3D seismic data, leave open the possibility of various underlying formations such as the Al Wajh, Burqan, or Magna formations. Each of these formations exhibits distinct lithological characteristics, pressure regimes, and permeability, which may significantly influence reservoir properties.

Deep geothermal drilling is essential to substantially reduce these uncertainties. Although advanced geoscience exploration techniques are available and can mitigate some of the system's uncertainties, the Midyan area is presently characterized as a hot sedimentary geothermal system with no evident surface manifestations. Consequently, it is improbable to resolve all uncertainties entirely without drilling. We recommend transitioning to deep exploration drilling, as the current geothermal system interpretation, while adequate, can be significantly enhanced with additional data.

Keywords: closed-loop geothermal system, idle geothermal well, heat transfer, pump power

ABSTRACT

Many geothermal fields experience derating or decreased power output. This can be caused by the decline in well productivity or, in the worst case scenario, the wells stop flowing. They can be idle and not used as production wells for a period of time, while still maintaining sufficient heat to be utilized. A tubing system may be inserted into the idle wells while working fluid is pumped through it, extracing heat from the surrounding formation through conduction and convection whenever geothermal fluid is available in the wellbore. The hotter working fluid leaving the tubing system can be used direcetly generate electricity. The purpose of this study is to conduct numerical analysis of heat extraction by using a closed loop system in an unproductive geothermal well. This research uses four different working fluids, namely water, carbon nanotubes, graphene, and titanium oxide, each with a mass flow rate of 1 kg/s. Numerical simulations using COMSOL Multiphysics software are conducted to determine the outlet temperature of the working fluid and the pump power required to move the fluid. The results showed that the carbon nanotube (CNT) working fluid yields a superior outlet temperature compared to the other fluids, while water produces the lowest outlet temperature. The highest outlet temperature recorded reaches 156°C, while the lowest outlet temperature is at 140°C. The pump power required to move the graphene fluid is relatively low at 3.048 kW, whereas the carbon nanotube fluid requires the highest pump power at 3,398 kW.

1. INTRODUCTION

The primary advantage of closed-loop geothermal heat extraction is its ability to operate effectively regardless of reservoir permeability and the nature of the fluid present (Yuan et al., 2021). Currently, most geothermal exploitation still adopts the traditional approach, namely by extracting geothermal fluid, in the form of steam or hot water, directly from reservoirs. However, this approach can cause a number of problems. For example, production fluids can contain chemical solutions from rocks that can damage wells and surface equipment due to their corrosive properties. Additionally, production fluids may carry hazardous chemicals, such as acid gases, from reservoirs to the surface, which should be considered hazardous pollutants. The reservoir fluid itself may be hazardous and require special handling. The reaction between the injected working fluid and the rock can also cause formation damage. Additionally, reservoir permeability may be insufficient to inject or recover working fluid at adequate flow rates. One solution to overcome this problem is to isolate the reservoir fluid from the geothermal energy extraction infrastructure using a downbore heat exchanger (DBHX) circulation system. In this system, the working fluid does not come into direct contact with the hot rock, and this method is currently generally applied to closed-loop systems. Closed-loop systems are systems that are installed in idle and existing wells and do not require subsurface permeability because they use closed pipes that are specially designed to deliver heat transfer fluids through rock layers and then up to the surface. In closed loop systems, it is possible to use alternative heat transfer fluids that are superior to water in certain conditions. Closed loop systems can take heat from temperature resources (when permeability is generally very limited), where there is more efficient power generation. In addition, this technology is very suitable for use in hot dry rock conditions where water is not naturally available at that location. Magma only heats the dry rock above it. Therefore, a closed loop system is needed to capture heat in the dry rock.

In a closed-loop system, the fluids used are water and supercritical carbon dioxide (sCO_2). These two fluids are quite good in closed loop systems, but still have many shortcomings in heat transfer. Therefore, many methods have been developed to increase heat transfer. There are two ways to increase heat transfer, namely active and passive methods. The active method is an increase in heat transfer influenced by external factors, such as the use of geothermal pumps and the use of efficient heat exchangers. Meanwhile, passive methods refer to efforts to increase heat transfer efficiency without involving the use of external resources or additional energy, such as increasing thermal conductivity by injecting nanofluids as working fluids. Nanofluids are liquid suspensions in which nanomaterials are dispersed into a base fluid. Nanoscale additives produce superior thermophysical

properties compared to base fluids. In general, nanofluids are used to increase the thermal conductivity of fluids, which can be useful in a variety of applications, including cooling or heating systems (Wang et al., 2023). Some characteristics of nanofluids involve very small particles and good dispersion in the carrier fluid. According to several researchers, nanofluids that are often used are TiO_2 (Abbasi et al., 2015), CuO (Du et al., 2020), $CNTs$ (Ali et al., 2021), Al_2O_3 (Kapicioglu et al., 2020), Graphene (Ali, 2022), Fe_3O_4 (Cobanoglu et al., 2022).

