Sanksi Pelanggaran Pasal 72 Undang-Undang Nomor 19 Tahun 2002 Tentang HAK CIPTA

1. Barangsiapa dengan sengaja dan tanpa hak melakukan perbuatan sebagaimana dimaksud dalam Pasal 2 ayat (1) atau Pasal 49 ayat (1) dan ayat (2) dipidana dengan pidana penjara masing-masing paling singkat 1 (satu) bulan dan/atau denda paling sedikit Rp. 1.000.000,00 (satu juta rupiah), atau pidana penjara paling lama 7 (tujuh) tahun dan/atau denda paling banyak Rp. 5.000.000.000,00 (lima miliar rupiah).
2. Barangsiapa dengan sengaja menyiarkan, memamerkan, mengedarkan, atau menjual kepada umum suatu Ciptaan atau barang hasil pelanggaran Hak Cipta atau Hak Terkait sebagaimana dimaksud pada ayat (1) dipidana dengan pidana penjara paling lama 5 (lima) tahun dan/atau denda paling banyak Rp. 500.000.000,00 (lima ratus juta rupiah).

SPEAKERS

H.E. Ir. H. Joko Widodo, President of the Republic of Indonesia

Hon. Bahlil Lahadalia, Minister of Energy and Mineral Resources of the Republic of Indonesia

Hon. Rosan Roeslani, Minister of Investment of the Republic of Indonesia (Represented by **Dedi Latip**, Deputy for Investment Planning, Ministry of Investment/Investment Coordinating Board)

Jisman P. Hutajulu, Director General of Electricity, Ministry of Energy and Mineral Resources of the Republic of Indonesia (Represented by **Wanhar**, Director of Electricity Program Development, the Ministry of Energy and Mineral Resources (ESDM)

Julfi Hadi, President Director of PT Pertamina Geothermal Energy Tbk

Hanif Osman, Director of Finance, Risk Management & General Affairs of PT Geo Dipa Energi (Persero)

Ahmad Yani, Director Operation of PT Pertamina Geothermal Energy Tbk

Peter Scrivener, Regional Director of Solenis

Vinesh Krishnan, Vice President, Energy Solution, Hub Asia of ABB Energy Industries

Novianto, VP Geothermal and General Manager of Medco Power Indonesia

Shuichiro Ikeda, Chief Operating Officer of Supreme Energy

H.E. Kevin Burnett, ONZM, New Zealand Ambassador to Indonesia

Eddy Soeparno, Deputy Chairman of Commission VII DPR RI

Eniya Listiani Dewi, Director General of New, Renewable Energy and Energy Conservation, Ministry of Energy and Mineral Resources of the Republic of Indonesia

Satyawan Pudyatmoko, Director General of the Conservation of Natural Resources and Ecosystem, Ministry of Environment and Forestry of the Republic of Indonesia

Hendra Soetjipto Tan, Group Chief Executive Officer of Star Energy Geothermal

Dr. Yan Tang, President Director of KS Orka Renewables Pte Ltd

Ann Robertson-Tait, President of SLB's GeothermEx Consulting Services

Ajit Menon, Vice President of Geothermal Baker Hughes

Ran Reshef, Vice President International Sales of Ormat Technologies

Ardyanto Fitrady, Center for Energy Studies, Gadjah Mada University (PSE UGM)

Marit Brommer, Executive Director the International Geothermal Association

Paul Ngugi, Managing Director & CEO of Geothermal Development Company - Kenya

FOREWORD PRESIDENT OF INAGA

Global climate change remains one of today's most pressing challenges. Energy security is another critical issue exacerbated by the complex geopolitics unfolding globally. The transition toward renewable energy, particularly geothermal energy, has emerged as a vital solution to address these issues. Indonesia, with its vast geothermal resources lying untapped beneath chains of volcanoes, holds immense potential to accelerate the transition toward a sustainable energy future. This resource is key to Indonesia's renewable energy future, showcasing innovation and adaptability.

The 10th Indonesia International Geothermal Convention & Exhibition (IIGCE) 2024, held on **September 18 - 20, 2024**, at Assembly Hall, Jakarta Convention Center, was officially opened by **President of the Republic of Indonesia, His Excellency Joko Widodo**. Marking a decade of commitment to advancing geothermal development, this event continued to serve as a platform for dialogue and collaboration among geothermal stakeholders. With the theme **"Powering Together: Stakeholder Unity in Geothermal Innovation and Acceleration"**, IIGCE 2024 explored breakthroughs and solutions to support the global energy transition. Discussions emphasized overcoming commercial bottlenecks, fostering collaboration to refine business models for managing exploration risks, reducing development costs, optimizing production through technology, and working with the government to establish workable incentives.

As part of the 10th IIGCE, the **24th Annual Scientific Meeting (PIT)** achieved remarkable milestones, reflecting the growing enthusiasm for advancing geothermal research and development. A total of 278 abstracts were submitted, with contributions from professionals and academia, showcasing diverse perspectives.

These contributions spanned topics including Earth Science, Engineering, Resource Management, Beyond kWh, and other special focus areas. The Technical Papers Session served as an invaluable opportunity to share knowledge, insights, and best practices for the geothermal community.

I would like to take this opportunity to express my gratitude and appreciation to the Technical Paper Committee, Chairpersons, Authors, Presenters, and all contributors who made the 2024 Technical Papers Session a success. Your dedication and expertise ensured the continued impact of this platform, reflecting the innovation and collaboration that drive geothermal energy development forward.

On behalf of INAGA, I am pleased to present this year's Technical Papers Session, a valuable resource for our geothermal community. Let us collaborate to unlock geothermal's full potential for a sustainable future.

Yours Truly,

Julfi Hadi
President of INAGA

Keywords: Superconducting Quantum Interference Device (SQUID), Transient Electromagnetic (TEM), 3D inversion, grounded wire

ABSTRACT

We have developed a novel exploration system for the transient electromagnetic method (TEM) utilizing a superconducting quantum magnetic sensor (SQUID) with ultra-high sensitivity. Our SQUID-TEM enables the user to obtain a high-resolution three-dimensional (3D) geoelectrical imaging for any depth of interest (a few tens meters up to 3000-4000 m) in a quite user-friendly manner (e.g., a small amount of liquid nitrogen, less complicated pre-job preparation and simple field operation, etc.). Based on our field-deployment history in Indonesia, Japan, and some Middle East countries, it should be noted that SQUID-TEM, with 3D inversion data analysis, is able to contribute to the acceleration of the geothermal field-development process. The SQUID-TEM method can be a powerful tool not only for green-field geothermal development in the future but also to maintain or increase the generation capacity of geothermal power plants currently in operation, which largely contributes to the promotion of geothermal power generation.

1. INTRODUCTION

In 2009, we began developing a transient electromagnetic (TEM) exploration device using a superconducting quantum magnetic sensor SQUID that can be used at a liquid nitrogen temperature, and since 2012, it has been used by JOGMEC for mineral resource exploration (Hato et al., 2013). Subsequently, in order to realize equipment with the exploration depth of over 3000m required for geothermal exploration and carbon dioxide capture and storage (CCS) monitoring, we developed a SQUID sensor that operates more stably even in strong magnetic fields and a system that enables long- period TEM measurements as well as sufficiently long operation duration. We have also developed reliable cooling technology, signal processing technology that can efficiently remove noises, and 3D inversion technology.

There are four advantages to using the SQUID-TEM method in geothermal exploration.

- Among various electromagnetic exploration methods, the TEM method measures signals proportional to the cube of stratum conductance (Kaufman and Keller, 1983), while the magnetotelluric (MT) method and controlled source electromagnetic (CSEM: frequency domain) method observe signals only proportional to the first power. Thus, the TEM method is expected to provide a physically higher resolution.
- Since the TEM method uses an artificial magnetic field, repeated measurements are possible, and noise can be suppressed even in noisy environments. In addition, since the magnetic field signals from underground are measured after the artificial magnetic field is shut off, the artificial magnetic field does not influence the measured signals.
- SQUID measures the magnetic field itself, not the derivative of the magnetic field, as in the case of the induction coil sensor. Since the magnetic field attenuates more slowly than its derivative, the use of a highly sensitive SQUID sensor is advantageous for the measurement of late-time transients required for deeper exploration.
- SQUID magnetic sensor has advantageous characteristics for the TEM method - The sensitivity of sub-pico tesla, as well as the wide dynamic range and wide frequency bandwidth from DC to MHz range, make deep TEM exploration over 3000m possible. The conventional TEM method using an induction coil as a magnetic sensor does not have sufficient sensor sensitivity at low frequencies and thus has been used for exploration of relatively shallow underground below 1,000 meters depth, such as the case for mineral resource exploration.

As specific usage methods of SQUID-TEM in geothermal fields, we are considering two cases, as shown in Figure 1. One is the reduction of geothermal development risks through the hybrid use of MT and TEM methods. The exploration area of the TEM method is limited by the arrangement of the grounded wire source for the application of magnetic fields, which is a disadvantage compared with the MT method. As a result of a wide-area resource survey using the MT method, detailed exploration will be carried out using the TEM method at potential development sites. MT method using an electric field is sometimes affected by the relief of the ground, and MT data analysis without considering the relief of the ground produces distorted results. The SQUID-TEM method uses only a magnetic field, unaffected by the ground relief. The results obtained are useful for verifying the MT data analysis. We believe this hybrid approach effectively reduces risks in the early stages of geothermal exploration.

Another use of the method is for the exploration in the vicinity of geothermal power plants that are already in operation. Although it requires operation in a noisy environment, it is possible to explore using the SQUID TEM method, which can suppress noises. It is expected that the need to maintain and increase the output of geothermal power plants will increase in the near future.

The TEM method helps to determine the location of drilling for additional production wells and reinjection wells. We believe that such utilization will accelerate geothermal development.

In this paper, we describe the characteristics of the SQUID-TEM method and report on the interesting results of exploration case studies.