2. NUMERICAL MODELING

Numerical modeling of closed-loop geothermal systems in idle geothermal wells is studied using numerical simulations using COMSOL software. The well is modeled in 2D axisymmetric space dimensions which will later be revolved to reflect the original condition of the well. This calculation uses the nonisothermal flow multiphysics package which combines the laminar flow physics package with heat transfer in the solid and liquid physics packages. The simulation in this research is in steady conditions and in this section the equations used, the domain model, and the boundary conditions of the numerical simulation are presented.

2.1. Governing Equations

In COMSOL software, mass, energy and momentum conservation parameters can be solved. The equations that govern the laminar flow physics package are stated in Equations (1), (2), and (3).

$$\rho(\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = \nabla\cdot[-\rho\boldsymbol{I} + \boldsymbol{K}] + \boldsymbol{F} \quad (1)$$

$$\rho\nabla\cdot(\boldsymbol{u}) = 0 \quad (2)$$

$$\boldsymbol{K} = \mu(\nabla\boldsymbol{u} + (\nabla\boldsymbol{u})^T) \quad (3)$$

The equations that govern heat transfer in solid and fluid physics packages are expressed in Equations (4), (5), and (6) as follows (COMSOL, 2018):

$$\rho c_{\boldsymbol{p}}\boldsymbol{u}\cdot\nabla T + \nabla\cdot\boldsymbol{q} = Q + Q_{ted} \quad (4)$$

$$\rho c_p\,\boldsymbol{u}\cdot\nabla T + \nabla\cdot\boldsymbol{q} = Q + Q_p + Q_{vd} \quad (5)$$

$$\boldsymbol{q} = -k\nabla T \quad (6)$$

where **ρ** is the density of the fluid (kg/m^3), **u** is the fluid flow velocity vector (m/s), **I** is the unit matrix, **F** is the object force vector (N/m^3), **μ** is the dynamic viscosity of the fluid (Pa s) , **T** is the absolute temperature (K), $\mathbf{c_p}$ is the specific heat at constant pressure (J/kg-K), $\dot{\mathbf{q}}$ is the heat flux by conduction (W/m^2), $\dot{\mathbf{Q}}$ is the heat source other than viscous heating (W/m^3), $\dot{\mathbf{Q}}_{\mathbf{ted}}$ is the thermoelastic damping heat source (/m^3), $\dot{\mathbf{Q}}_{\mathbf{p}}$ is the heat source due to pressure changes (W/m^3), and $\dot{\mathbf{Q}}_{\mathbf{vd}}$ is the viscous dissipation (W/m^3).

2.2. Model Description

Figure 1 models a closed loop geothermal system for an inactive geothermal well which is the numerical simulation domain in this research. This inactive geothermal well was created to approach original conditions in the Mataloko MT-3 well in eastern Indonesia with a depth of 613 meters with a temperature of 170°C in the reservoir section. This well has a mass flow rate of 1 kg/s with a pressure of 6.5 bar. A coaxial borehole heat exchanger is inserted into the well to extract nanofluid heat by inserting water as a working fluid into the annulus space of the borehole heat exchanger. The inner tubing in the borehole heat exchanger is isolated to prevent heat energy loss and, in this study, the inner tubing is assumed to be completely isolated. The outer tubing is made of thermally conductive material, allowing maximum heat transfer. In addition, inactive geothermal wells are assumed to be surrounded by homogeneous rock and the rock layers are impermeable and non-porous. This rock is assumed to have a conductive base with a temperature of 170°C and a surface temperature of 25°C (Wahyuningsih, 2004).

Table 1: Properties of Materials (Hu et al,. 2020).

Parameter	Unit	Casing Pipe	Insulation Pipe	Cement	Rock
Thermal conductivity	W/m-K	44.5	0.26	Comsol	Comsol
Specific heat	J/kg-K	475	1700	2000	1000
Density	kg/m^3	7850	1150	2300	2600

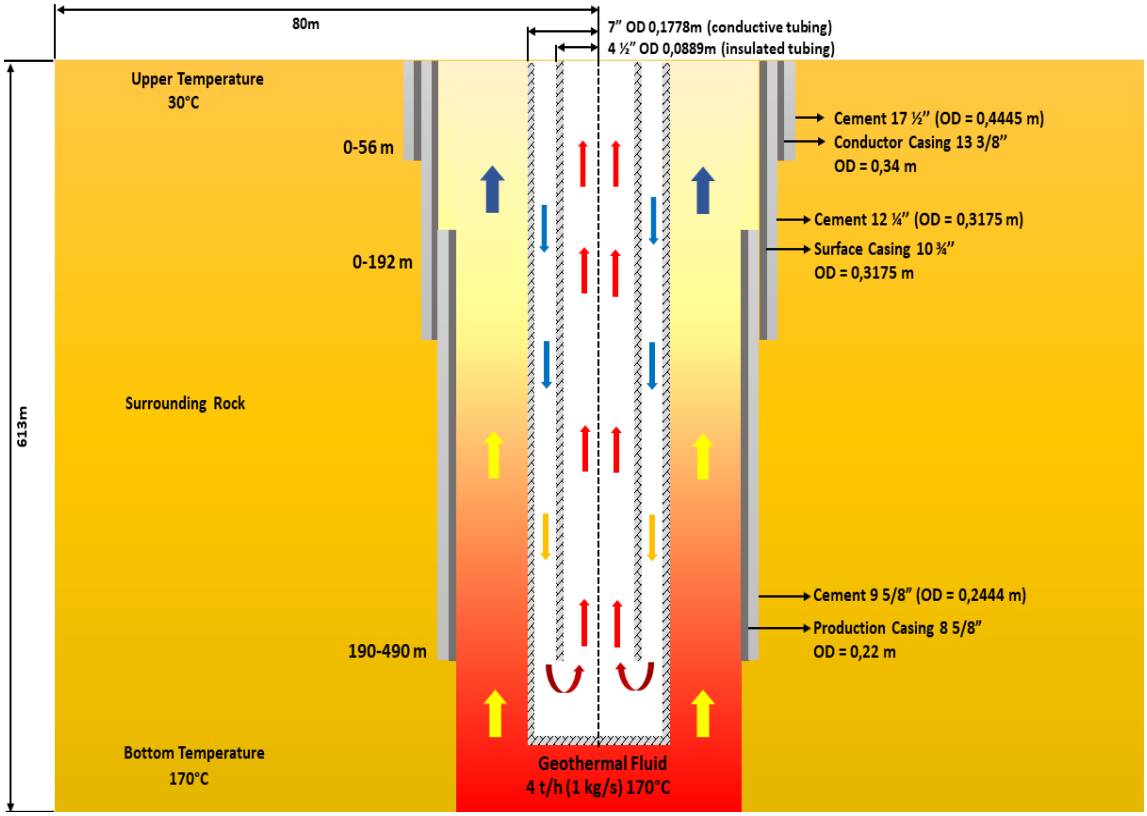

Figure 1: Schematic of the simulated Closed-Loop Geothermal system in an idle geothermal well.

2.3. Boundary Conditions

To enable closed-loop geothermal system simulation model on the inactive Matalako MT-3 geothermal well described in Section 2.2, the boundary conditions used are listed in Table 2. These values were obtained from several literatures and conditions in the field.

Table 2: Boundary conditions of the numerical simulation.

Parameter	Unit	Value	References
Nanofluida mass flow rate	kg/s	1	(James & Gould, 1987)
Nanofluida inlet temperature	^oC	28	(Wahyuningsih, 2004)
Nanofluida inlet pressure	bar	1	(Hu et al., 2020)
Working fluid injection flow rate	kg/s	1	(Hu et al., 2020)
Working fluid injection temperature	^oC	28	(Wahyuningsih, 2004)
Working fluid inlet pressure	bar	1	(Hu et al., 2020)
Working fluid outlet pressure	bar	1	(Hu et al., 2020)
Reservoir temperature	^oC	170	(Wahyuningsih, 2004)
Ambient temperature	^oC	25	(PT. PLN, 2019)

3. RESULTS AND DISCUSSION

Before carrying out simulations related to closed-loop geothermal system, the numerical model of inactive geothermal wells must be validated by matching the shut-in pressure and temperature conditions, then compared with inactive geothermal wells without a closed-loop system. From this step, then we can find out whether the results of this numerical simulation can describe real conditions in the field or not. Apart from that, to see an increase in heat transfer, variations in the given nanofluids were used.

3.1. Natural State Validation

This well flow simulation is needed to validate the actual conditions of the well using a simulated well that has not been added with tubing by comparing temperature profiles at various depths. In Figure 2, the actual temperature profile from Well MT-03 is compared with the temperature profile from the simulated well (in yellow) with the same mass flow rate, namely 4 tonnes per hour or 1 kilogram per second (in red). From this

graph, the temperature profile of the well flowing at a rate of 4 tons per hour has a similar pattern to the temperature profile from the simulation, but there is a temperature difference at a depth of 200 meters. This is because the definition of rocks around the well is different from the conditions that occur in the field. However, it can be concluded that the simulated well is able to reflect the conditions of the actual well.