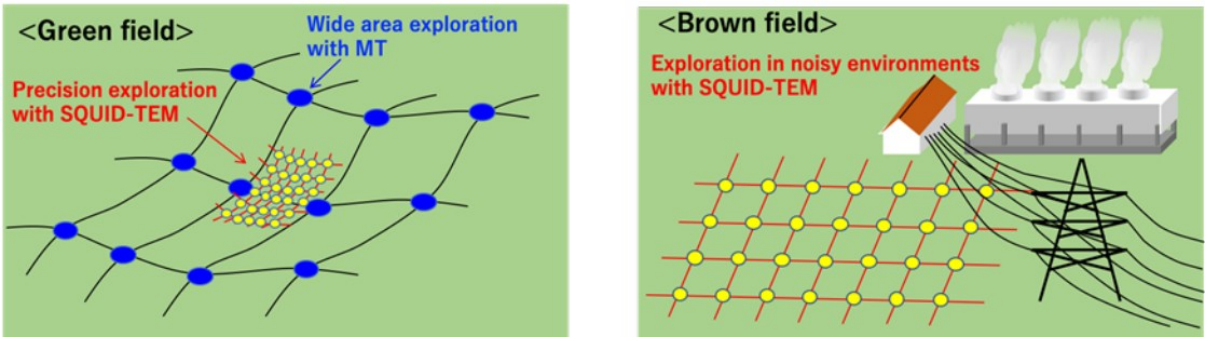

Figure 1: Image diagram of reducing geothermal development risks and accelerating development by utilizing SQUID TEM in green fields and brown fields around operating geothermal power plants.

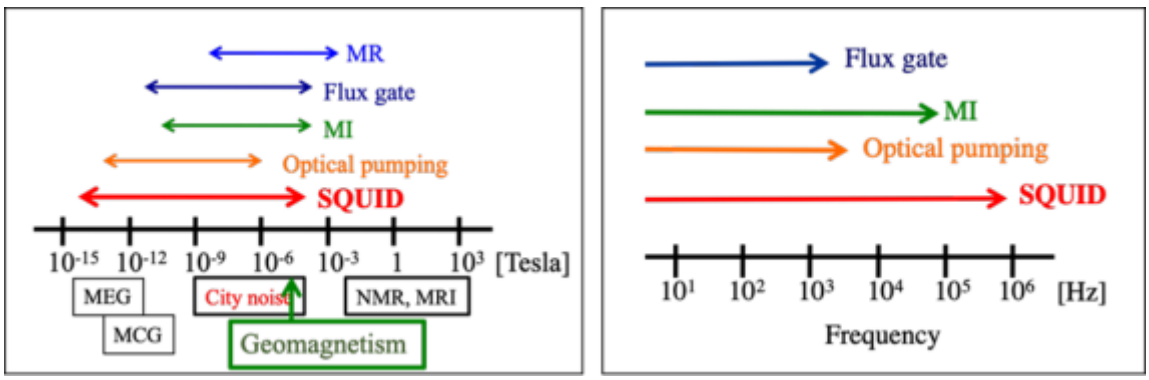

Figure 2: Dynamic range and frequency band of various magnetometers.

2. FEATURES OF SQUID-TEM

The significance of using a magnetometer such as a SQUID in the TEM method is that it allows direct observation of the magnetic field rather than the time derivative of the magnetic field, as is the case for induction coils. In geothermal exploration, cap layers and reservoirs have low resistivity, which slows down the decay of the magnetic field. In the TEM method, the attenuation of the magnetic field is measured after the primary magnetic field is shut off, but in order to conduct deep exploration, it is necessary to measure at late times. Direct measurement of the magnetic field reaches a noise level substantially later than time-derivative measurement, which is advantageous for deeper exploration. Figure 2 shows the dynamic range and frequency band for several types of magnetometers, including SQUID. SQUID magnetometer has (1) a sufficiently large dynamic range and (2) a wide frequency bandwidth from several hundred kHz to DC, which is suitable for the TEM method.

On the other hand, the issues that need to be overcome with SQUIDs are (1) the ability to follow changes in the magnetic field (slew rate), which is sufficient for stable operation when used outdoors, and (2) ease of cooling. Since we are able to design and manufacture SQUID magnetic sensors by ourselves, we have developed a specially designed SQUID for TEM measurements, which has a good balance between stability and high sensitivity for outdoor use. Figure 3 shows a photo of the developed TEM system named SUSTEM with three SQUIDs to measure x, y, and z field components. The total weight is approximately 20 kg. The SQUID is fabricated using high-temperature superconducting materials and can be operated at a liquid nitrogen temperature. By improving cooling and mounting technology, it is possible to operate the system continuously for up to 17 hours with 0.7 liters of liquid nitrogen. As a result, even if we carry it on expeditions in mountainous areas, once we fill it with liquid nitrogen, it can be used all day without having to refill it.

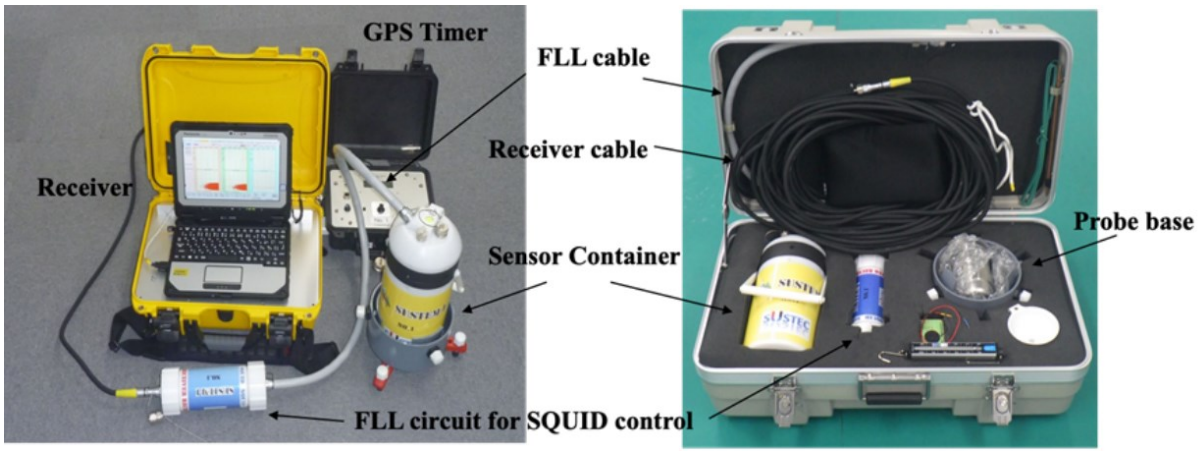

Figure 3: SQUID-TEM exploration system (SUSTEM®).

Figure 4 shows photos the system's transportation to a measurement site and its on-site operation. One set of measurement system can be transported by one person on flat ground, and two people can transport it even in mountainous areas, as shown in the photo. Both the sensor part and the receiver are installed on the ground surface to perform measurements without digging holes, making the measurement highly efficient and environmentally friendly. The area required to install the sensor section is approximately 50 cm square, and the receiver is installed approximately 30 m away from the sensor to avoid magnetic noises due to vibrations, for example, induced by the movement of people.

Figure 4: On-site operation of the SQUID-TEM system.

In the TEM method, we measure temporal changes in the secondary magnetic field created by the underground current induced and diffused after the primary DC magnetic field is shut off. Environmental noise is suppressed by performing averaging processing, such as stacking of the transients in response to a repetitive rectangular wave, as shown in Figure 5. This makes it possible to explore deep underground by measuring attenuated secondary magnetic field at late enough times. For the case of exploration depth of over 3000 m, a measurement time of 2 seconds is often required after the primary magnetic field is shut off. In that case, the measurement is usually repeated 1000 times with one cycle of 2 seconds plus ON, 2 seconds OFF, 2 seconds minus ON, and 2 seconds OFF, and each measurement at one point takes about 2.5 hours. By using two or three systems at the same time, it is possible to measure six points a day and 60 points in 10 days. The example shown in the measurement screen in Figure 5 shows a case of measurements with different time ratios, with ON for 1 second and OFF for 2 seconds. In this case, 1000 repeated measurements can be carried out in about 1.5 hours. It is possible to increase the efficiency of measurement further. For example, nine points can be measured per day, and 60 points can be measured in seven days when it is easy to approach the measuring points. The measured data undergo filtering,

trending, and stacking to remove noises such as those from power lines and geomagnetic fluctuations before resampling and inversion analysis.

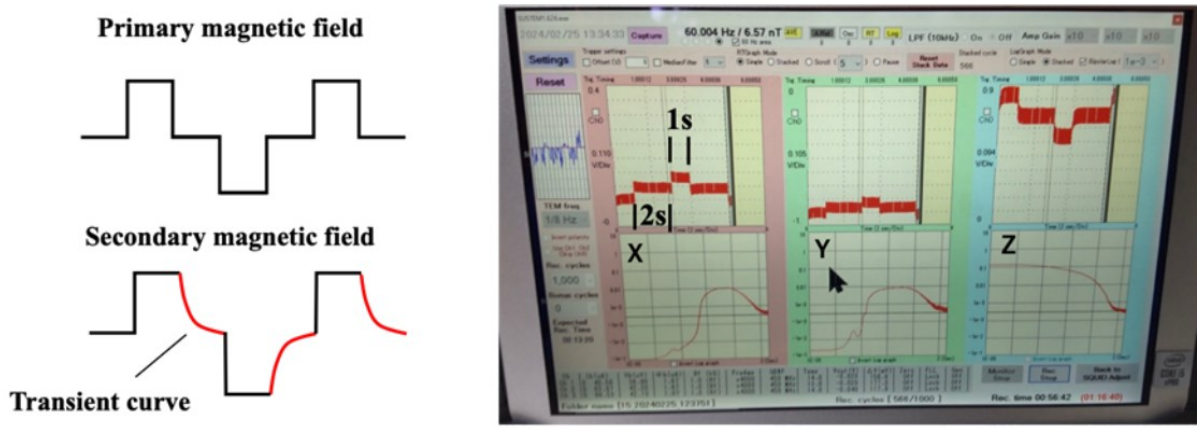

Figure 5: Transmission and reception signals in TEM method and real-time measurement screen of SUSTEM. (On the real-time measurement screen, the upper row shows the real-time received waveform of X, Y, and Z axis for each period, and the lower row shows the stacked waveform (decay curves) after the primary magnetic field is shut off).

3. EXAMPLE OF EXPLORATION IN GREEN FIELD

In Sumatra, Indonesia, an exploration was conducted using a grounded-wire source and the measurement point arrangement shown in Figure 6. The total length of the grounded-wire source was 5.1 km, and the measurement area was approximately 5 km east-west and 4 km north-south. In the figure, the points marked with crosses were not used in the analysis because they are close to the grounded-wire source and are greatly influenced by the shape of the grounded-wire source. In the 3D inversion, the shape of the grounded-wire source was assumed to be a straight line, indicated by the blue line. The analytical model shown in Figure 7 is 7 km east-west, 8 km north-south, 3500 m deep, and has a mesh size of 25 m x 25 m x 25 m.