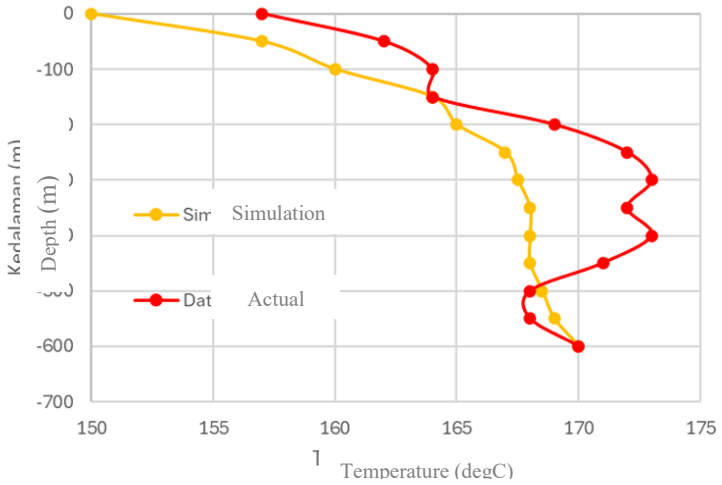

Figure 2: Comparison between Closed-Loop Geothermal System and Actual Well.

3.2. Temperature Profile and Contour in Well MT-03 Model with Nanofluid Variations

The simulation results show that there is a relationship between the temperature gradient in the well wall area and the properties of the working fluid used. From the simulation results, an analysis process can be carried out to determine the heat distribution that occurs in each fluid used.

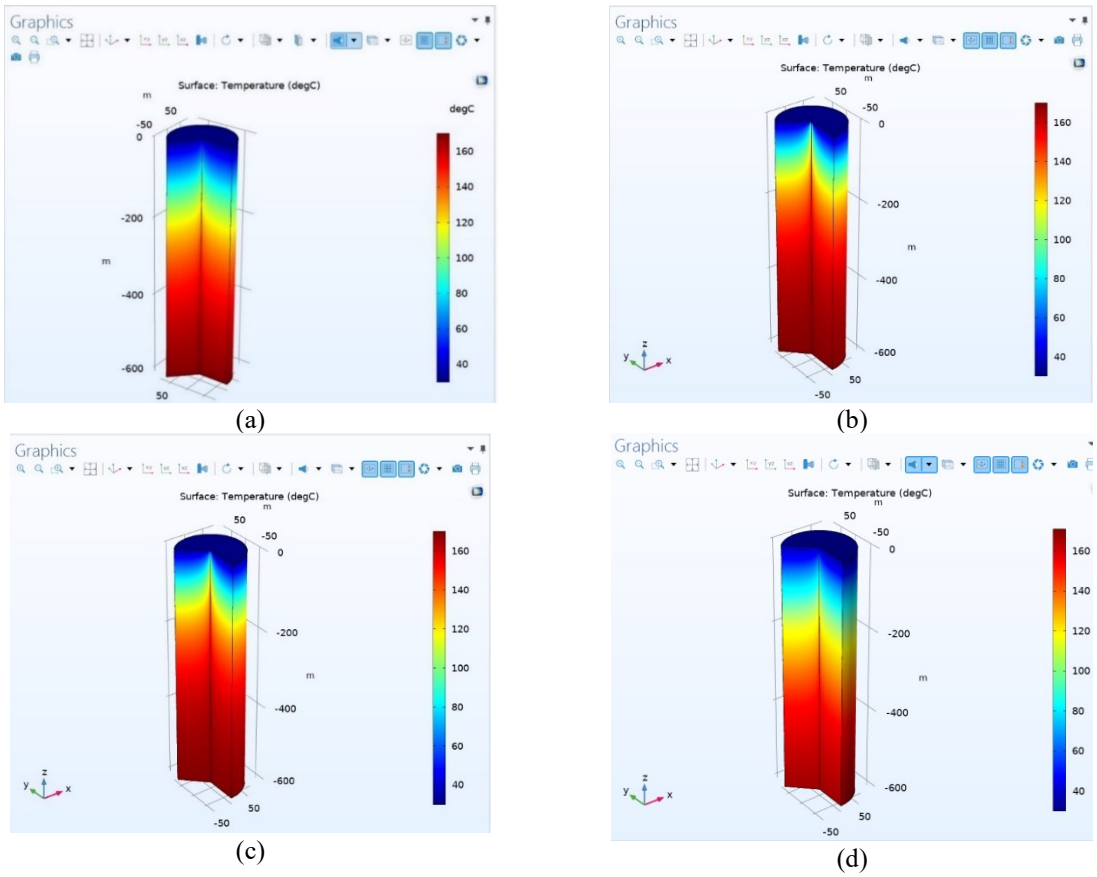

Figure 3: Temperature profile: (a) Graphene nanofluid (b) CarbonNanotube nanofluid (c) Titanium Oxide nanofluid (d) Water fluid.