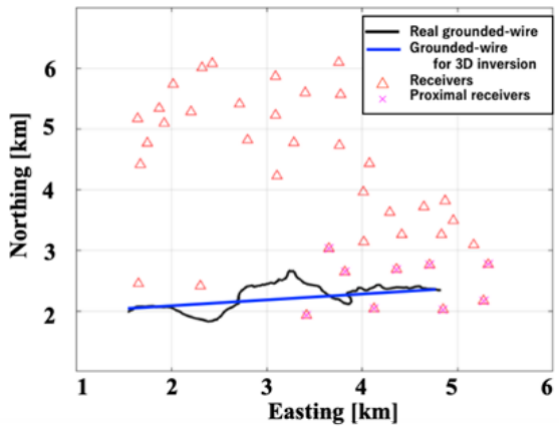

Figure 6: Arrangement of grounded-wire source and measurement points.

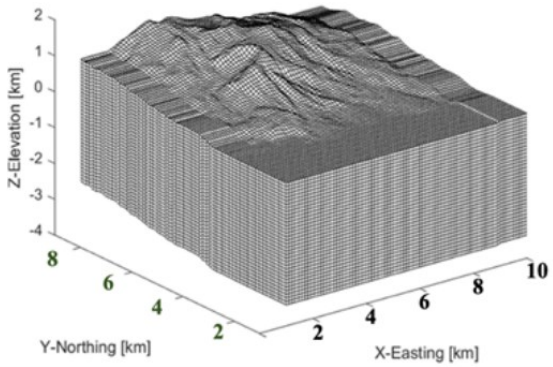

Figure 7: Mesh structure used for analysis.

In order to obtain unique and stable data, regularization is necessary, and a method that minimizes the Tikhonov objective function $P\alpha(\mathrm{m})$ was used (Tikhonov and Arsenin, 1977).

$$P\alpha(\mathrm{m}) = \phi(\mathrm{m}) + \alpha s(\mathrm{m}) = \min \tag{1}$$

Here, ϕ (m) is a misfit functional between the predicted and the observed SQUID TEM data, s(m) is the stabilization functional, and α is the regularization parameter that balances the misfit and stabilizing functional. The minimization problem formulated by (1) was solved via the re-weighted regularized conjugate gradient (RRCG) method (Zhdanov, 2002).

We used a data weighting scheme based on the known standard deviation to reduce the input of noisy data into the inversion result. Data weights were determined by using observed error Err_o (standard deviation of measurements) and theoretical errors Err_t as,

$$W_d = max\ (Err_o,\ Err_t)^{-1} \tag{2}$$

Theoretical errors Err_t were calculated assuming that the measurements are accurate to 1 pT or 3% of the observed fields B_{obs}.

$$Err_t = 1\ \text{pT} + 0.03 \cdot B_{obs} \tag{3}$$

The inversion converged to a global misfit χ^2 which is given by

$$\chi^2 = \frac{1}{N}\sum (W_d(d_i^p - d_i^o))^2 \tag{4}$$

where d^p are the predicted data and d^o are the observed data, respectively.

Figure 8 shows examples of decay curves of the observed with predicted data and the distribution of the local RMS misfit to illustrate the SQUID TEM data fit. The inversion converged to a global RMS misfit χ^2 of 3.61, which is a very statistically reasonable value indicating a relatively low misfit level between the observed and predicted data.

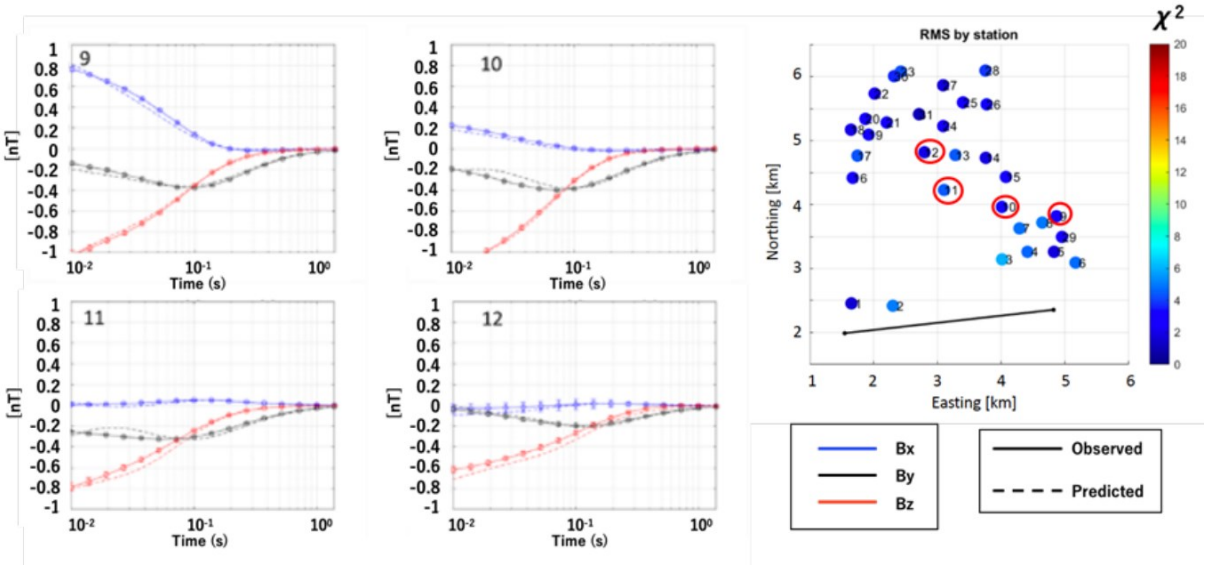

Figure 8: Observed and predicted decay curves for the measurement point 9-12, and the distribution of the local RMS misfit.

EMVision® software, developed by TechnoImaging, was used for the inverse analysis, with a starting homogeneous half-space background model of 25 Ωm, an upper limit of 10 kΩm, and a lower limit of 0.1 Ωm of the inverse resistivity. The iterative inversion of the RRCG method was terminated when the changes due to iterations became less than 0.1%. The contraction integral equation method was used for 3D numerical forward simulations (Zhdanov, 2018).

The isosurfaces of resistivities of 1, 10, and 100 Ωm are used. Red color corresponds to 1Ω m, yellow represents 10Ω m, and green corresponds to 100Ω m. Figure 10 presents a combination of several vertical sections (on the left) and a horizontal section at a depth of 500 m (on the right) to show the low resistivity anomaly. There are two zones of a few Ωm resistivity located at a depth of 500 m to 1000 m divided into two areas, and these are considered to be the clay cap layer of the geothermal reservoir.

This geothermal area has been explored using the MT method in the past. Therefore, we compared the results of the MT method and the SQUID-TEM method. Figure 11 shows a vertical cross section of resistivity at the same location. The intervals between the measurement points are almost the same, and the measurements were not made with increased measurement density, as shown in Figure 1. Analysis using the MT method shows that a low resistivity layer of several Ωm is spread over a wide area of more than 6 km, while analysis using SQUID-TEM shows almost the same depth but in a limited area of about 1.5 km. This suggests the existence of a low resistivity region in the area and points to a connection with a low resistivity region near the surface, indicating fumaroles

confirmed on the ground surface. In the future, it will be necessary to carry out a detailed investigation through drilling, but we believe that we have obtained relatively clear exploration results.

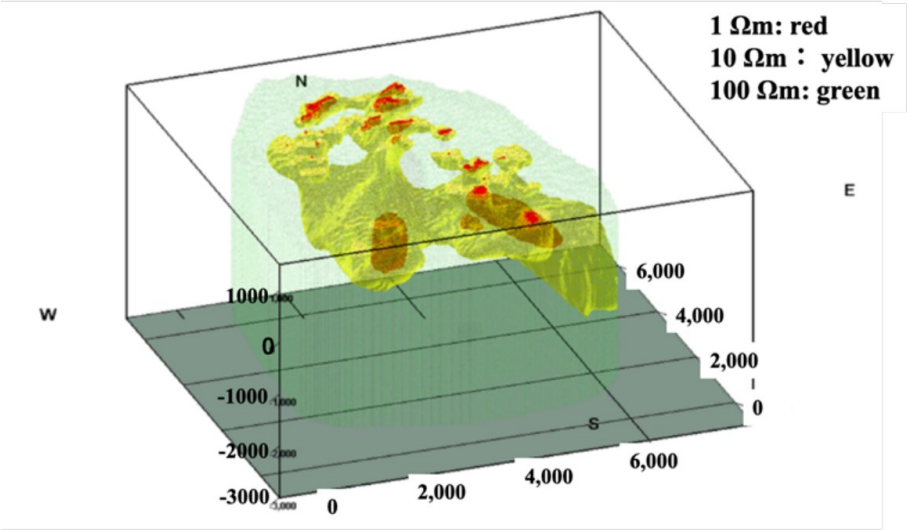

Figure 9: 3D view of the inverse model represented by isosurfaces at 1, 10, and 100 Ωm shown by red, yellow, and green color, respectively.

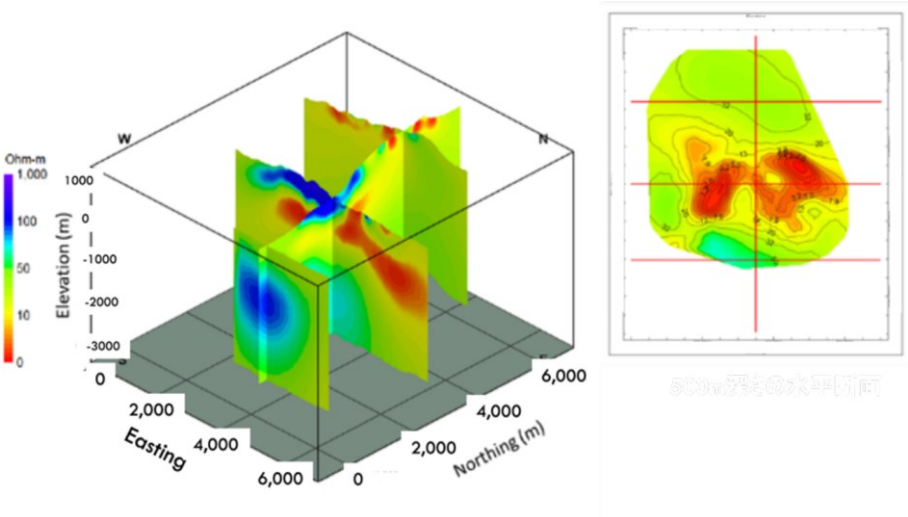

Figure 10: 3D image of resistivity distribution obtained by 3D inversion and horizontal section at 500 m depth.