From Figure 3, it can be seen that the temperature gradient is linear from 170°C at the bottom of the well which indicates the reservoir temperature, and the ground surface temperature is 30°C as the environmental temperature.

In this research, a model was used with an inflow velocity of 1 kg/s. This can be seen in Figure 3 that the simulation results show a temperature profile that forms a cone shape around the geothermal well due to geothermal extraction. Geothermal energy production causes a sharp upward curve along with the nanofluid's good ability to conduct heat. When using graphene and water, the temperature profile shows the depressions that occur are not too sharp compared to the other two nanofluids, namely CarbonNanoTube and Titanium Oxide. In addition, at a depth of ± 200 meters, based on the temperature profile, the use of CarbonNanotube and Titanium Oxide nanofluids can reach 120°C, while graphene nanofluids and water at that depth only produce temperatures of 100°C. This shows that graphene and water nanofluids have a worse ability to conduct heat than other nanofluids.

3.3. Temperature Distribution and Working Fluid Performance

The simulation results show a uniform well model using a variety of working fluids, namely water, graphene, titanium oxide and carbon nanotubes. From the simulation results, an analysis process was carried out to determine the heat distribution in each nanofluid used. The difference in the temperature increases of the working fluid as it enters in annulus and as it flows out of the well is clearly illustrated in Figure 4. When the working fluid enters the well, its temperature will increase with the depth of the well. The temperature reaches its peak as it approaches the bottom of the well because at that point, the working fluid first interacts with the reservoir or surrounding hot rock. The heat energy carried by the working fluid is maintained when it exits the well to prevent heat energy loss to the environment during its journey to the surface. When using graphene as a working fluid, the output temperature of 140°C increases by 110°C compared to the inlet temperature of the well, which is 30°C. As a comparison, using titanium oxide as a working fluid, it produces an output temperature of 154°C with an increase of 124°C from the well inlet temperature and carbon nanotubes produce 156°C and an increase of 126°C.

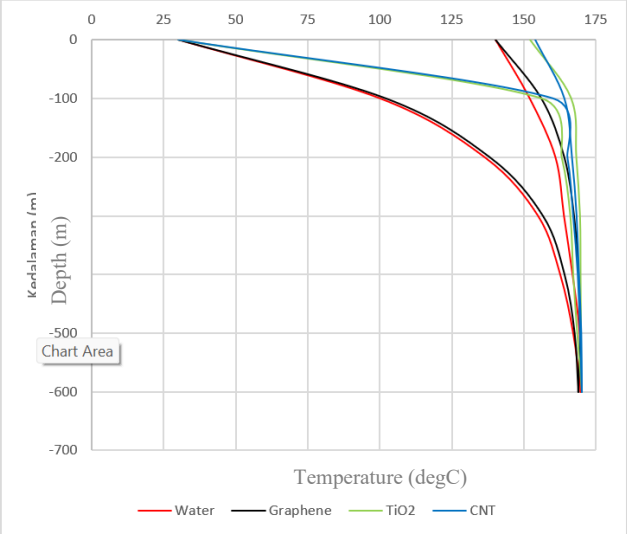

Figure 4: Temperature distribution profile at the inlet and outlet holes in the tubing.

Figure 4 shows the temperature increase profile with variations in each fluid used. The fluid enters with a temperature of 30°C to the end of the well and returns to the ground surface. Carbon nanotube and titanium oxide fluids are easier to conduct heat when they are at the initial depth. This is because the properties of these two fluids are almost the same. Apart from that, carbon nanotubes and titanium oxide have a lower specific heat than water and graphene, which is around 700-1000 J/kg.K, while water and graphene have almost the same specific heat of 4100-4200 J/kg.K. With a lower specific heat, carbon nanotube and titanium oxide fluids can heat up more quickly because the heat required to raise one degree of temperature is less and fluids that have a high specific heat have better temperature stability. In Figure 4, it can also be seen that the graph of the increase in fluid temperature of water and graphene is more stable. Meanwhile, carbon nanotube and titanium oxide fluids have high specific heat, therefore the temperature increase is very significant.

Figure 5 shows the pump power needed to move fluid from the bottom of the well to the surface. The pump power produced is caused by the large pressure drop that occurs in the tube. The greater the pressure drop that occurs in the tube, the greater the pump power required to move the fluid. The pressure drop that occurs is influenced by several factors such as fluid speed, friction that occurs, and the density of the fluid itself.