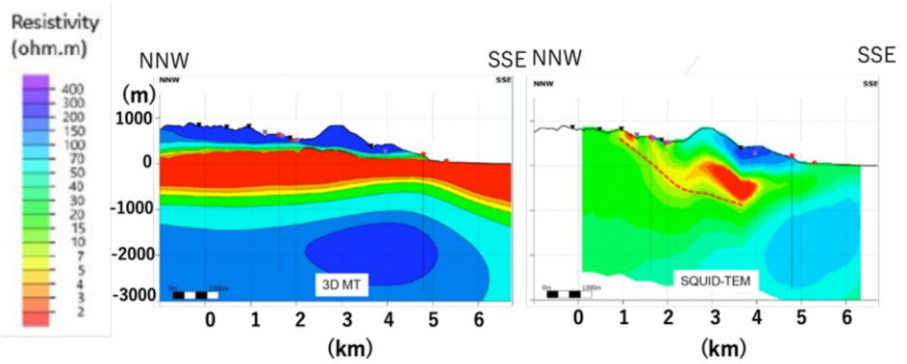

Figure 11: Comparison of the distributions of resistivity obtained by MT method (left panel) and SQUID-TEM method (right panel).

4. EXAMINATION OF EXPLORATION IN BROWN FIELD

We believe that the demand for exploration in so-called brownfield areas, which are areas around geothermal power plants that are already in operation, will continue to increase in the future.

There are following significant challenges in brownfield exploration:

- Electromagnetic noise from power plants and power lines.
- Influence on measurement of induced current generated in buried steel pipes of production wells and reinjection wells.

First, an example of measurement data taken in a field near a geothermal power plant and power lines is shown in Figure 12.

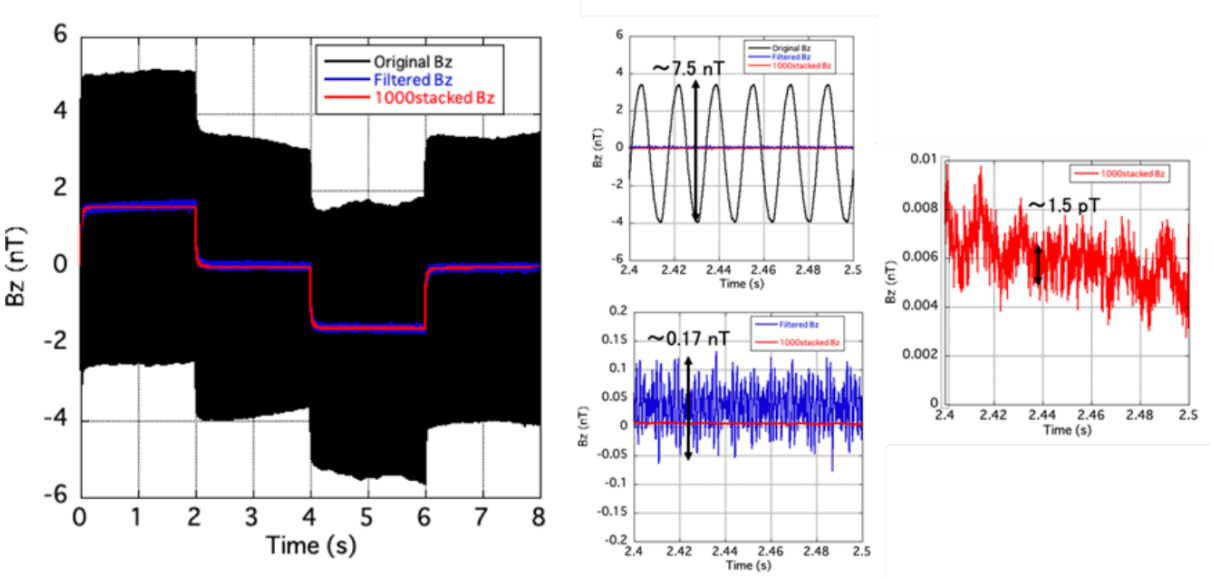

Figure 12: Effect of noise reduction by TEM method from measurement data taken in a brown field.

The figure on the far left shows an observed Bz waveform for one cycle. The amplitude of the noise with a sinusoidal waveform, mainly due to the power line in original Bz, reached 7.5 nT, as plotted in black. By using a filtering technique, the noise amplitude was reduced to 0.17 nT, as shown in blue. We took 1000 cycles of data and stacked them after the filtering process. Then the noise was reduced to pico tesla level. The theoretical noise level is given by

$$4 \times N_w \times \sqrt{\frac{f_s}{2}} \div \sqrt{N_s} \tag{5}$$

where N_w is the white noise level of the magnetometer, f_s is the sampling frequency, and N_s is the number of stackings, respectively (Hato et al., 2013). We used a SQUID sensor with a noise level of 50 fT/ √ Hz, sampling frequency of 50 kHz, and 1000 times stacking. The theoretical noise level is calculated to be 1.5 pT. We confirmed that the noise level of measured data is reduced to the theoretical noise level limited by the ultra-sensitive magnetometer, even in a brown field.

To examine the influence of steel pipes on production well, we carried out a forward simulation for models with and without steel pipes, assuming steel pipes and transmission sources in an actual brown field. Figure 13 shows the arrangement for the forward simulation. The borehole with a steel pipe is located at a distance of 1 km from the grounded wire source. Measurement points of No.35 and No.36 are placed just near the well entrance and almost directly above the steel pipe path. In this simulation, the transmission current was assumed to be 28.1A. The characteristics of the steel pipe were assumed to be 10 cm in diameter, 3 mm in thickness, and 10-7 Ohm-m in electrical resistivity.

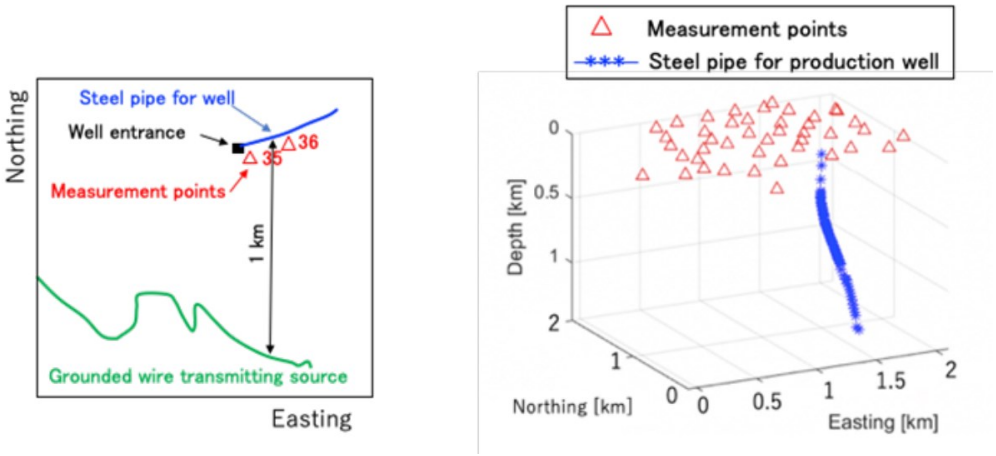

Figure 13: Arrangement for consideration of steel pipe influence on measurement.

The influence of the steel pipe on the magnetic field transients generated by underground induced currents was found to be less than 0.04%, even at these measurement points near the well. This is considered to be due to the small volume of the steel pipe and the structure that makes it difficult for a circulating current to occur. This result suggests that steel pipes in wells do not need to be considered in measurement point selection or analysis.

It is thus confirmed that the influence of power line noise can be effectively removed by signal processing utilizing repeated measurements in the TEM method, and the influence of the well steel pipe is limited. These results indicate that the SQUID-TEM method is an effective technique for geothermal development in brown fields.

5. SUMMARY

In order to accelerate the development of geothermal power generation, we have developed a TEM system with superconducting quantum magnetic sensors suitable for outdoor use, which enables exploration at over 3000 m depth. We applied 3D inversion analysis to SQUID-TEM exploration data collected at a geothermal site for the first time. This SQUID-TEM technology has already begun to be used at various sites, and it has been demonstrated that it is possible to clearly identify zones of conductivity anomaly.

It has been demonstrated that the noise level of measurement data, even in brown fields, can be reduced to near the theoretical limit calculated from the sensor's sensitivity by using this technology.

Noise-resistant electromagnetic exploration using artificial transmission sources enables deep exploration and is used not only for new geothermal development but also for exploration to maintain and increase the output of geothermal power plants already in operation. We believe that this will contribute to the acceleration of power generation.

ACKNOWLEDGEMENT

We received grants from NEDO for technology development, the Mitsubishi UFJ Technology Development Foundation, and Toshiaki Ogasawara Memorial Foundation for system mass production, and the Agency for Natural Resources and Energy for support to exploration in Indonesia.

Stress Distribution Analysis to Characterize the Fault Permeability in Nage Field, Indonesia

Muhammad Ikhwan

The University of Auckland, New Zealand

ikhwan8823@gmail.com

Keywords: Nage, in-situ stress, geomechanics, structural geology, reservoir modelling

ABSTRACT

The fault zone is one of the critical aspect that controls permeability in the Nage geothermal field. It is composed of conjugate strike-slip faults that likely framework the hydrology in the field. Each fault has its own discontinuities and geometry, the most favorable part to host localized permeability. The boundary element method characterizes the stress distribution along these faults and maps the stress localization caused by fault intersections, orientation changes, or fault termination. The results show that these fault attributes generate local stress, indicated by the coulomb shear traction, dilation and normal traction changes. The highest stress perturbation is induced by the fault orientation changes, followed by termination and intersection. These local stress permeability-induced features are consistent with the occurrence of surface thermal manifestations in Nage, indicating that hydrothermal flow is most likely local and focused, and is strongly controlled by a discontinuity in the geological structures. These localized permeable zones accommodate the reservoir fluid's upwelling flow while also hosting the geothermal system. This study can support the geothermal conceptual model and well-targeting strategy for the next phase of Nage field exploration.

1. INTRODUCTION

Many geothermal fields are secondary permeability dependent where fault and fractures dominantly control the hydrology of geothermal fluid. They can act as the conduit or the horizontal barriers that dictate a geothermal reservoir continuum. As a result, many geothermal wells targeting these features expect the well will encounter a good permeability zone that can enhance the well's output. Therefore, it is critical to detail the fault and fracture zone mechanism and characterization to better understand these features.

The movement of faults, involving both kinematic and dynamic processes, has been suggested as an explanation for the positioning of hydrothermal upwelling relative to structural settings (Curewitz and Karson 1997; Siler et al. 2018). When a fault undergoes movement, stress is released along the faulted segments and transferred to the surrounding crust, resulting in strain, including shortening and dilation, in the adjacent areas. Studies have demonstrated that areas experiencing the highest stress and dilation are often associated with extensive geothermal features such as fumaroles, mud pools or hot springs. While any immediate increase in permeability from fault activity is expected to diminish rapidly due to secondary mineralization, repeated fault slips continue to generate and sustain permeability in specific stressed and strained areas. With successive earthquake cycles, these areas are continually subjected to stress and relief from minor slips, leading to the development of denser fracture networks or more open fractures compared to the surrounding crust. This makes these areas particularly conducive to hosting hydrothermal circulation.

Nage geothermal field considerably undergoes a complex tectonic and volcanic mechanism. This results in noticeable structural features and also the occurrence of surface thermal manifestation that seems to interconnect with each other. To assess the impact of fault slip on the development of permeability and fluid flow at structural discontinuities in Nage, and to understand the permeability development and surface thermal manifestation occurrence, I conducted stress distribution modelling focused on detected faults in Nage which play a key role in the geothermal systems, respectively. The research method and format in this paper were initiated by Siller (2023) and it is fairly applicable to understanding the relationship between structural framework with the hydrothermal fluid pathway in Nage. The data used in this work refer to a published previous geological study by Pradipta et al. (2021). This analysis provided with assumed geomechanics parameter for the slip and distribution modeling. Furthermore, applying these concepts to geothermal fields allows for a delineation of the favorable zones to drill the well in further development.

2. GEOLOGY AND STRUCTURAL SETTING IN NAGE

The island of Flores is situated within the Sundaland Block and lies at the boundary between the Eurasian and Indo-Australian Plates. The interaction between these two plates is characterized by the subduction of the Sunda

Arc to the west and the Banda Arc to the east, where the Indo-Australian oceanic crust subducts beneath the Eurasian Plate. The Indo-Australian Block is moving relatively north-northeast towards the Eurasian Plate, causing a counterclockwise rotation of Flores Island. This rotation has led to the formation of en-echelon volcanic chains on Flores Island, such as in the Nage area (Mccaffrey, 1988).

Research conducted by Koesoemadinata et al. (1994) and Muraoka et al. (2002) indicates that the Nage area consists of volcanic rocks ranging from the Tertiary to the Quaternary. These volcanic rocks in the research area are believed to originate from the eruptions of several volcanic cones, including Wolo Kenowe, Wolo Deru, Wolo Batulaba, Wolo Piu, Bena, Sinder Cone, and Mount Inirie. Generally, the volcanic rocks in the Nage area comprise lava, pyroclastic flows, pyroclastic falls, and alluvial deposits (Figure 1a). The lava has an andesitic composition, ranging from porphyritic to aphanitic texture, with occurrences of clay mineral alterations and columnar and sheet joints. Besides volcanic rocks, hydrothermal alteration with moderate to strong intensity has been observed in the research area, characterized by clay minerals found around fumarole manifestations in Wolo Puti, Keli hot springs, Nage hot springs, and the northern and eastern walls of the caldera.

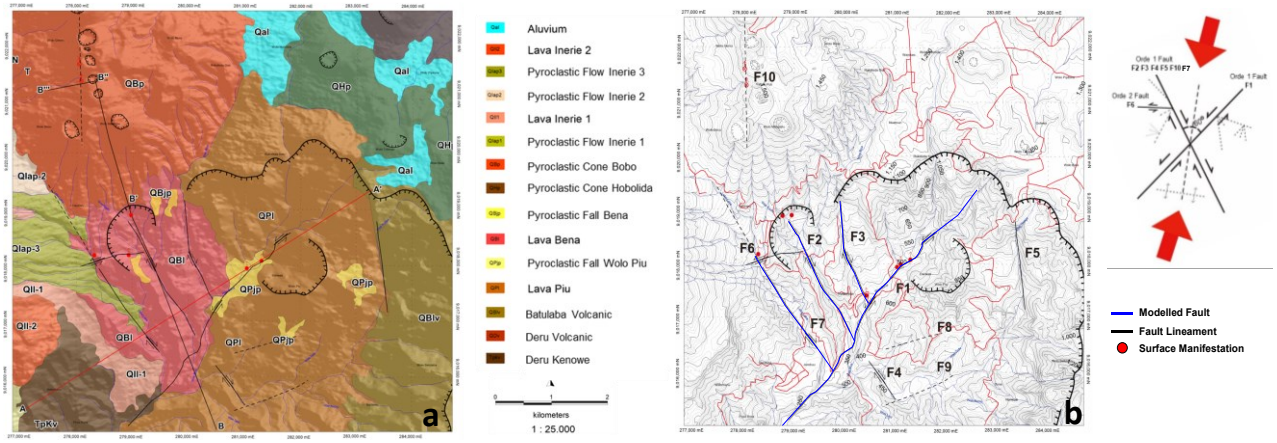

Figure 1: The geological information adapted from Pradipta et al. (2021): a) The geological map of the Nage field. b) The structural map of the Nage field. The blue line is the fault lineaments used for the stress transfer modelling

The geological structures in Nage were delineated by Pradipta et al. (2021) in Figure 1 by using the DEMNAS (Indonesia National Topographic) imagery and direct structural measurement on the surface. From the imagery, the noticeable structure also includes circular features indicating calderas and craters, as well as linear alignments of cinder cones oriented north-south. Field observations also reveal associated fault structures and zones of crushed rocks indicating strike-slip faulting oriented northeast-southwest and northwest-southeast. These structures are believed to influence the appearance of geothermal manifestations in the Nage area. They consist of secondary structures including oblique slip faults with a normal component in Nage noted as F1, oblique slip faults with a normal component noted as F2, oblique slip faults with a reverse component in noted as F3, oblique slip faults with a normal component noted as F4, oblique slip faults with a normal component in noted as F5, left-lateral slip faults in noted as F6, and oblique slip faults with a normal component noted as F7. DEMNAS imagery observations reveal several discontinuity surface lineations (faults noted as F8 and F9) and alignments of cinder cones believed to be structures representing faults noted as F10. In this study, I only use the prominent fault used has a clear appearance both on the surface and imagery, interpretatively. These faults are also been measured by the geological survey on Pradipta et al. (2021). They are F1, F2, F3 and F7. The maximum horizontal stress in the Nage field is interpreted relatively NNE-SSW or around N25^{o}E which is aligned with the regional horizontal stress in the southern cross of the Flores island as the result of subduction.

3. METHOD

Several factors that influence a fault mechanism and properties such as stress magnitude, lithology, rheology, and mineralization can result in a highly localised permeable zone that acts as the conduit for the fluid flow (Rowland & Sibson, 2004). This permeable zone can develop on the main fault segment and in the surrounding part of the fault including the structure near the slipping fault. The later condition is prone to better maintain the permeability due to its sensitivity to the stress changes during and afterslip, preventing rapid mineralization that can reduce the permeability magnitude. Therefore, the location of this well-maintained permeable zone will highly depend on the fault plane geometry, stress magnitude, and the fault and stress orientation.

The detail of the stress distribution analysis method was explained by Siller (2023). He used the boundary element method to calculate the three-dimensional displacement on triangular elements called Cut and Displace. The faults geometry was assigned to the 3D model and justified with the input stress. Two main aspects will be calculated on these inputs including the slip tendency of faults and the stress and strain changes on the fault planes and surrounding crust, resulting in four geomechanics parameters that can point out the local stress distribution impact including; 1) coloumb shear traction or coloumb friction, 2) dilation, 3) normal stress, and 4) shear stress.

Coulomb shear traction or coloumb friction refers to the force required to overcome the friction between two surfaces as they slide or move relative to each other. This force depends on factors such as the materials involved, the roughness of the surfaces, and the normal force pressing the surfaces together. The Coulomb friction model is often used in mechanics and engineering to calculate the forces and stresses in systems where sliding or relative motion between surfaces occurs. If the Coulomb friction is high, it means that there is a strong resistance to sliding or relative motion between the two surfaces in contact. In practical terms, this could mean that it requires a significant force to move or slide one surface against the other. High Coulomb shear traction can lead to difficulties in movement, increased wear and tear on materials, and potentially reduced efficiency in mechanical systems. On the other hand, if the Coulomb shear traction or friction is low, it indicates that there is less resistance to sliding or relative motion between the surfaces. This can make it easier to move one surface against the other with less force.

In geomechanics, dilation refers to the expansion or increase in volume that occurs within a rock mass when it is subjected to external forces. This concept is particularly relevant in the study of the mechanical behaviour of rocks under stress. When a rock is subjected to stress, such as compression or shearing forces, it can undergo deformation. Dilation specifically refers to the tendency of the material to increase in volume or expand perpendicular to the direction of the applied stress. This expansion occurs due to the rearrangement of particles or grains within the material as it experiences stress. The normal traction, also known as normal stress or normal force, refers to the force per unit area acting perpendicular (normal) to a surface, while shear traction, also known as shear stress, represents the force per unit area acting parallel to a surface or along a plane within a material.

The F1, F2, F3 and F7 faults are derived from the previous study. Due to subduction in the Flores, the Nage field is controlled by a compressional regime and by considering the topography of the field, the sense of movement of those faults is dominantly strike-slip faults. For the strike-slip faulting stress regime, the maximum horizontal stress (SHmax) is larger than the vertical stress (Sv), which is larger than the minimum horizontal stress (Shmin). For these structural settings which contain left and right-lateral strike-slip faults, SHmax is oriented to azimuth N25°E for the fault geometries. In the need stress modelling process, I assumed that strike-slip faults dip will be vertical as proposed by Anderson (1905).

The stress transferring model needs the input principal stress magnitude. For the input stress, I use the coefficient of friction of 0.6 and the crustal density of 2600 kg $^{m-3}$. The top of the reservoir in Nage is assumed distributed at 0 mASL which is typical of the top of the reservoir of the geothermal field on Flores Island (Muraoka et al., 2002). The mean surface level in the Nage field is assumed at 500 mASL, so the vertical overburden distance from the surface to the top of the reservoir will be 500 m in depth. An assumption was also made that the surface's stress and pore pressure values are zero and the overburden stress gradient is linear to depth.