3.4. Required Pump Power

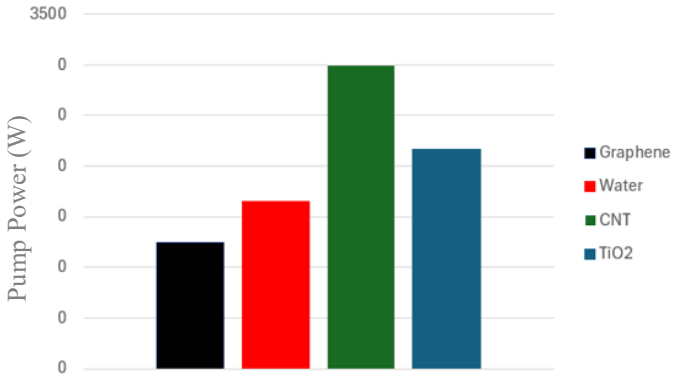

Figure 5: Nanofluids Pump Power.

Carbon nanotube fluid is a fluid that requires the greatest power among other fluids. Carbon nanotube fluid has a greater speed compared to other fluids, namely it has a speed of ±0.1725 m/s. The relatively large fluid velocity in the pipe will increase the friction between the fluid and the walls of the pipe channel will be even greater. In addition, the energy required to overcome this friction will increase and there will be an increase in energy consumption. Meanwhile, water fluid and titanium oxide almost have the same speed results, it's just that the density of the water fluid is lower than titanium oxide so the power used to move the graphene fluid is less than the titanium oxide fluid. This is because low density will also produce low hydrostatic pressure, so that when the hydrostatic pressure is low, the pump will provide less energy to the fluid to overcome the lower hydrostatic pressure. Graphene fluids tend to require a small force to move the fluid from one location to another. This fluid has a speed of 0.161 m/s and a density of ±937.66 kg/m^3. This factor influences the power to move graphene fluid because the speed tends to be low and the density is not too high when the fluid reaches a temperature of 170°C at the bottom of the tubing.

4. CONCLUSIONS

Based on research that has been carried out using COMSOL Multiphysics 6.1 software and analyzing the results of the simulation process, and also from the simulation and calculation results it is found that:

1. The thermal properties of the working fluid influence the fluid's ability to conduct heat. Carbon NanoTube and Titanium oxide nanofluids produce higher exit fluid temperatures than Graphene and water. This is because graphene and water have a higher specific heat capacity than these two fluids. Therefore, the amount of heat used to increase 1 degree of temperature per unit mass becomes higher. Carbon NanoTube nanofluid has more significant heat transfer results because it has a lower specific heat than other nanofluids.
2. The speed of fluid flow and the density of the fluid affect the power capacity of the pump used to move fluid from one location to another. Carbon NanoTube nanofluid has a higher speed than other nanofluids. The higher the speed, the greater the pressure drop and pump power required, causing energy loss. Carbon NanoTube nanofluid has a pump power of 3.398 kW. Meanwhile, Titanium Oxide and Graphene nanofluid have almost the same speed during the simulation process, but Graphene nanofluid has a lower density value. This affects the pressure drop and friction force because the greater the density, the more molecules will interact with the walls. Graphene has the lowest pump power for moving fluid, namely 3.048 kW.

ABSTRACT

The number of Geothermal exploration drilling projects over the last decade has been relatively low, with a significant gap between the stages and a very low success ratio, resulting in a lack of learning curve for geothermal exploration projects. With a limited number of geothermal explorations in Indonesia and only a few companies performing the exploration, almost all geothermal companies in Indonesia are not prepared for an experienced project organization to handle the geothermal drilling exploration project, which faces the challenge of a large volume of work while staying within budget and exploration time window. The majority of geothermal project tasks were carried out by a separate team for each stage, and they finished when their work was accomplished. With a transition time between stages, there was a gap of and unsynchronized information, which most of the time resulted in remedial and additional work in each stage. Having a reliable exploration team is one of the most critical factors in the success of geothermal exploration project drilling execution. Because exploratory projects are typically short in duration, have a wide range of work scopes, and are cost sensitive, the project team must be small, multitasking, problem solvers, quick learners, collaborative, and have expanded roles and responsibilities. This paper will discuss some innovative approaches to build a reliable project drilling execution team that has proven to complete project on time and within budget.

1. INTRODUCTION

The geothermal prospects are distributed across Indonesia from west to east, however only the western part of Indonesia is actively developed compared to the eastern part of Indonesia. Most of the highest reserves that has more than 100 Mwe are in the western part of Indonesia, many of these high-reserve fields are already developed or in the progress of development, while the other remaining fields are being delayed due to permitting issues, regulatory hurdles, land-use conflict, or low project's economic due to reserve capacity size and location.