Table 1: Input parameter for modelling

Young's modulus	75 Gpa
Poisson's ration	0.25
Coefficient of friction	0.6
Cohesive strength	0 Mpa
S_{Hmax} magnitude (at -0 mASL)	16.77 Mpa
S_{Hmax} direction	northeast – southwest
S_v magnitude (at -0 mASL)	12.74 Mpa
S_v direction	vertical
S_{Hmin} magnitude (at -0 mASL)	8.71 Mpa
S_{Hmin} direction	northwest-southeast
Pore pressure	9.79 Mpa

Stress variations and deformation arising from the simulated slip are computed across a grid of 256 points spaced evenly at 200-meter intervals within a 3-kilometre by 3-kilometre area, situated 500 meters below the surface. The input faults, extending beyond the grid by 1 kilometer, are assumed to have no stress or strain effects at the grid's edges. The stress changes are quantified in terms of Coulomb shear and normal tractions, specifically focusing on fractures with the greatest increase in Coulomb shear traction and a decrease in normal traction within a deviation of ± 1 standard deviation from the strike, dip, and rake of the input faults. These stress-induced

dilatation and shear tractions could potentially create permeable zones conducive to the upward flow of hydrothermal fluids to the surface.

The stress alterations are expressed as Coulomb shear and normal tractions. These are computed for fractures exhibiting the highest increase in Coulomb shear traction and the greatest decrease in normal traction for all fracture orientations within ± 1 standard deviation of the strike, dip, and rake of the input faults. Essentially, the stress changes discussed pertain to fractures that are optimally oriented similarly to the input faults. Assuming all strain is elastic, dilatation is calculated as the percentage of volume increase. The stress effects are illustrated as the percentage change in Coulomb shear traction and the percentage change in normal traction relative to the original (pre-slip and static) stress state (Siller 2023).

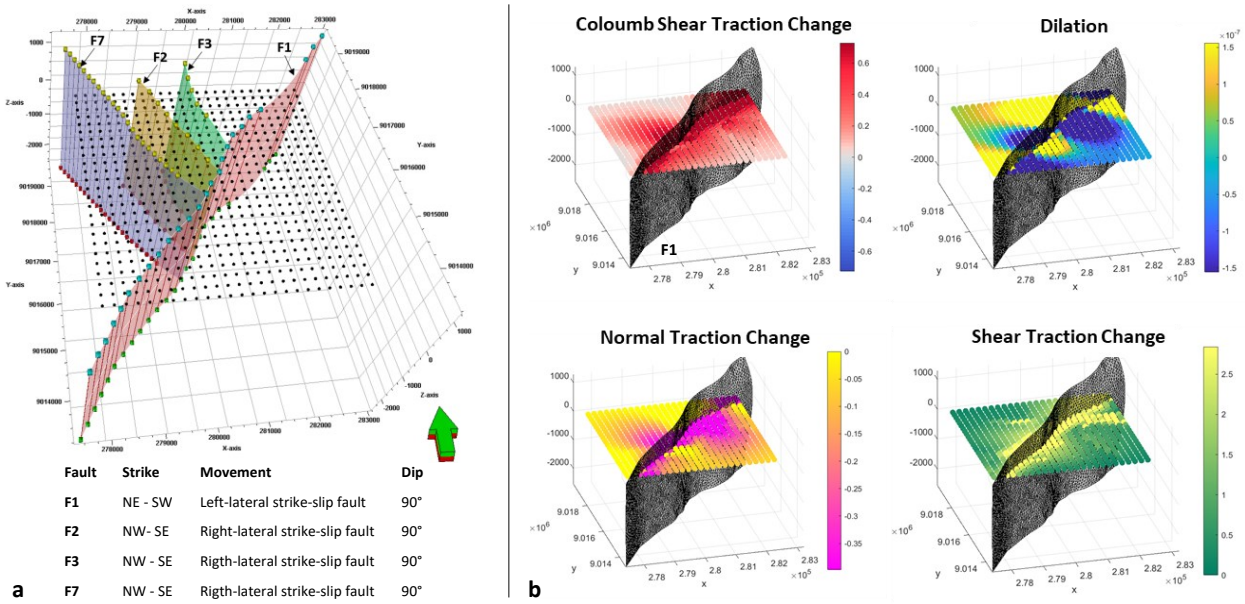

Figure 2: The modelling process to map the stress distribution on faults. A) The 3D view of the four modelled faults included in the study with the observation points at reservoir depth. B) The example of stress distribution analysis on Fault 1. Four stress components are measured on each observation point.

4. RESULT

4.1 Stress Distribution

In general, the fault orientation changes are the favorable area to undergo the stress changes impacted by the input stress parameter in the model. The stress changes could be both positive or negative, depending on the fault's geometry and orientation to the principle stress. Fault tip and fault intersections also experienced stress changes, that also correlate with the occurrence of surface manifestations.

For the percentage of coloumb shear traction change, the positive change (blue) indicates the resistance of the area around the fault plane that is hard to move while the negative change (red) indicates the opposite. Fault intersection between F1 and F2, F3 and the fault bend of F1 and F3 are the areas that have remarkable stress changes. The highest coloumb shear traction percentage decreasing (up to < 0.5% MPa) is concentrated at the most northern part of the F1, where the F1 strike significantly bends to far northeast about ~8°. This means that this area is prone to move when stress is applied due to the fault movement. The increase of the coloumb shear traction percentage occurs right on the intersection of F1 and F2, F3, remarks the most resistance area in the fault surrounding a movement. This also occurs on the fault bend area in the southern part of F2, whereas the relatively north-south fault bends ~15° to the southeast toward the F1. The resistance block around the fault will likely occur in the tips of the fault, such as the northern tips of F2 and F3 which indicates coloumb shear traction change increasing up to 3.25% MPa.

The dilation changes calculated from the input stress parameter follows the change of coloumb shear traction changes in the opposite way, if the coloumb shear traction changes are low in an area, the dilation changes should be positive. This is represented in the area of fault intersections, fault bends and fault tips. The most positive dilation change is located in the area between F1 and F2, right on the west side of the F1 strike bending, where the changes are up to 3.9×10^{-3}%. The dilation changes area could also controlled by the fault tips as shown by the northern tips of F2 and F3 with changes of 2.1×10^{-3}%. These areas with positive changes indicate the volume

increasing due to the applied stress. The negative dilation changes areas are controlled by the fault intersection as shown by the intersection of F1 with F2, F3 and F7, which remarks that instead of creating open space or permeability, the fault intersection zones are prone to compact under the applied stress parameters. Extensive negative dilation changes also appear on the east side of F3's northern tip. Most of these areas have < -1.2×10^{-3}% which indicates decreasing in area volume.

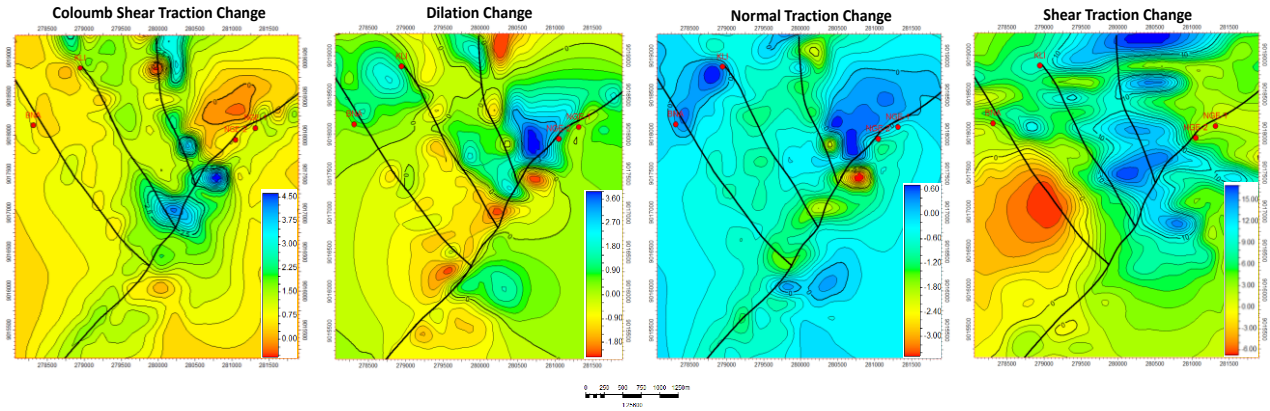

Figure 3: Contour maps show measured geomechanics parameters in the study area. The parameters anomaly mostly address the structural discontinuities zone, including fault bend, fault intersections and fault tips, and associates with the surface thermal manifestations.

The shear traction changes pattern also follows the coloumb shear and dilation, where the areas that undergo significant changes are controlled by the fault discontinuities. There are two areas that show the increasing shear stress, F1 northern fault bend and the northern tips of F2 and F3. The only area that indicates a significant shear stress decrease is the eastern side of the F1 and F3 intersection. This might also influenced by the bending of the F1. Meanwhile, the normal traction changes percentage in the Nage field is more distributed instead of focusing on the narrow area of the fault discontinuities. However, some thermal manifestations including KLI and BNA located on the location where the normal traction change increases. The increase of shear or normal traction should influence the fault slip susceptibility regarding the applied stress, which means that these areas are more prone to move.

4.2 Fault Slip Potential

Fault slip potential (FSP) analysis is a geomechanical assessment used to evaluate the likelihood of faults slipping or reactivating under certain stress and pore pressure conditions. If the stress distribution analysis investigates the stress on the rock around the fault, the fault slip potential analysis measures the stress along the fault sections. The application of fault slip potential is available in Walsh et al. (2023). Some assumption of stress parameters was made to predict the likelihood of the fault slip potential on structures in the Nage field, which required the stress gradients. I estimated the gradient of the maximum horizontal stress (SHmax) at 1.22 psi/ft, vertical stress (Sv) at 1.1 psi/ft, and minimum horizontal stress (Shmin) at 0.7 psi/ft, considering the possible formation composed of the Nage field. The assumption was also made for the initial reservoir pressure at 0.43 psi/ft. The fault slip potential analysis for the Nage field, as illustrated by the provided images and delta pore pressure (ΔP) colour bar, reveals significant insights into the stability and slip likelihood of key faults under varying pore pressure conditions. Some fault sections in F1, especially in the fault bend section, are shown in deep red on the fault map which requires the most minimal ΔP to slip, indicating it is critically stressed and highly sensitive to changes in pore pressure. Even minor increases in pore pressure could trigger slip along this fault section which means have a high favourability to create permeability. This also agrees with the occurrence of NGE-1 and NGE-2 thermal manifestations and the coloumb shear and dilation stress changes. The other sections of F1 also indicate slightly critically stressed sections. The north tip of F3 also indicates a similar fault section condition while the rest of the fault sections on F3 still need slightly moderate ΔP to slip. However, most of the F2 and F7 sections, depicted in yellow and orange, require moderate ΔP to slip, suggesting they are less sensitive than F1 and F3 but still pose a potential of reactivation under sufficient pore pressure changes. The Mohr circle diagram further supports this, showing red data points near the failure envelope for F1 and F3, while orange and yellow points for F2 and F7 are further from the envelope, indicating higher ΔP requirements for slip. The stereonet plot, which aligns maximum horizontal stress (SHmax) with fault planes, reveals that faults oriented in critical directions (red and orange) are highly susceptible to pore pressure changes. These results highlight that friction coefficient, SHmax azimuth, dip angle, fault strike orientation and also the relative location between faults are the most sensitive factors that control the fault slip potential measurement.

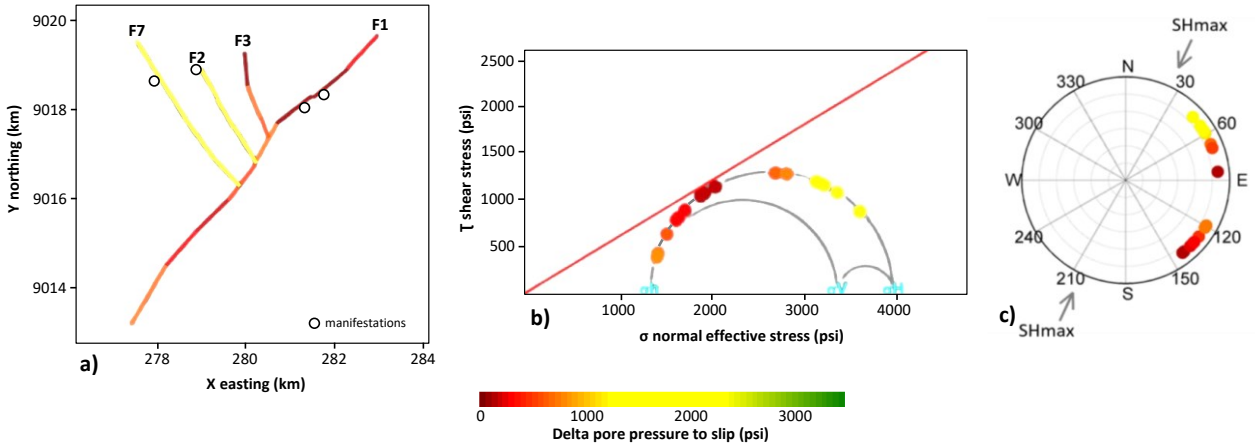

Figure 4: A) The fault map of the Nage field, identifying three major faults: F1, F2, F3, and F7 along with the fault sections on each of the faults. These fault sections are depicted in different colors indicating their slip potential. The colour scale at the bottom ranges from red (high slip potential) to green (low slip potential). B) Mohr circle diagram plotting the shear stress (τ) against the effective normal stress (σ effective) for the identified faults sections. C) Fault sections on the stereonet.

4.3 Hydrological Model

The occurrence of surface manifestation often relates to the permeability that provides the pathway to the hydrothermal fluid flow to reach the surface from the reservoir. These manifestations in the Nage field are interpreted as strongly controlled by the geological structure as they are all located in the vicinity of the prominent fault lineaments. The stress distribution analysis anomaly shows a good agreement between the changed stress area with the location of the surface manifestations. The NGE-1 and NGE-2 hotsprings exposed on the F1 fault bend or orientation changes, which conceptually will experience the stress changes. Accordingly, this area also indicates a favorable area to be fractured as it has negative coloumb shear traction change that indicates a weak zone, positive high dilation changes percentage as it indicates the volume increasing within the rock mass in this zone, and also the increasing of the shear stress that could trigger a slip of pre-existing fractures reactivation. This also happened for the BNA and KLI manifestations, where the stress distribution anomaly also supports the interpretation of surface manifestation pathways. These manifestations are concentrated at the north tips of F2 and F3. However, the magnitude of stress distribution anomaly intensity is not as high as the surrounding area of NGE-1 and NGE-2. This analysis supports the interpretation of structural-controlled permeability that accommodates the occurrence of surface thermal manifestation. The mechanism of structural discontinuities in the Nage field most likely forms a narrow secondary permeability (~500 m wide) that accommodates a vertically focused permeability. In addition, the interpretation of narrow and focused-vertical permeability in Flores is also strengthened by how the volcanic craters sporadically occur on the surface, forming the moon-liked surface topography.

Akasako et al. (2002) have concluded the geothermal conceptual model for the Nage field. There are two hydrology concepts proposed based on the occurrence of thermal manifestations in Nage and the surrounding area. First, the upway hydrology along the NE-SW fault, which also controls the occurrence of the Wae Bana River inside the Nage caldera, controls the NGE-1 and NGE-2 manifestations. Hot springs along the Wae Bana River, including NGE-1 and NGE-2, ranging from 7°C to 80°C, show significantly altered surfaces indicating strong hydrothermal activity, although the boundaries are unclear due to plant cover. This also indicates the localized permeability along this river and could be favorable in well targeting focusing on the fault bends section. Second, the lateral flow from the Wolo Bobo field on the northeast part of the Nage caldera. The volcanic activity along a north-trending fault across the Wolo Bobo to Nage caldera created numerous volcanic cones, indicating a good lateral permeability for a series of magma to arise. This relatively north-northwest flow is interpreted to control the occurrence of KLI and BNA surface manifestations. It could be a subsurface structure that is already covered by younger volcanic cone products and still permeable under the current stress condition. However, this interpreted fault is not included in this study as it is not discussed as a prominent fault in Pradipta et al. (2021). Therefore, a further study to detail the existence of this interpreted fault could be a benefit in interpreting the hydrology from Wolo Bobo toward the Nage caldera.

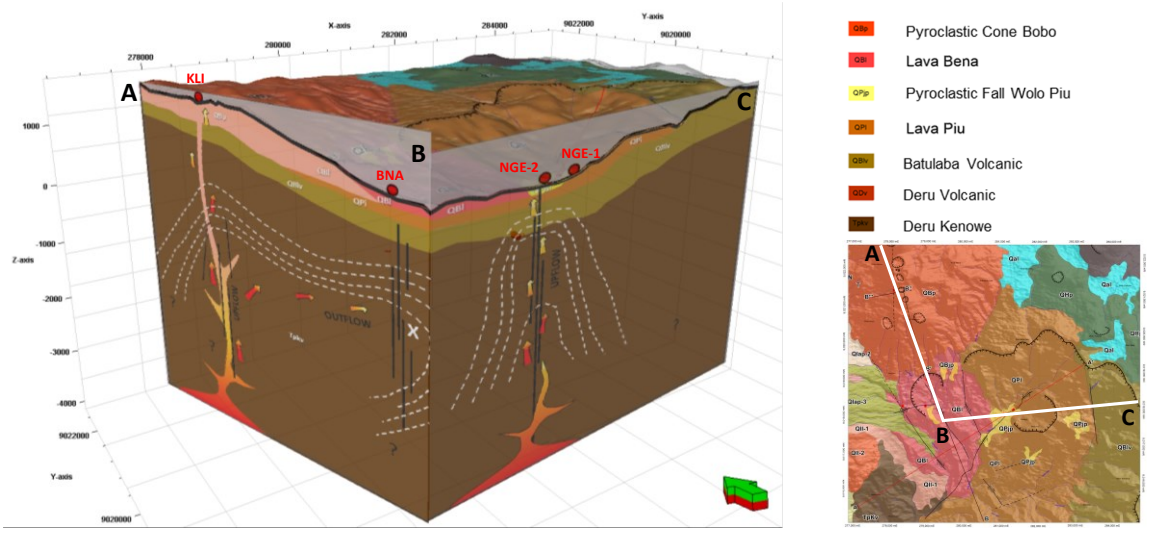

Figure 5: Proposed hydrology model of Nage geothermal field, which is strongly controlled by structure and fault damage zone. Vertical hydrology (upflow) controls the NGE-1 and NGE-2 manifestations while the BNA manifestation is interpreted as the outflow manifestation from the north-northwest upflow, indicated by the KLI manifestation.

5. DISCUSSION

The analysis of the stress distribution around fault planes in the Nage geothermal field reveals that certain fault discontinuities, such as fault bends or orientation changes, significantly enhance permeability. These discontinuities create vertical conduits for fluid flow, evidenced by substantial coulomb shear traction reduction and notable dilation increases. Areas around fault tips also contribute to permeability, particularly in regions where larger fault tips form positive or negative flower structures, facilitating fluid flow. Conversely, fault intersections are less favorable for permeability due to low coulomb shear traction changes and negative dilation, suggesting a higher rock strength resistance. The orientation of fault intersections relative to the maximum horizontal stress orientation plays a crucial role in this phenomenon.

The primary uncertainties in this study focusing to the assumptions about stress and mechanical properties, as well as fault geometry and propagation. The volcanic activity in the Nage area leads to varied volcano-stratigraphy, impacting overburden and sideburden stresses, potentially resulting in a non-homogeneous stress regime. Despite these uncertainties, the assumed stress parameters in this study seem to represent the current stress state in Nage fairly, as indicated by the alignment of results with expectations. Further detailed investigations into fault geometry, including lateral extensions and changes in strike and dip, are necessary due to their significant impact on stress distribution and anomalies across the study area.

6. CONCLUSION

This study emphasizes the critical role of fault discontinuities, such as fault bends or orientation changes, and fault tips, in enhancing permeability within the Nage geothermal field. The findings indicate that these features serve as effective vertical conduits for fluid flow, driven by stress-induced dilation and reduced coulomb shear traction. In contrast, fault intersections exhibit lower permeability potential due to their orientation relative to the maximum horizontal stress and inherent rock strength resistance. The primary challenges in this study include uncertainties in stress parameters assumptions and fault geometry, exacerbated by the varied volcanic stratigraphy in the Nage region. Nonetheless, the stress parameters used in this study provide a reasonable representation of the current stress state, supported by the agreement of the results with known conditions. Future research should focus on refining the understanding of fault geometry and propagation, considering their significant influence on stress distribution and permeability. Addressing these uncertainties will enhance the accuracy of permeability predictions and inform the development of more efficient geothermal resource exploitation strategies in volcanic regions. This comprehensive analysis contributes valuable insights into the permeability dynamics within geothermal fields, particularly those influenced by complex fault structures, and underscores the importance of integrating geological and geomechanical data for effective reservoir management.