The eastern part of Indonesia relatively has medium to low reserves which are spread across many islands, these medium and low reserves are suitable with the demography and electricity demands of eastern Indonesia that is relatively lower compared to the western part of the country. The peculiarity of geothermal in eastern region could be the best answer for mid-term electricity deficit while also providing regional energy security for long-term growth.

2. GEOTHERMAL EXPLORATION CHALLENGES

Despite the region's significant potential, developing geothermal projects in eastern Indonesia presents a number economic and logistical challenges, including scarcity of skilled workers, transportation and logistics, accommodation and living conditions, material and equipment costs, services and support, fuel availability and higher tariffs. These issues resulted in the project execution unable to operate 24/7, necessitating more transportation time and costs, and making it difficult to stay under budget. Despite having stronger infrastructure than the eastern region, exploration in the western region also has its own challenge such as protected natural forest and remote location with limited access.

The Preliminary Survey and Exploration License (PSPE) scheme legislation in recent geothermal exploration, combined with current geothermal exploration trends are more toward low-medium enthalpy, adds the exploration hurdles such as constrained budget, minimum number of wells, short exploration time windows, no room for error, with Zero Incident as the ultimate goal.

With all the hurdles and complexity issues, having a reliable project drilling execution team is essential for getting the project started and keeping it on track in terms of the schedule and budget. The project drilling execution team need at minimum to have competences of geothermal exploration exposure with a proven knowledges and experiences, working with the limited support and resource, be innovative and problem solver, good coordination and collaborative, good Individual soft and hard skill, multi-tasking and discipline and strong leadership.

Those competencies are very desirable and nearly impossible to obtain, yet they are required to ensure that the goal is met. In the recent geothermal exploration at the eastern Indonesia, the project team has innovated

approaches in a reliable exploration project drilling execution team, as shown in Figure 1, breaking the common practices in the exploration project and successfully meeting the objectives, and with their competencies, some achievements have been extraordinary.

2.1 A Small Project Drilling Execution Team with Extensive Role and Responsibilities

Given the limited budget and tight schedule of the exploration project, a small project drilling execution team is required to be agile and adaptable for rapid changes and complex problems. With a small project drilling execution team, there will be insufficient resources to manage simultaneous tasks, therefore the project team need to establish an extended role and responsibilities to keep the project drilling execution team lean while also providing cross-functional assistance.

During the civil construction, starting from preparation to commissioning, the civil site supervisor is assisted by QA/QC and EHS Officer for daily supervision on site. With this assistance, simultaneous activity in different areas may be closely monitored to assure the execution as per plan, and at the same time, it gave a new exposure for the drilling team members with the civil work activities, which will be an advantage when needed for maintaining civil infrastructure such as water intake, water supply system, well pad, access road, etc.

When the drilling rig started mobilization most of the civil work has been completed, the Drilling Team assisted by the Civil Site Supervisor to supervise the unloading process, mobilization from the port to stagging and from stagging to the site, this additional supervisor helped the drilling team to have 24/7 supervision on mobilization activities to ensure it's performed efficiently and safely. The Civil Site Supervisors also received a new exposure in supervising massive mobilization of drilling equipment continuously and time sensitive.

After drilling commenced, the drilling team also supported the Wireline Supervisor in operating the in-house wireline unit. Wireline supervisors were assisted in setting up the unit, performed logging operations and storing it. After drilling is completed, to conduct well testing, Well Testing Supervisor also help by the Drilling Team to mobilize the testing equipment to the site, set up and commission the equipment, inspection by regulator, perform well testing, moving from one pad to next pad, and storing the equipment.

2.2 A Professional with Demonstrated Exploration and Multidisciplinary Experiences

To enable a lean team to begin work immediately and efficiently after it is formed, each project execution team should be a professional with demonstrated exploration and multidisciplinary experience, capable of preparing and executing the detail execution plan in collaboration and synergy with the team's other disciplines. Hiring a professional with specific exploration experience, paired with project's short timeline, task complexity, and site location, proved to be a difficulty, but the project was successfully addressed by offering an extensive time frame combined with appealing benefits in compensation of extended role and responsibility.

2.3 Project Team Synergy Improves Work Efficiency

Fostering synergy within the project drilling execution team is beneficial for collaborative problem solving, effective communication and smooth information sharing, as well as work efficiency, but it is difficult to achieve, especially when the project drilling execution team is just getting started, there is little time for introductions, and there are different expertise and professional backgrounds. To achieve synergy, best practice for effective communication and coordination in drilling operation was introduce to project drilling execution team, along with reporting and work techniques.

2.4 Single Communication Channel

One communication channel for the project drilling execution team, assisting quick information alignment, which is powerful for work progress integrated monitoring and raise team awareness and initiative for collaboration, problem solving, and prompt corrective action.

3. A LEAN PROJECT DRILLING EXECUTION TEAM EFFECTIVELY MET OBJECTIVE WITH AN EXCEPTIONAL ACHIEVEMENT AND TEAM LEARNING (A SUCCESS STORY)

Effective communication and good cross functional collaboration in a lean project drilling execution team have successfully met project objective of completing the project ahead of schedule, within budget, with an exceptional performance, and providing good experience for the team members to learn new skills. The very first challenge for the project team was to begin the civil work immediately in order to have the first well spud before end of July 2023, as per the exploration time frame commitment with the regulator. The project execution team successfully build three (3) well pads, 2.8 kilometers access road, a laydown area, a drilling camp, a water intake, and water supply system within six (6) months, starting from December 2022 until June 2023.

Rig mobilization commenced after the major civil work has been completed, and it took seventy-three (73) days from the first day of mobilization at Cirebon – West of Java Island to spud-in at Wapsalit – Buru island, which is 17 days faster than the target days. Before the first shipment arrived at Namlea port at Buru island, local road and bridge authorities notified that two (2) out of thirty-two (32) bridges along the road from Namlea port to Wapsalit site are not capable to support the maximum load of the rig equipment. To address the bridges issues, the project drilling execution team successfully constructed two (2) sixty tons (60 T) temporary bridges with lengths of 12 meters and 18 meters in less than a month as shown in Figure 2 for both the bridges. The 12 meters bridges installation was completed in seven (7) days and the 18 meters was completed in ten (10) days with the installation cost less than USD 190,000 for both bridges. Both bridges were successfully tested and safely supported the rig equipment mobilization with maximum load of fifty-four (54) tons.

Figure 2: Wapsalit Temporary Bridge Installation.

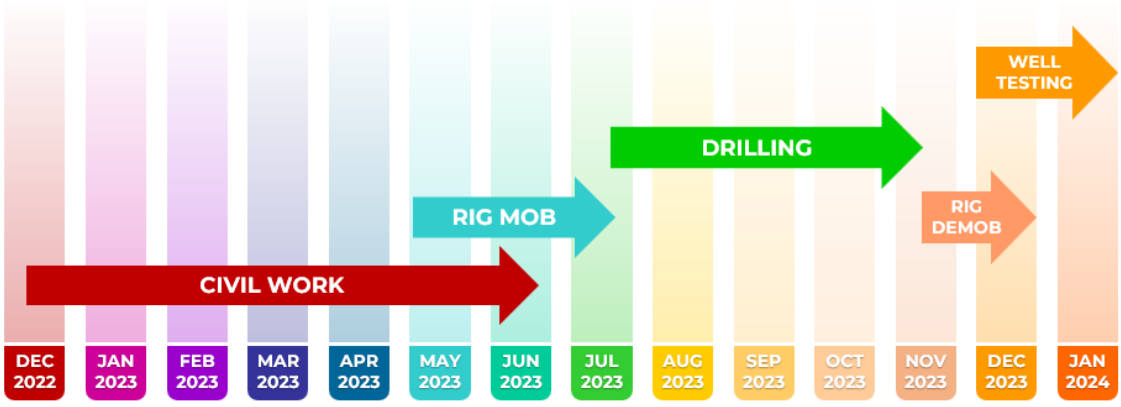

Figure 3: Project Timeline.

The first well was successfully spudded two (2) weeks before the end of commitment date, which was a significant accomplishment for the entire exploration activities. The first well was completed drilled safely to the target depth within the budget, while the second well drilled 513 meters deeper than first well with meter per day doubled than the first well and dollar per meter fifty percent lower than the first well. During drilling, in house wireline unit

was operated to run down hole tool and execute logging task, resulting in significant cost saving on wireline unit rentals. After drilling was completed, the drilling team aided the well testing supervisor with aerated package operation and heavy equipment supervision to mobilize, set up, move, and store well testing equipment, which was extremely beneficial in conducting the well testing job cost and time efficiently.

4. CONCLUSION

The innovation of a lean and collaborative project drilling execution team has effectively break away from a traditional method of geothermal project execution in Indonesia, resulting in project execution that not only satisfied the project objectives of time and cost efficiency but also a safe operation.

The efficient time and cost performance delivered by the project drilling execution team easily justifies the project team's outstanding compensation benefit. In addition, a lean project drilling execution team also provides an opportunity for the team to gain new skills. This lean project organization will help to accelerate the geothermal exploration by addressing the lack of skilled individuals and project continuity.