ABSTRACT

These days, the globalization of energy transition efforts towards new renewable energy sources is intensively underway. In support of this, Indonesia is committed to achieving a target of 23% new and renewable energy (EBT) in the energy mix by 2025. As much as 40% of the world's geothermal reserves are located in Indonesia. However, in reality, geothermal exploration efforts in Indonesia still face several challenges, including many prospect areas that are difficult to reach, cost efficiency, and funding issues. This research was conducted to identify geothermal manifestations in the Mount Slamet area using remote sensing methods to minimize the existing exploration challenges. ASTER (Advanced Spaceborne Thermal Emission and Reflection) data with NDVI (Normalized Difference Vegetation Index) analysis is used to determine vegetation density, and LST (Land Surface Temperature) analysis is used to determine earth surface temperature anomalies. DEM (Digital Elevation Model) is used to conduct FFD (Fault Fracture Density) analysis, and Landsat-8 imagery to determine the distribution of hydrothermal alteration minerals as supporting parameters. The results of the LST (Land Surface Temperature) analysis found that the lowest temperature reached 9.1oC and the highest temperature reached 30.4oC. FFD (Fault Fracture Density) analysis shows the highest alignment density value of 3.3-4.4 km/km2. The results of data integration show that there are 8 new geothermal manifestation points in the study area. This research can be used as a reference in determining geothermal manifestation points, especially in this study the identified geothermal manifestation points are by the location of the manifestations that have been found previously.

1. INTRODUCTION

Geothermal is one of the energies currently being popularly looked for because it is a renewable energy that supports the energy transition process. The world is turning to new renewable energy, one of which is geothermal energy. Indonesia has over 40% of the world's geothermal reserves. Indonesia is committed to achieving a target of 23% new and renewable energy (EBT) in the energy mix in 2025 (ESDM, 2021). However, in reality, geothermal exploration efforts in Indonesia still face several challenges, namely the large number of prospect areas that are difficult to reach, to cost efficiency and funding issues. Therefore, there needs to be another alternative to identify manifestations of geothermal potential, one of which is the remote sensing method. This method can ease exploration challenges in terms of time efficiency, cost, and accessibility to exploration sites.

The Gunung Slamet area is an area with a geothermal potential of 110 MW which has a potential prospect area of about 60% of the Central Java region. From the results of research by Widagdo (2013), there are 5 geothermal manifestation points in the Gunung Slamet area (Table 1). Therefore, this research is expected to prove and identify potential points in the Gunung Slamet area using a more effective method.

2. METHODS

The method used is remote sensing. This research utilizes three data types, namely ASTER, Landsat-8 OLI/TIRS, and DEM, to identify geothermal potential based on geological and geomorphological data, nighttime surface temperature anomalies, lineament density, and land cover evaluation. Geological and geomorphological data serve as the basis for determining the presence of geothermal systems. Fault Fracture Density (FFD) and night time LST are used to locate geothermal manifestations such as hot springs and fumaroles. Meanwhile, the land cover map is used to evaluate areas that may become geothermal manifestations, such as disturbances in land cover. We used the analysis method of (Ghaly et al, 2023) modified with the addition of hydrothermal alteration map and only used ASTER Night Time data.

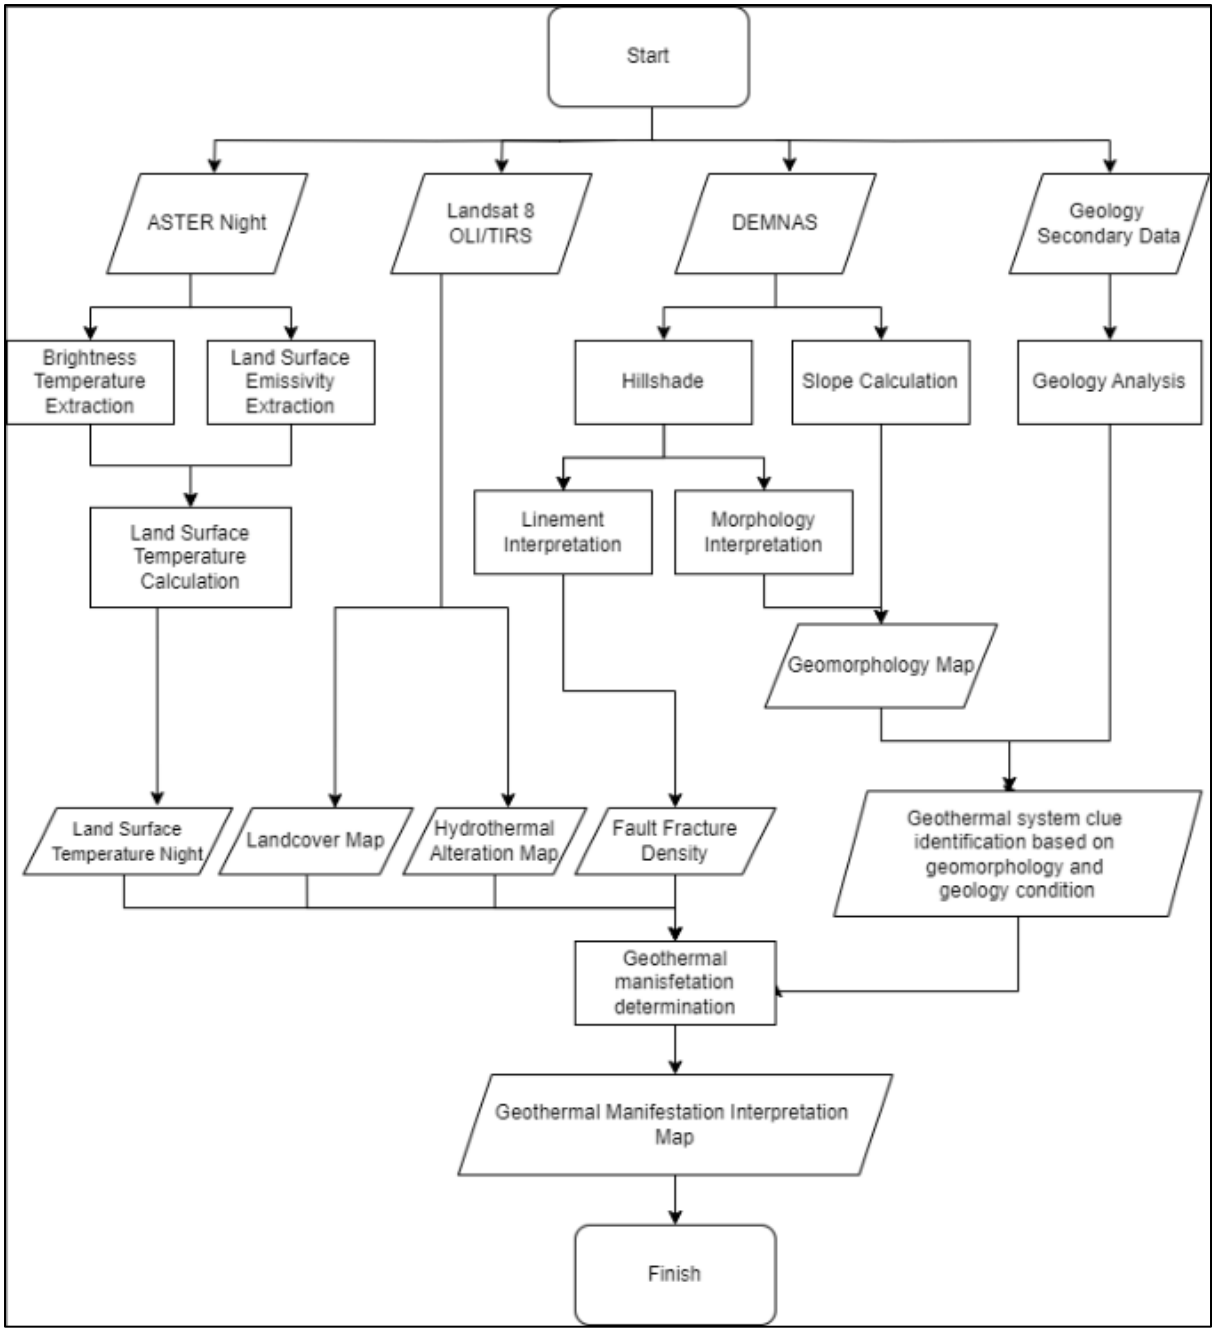

Figure 1: Research Flowchart.

Table 1: Location of Geothermal Manifestation Points (Widagdo, 2013).

No	Name	Location
1	Pancuran 5	Guci, Kec Bumijawa, Tegal
2	Pancuran 13	Guci, Kec Bumijawa, Tegal
3	Pancuran 7	Ketenger, Baturaden, Banyumas
4	Sigedong	Batusari, Kec Sirampok, Brebes
5	Pancuran 3	Karangmangu, Baturaden, Banyumas

Table 2: Image Data Use.

Image Name	Band	Resolution	Acquisition time
ASTER Night Time	TIR (10-14)	90 m	October 9th, 2023
Landsat-8 OLI/TIRS	Band 1- 6	30 m	September 8th, 2020
	Band 8	15 m	
DEMNAS		0.27 Arc second	Accessed on April 21th, 2024

2.1 Surface Temperature Calculation

This analysis uses ENVI software with nighttime ASTER data. The analysis begins with radiometric calibration correction and atmospheric correction to eliminate radiation errors. This is followed by temperature extraction using the emissivity normalization tool applied to the nighttime ASTER data.

2.1.1 Land Surface Emissivity (LSE) Calculation

Land Surface Temperature values require LSE values. Land Surface Temperature is obtained from NDVI processing, vegetation proportion, and emissivity calculations on ASTER images (Ndossi & Avdan, 2016). Normalized Difference Vegetation Index (NDVI) is a comparison of the reflectance value of the red band (Red Band) with the near infrared (NIR Band) which is normalized due to the reflection of land cover such as vegetation. This data can be used to estimate the density of vegetation on the earth's surface (Weirer, 2000 in Laksono, 2020).

To determine the NDVI value of the study area, we used band 4 (Red) and band 5 (NIR) data from the Landsat 8 OLI/TIRS image. With the following formula (Ndossi & Avdan, 2016):

a. NDVI (Ndossi & Avdan, 2016)

$$\text{NDVI} = (NIR - RED)/(NIR + RED) \quad (1)$$

NIR refers to reflected light in the near-infrared band, while RED refers to reflected light in the red channel on the ASTER instrument.

b. Proportion of Vegetation (Ndossi and Avdan, 2016)

$$Pv = (NDVI - NDVIs)/(NDVIv - NDVIs) \quad (2)$$

NDVIv refers to NDVI values for vegetated surfaces, while NDVIs refer to NDVI values for non-vegetated surfaces, which are obtained from sampling values at NDVI raster pixels.

c. Land Surface Emissivity

$$\varepsilon = \varepsilon v \times Pv + \varepsilon s(1 - Pv) \quad (3)$$

εv is the emissivity of the vegetated surface, while ε_s is the emissivity of the bare ground surface. These two values were obtained through sampling of PV values and then calculated using the following formula:

$$\varepsilon = 0.941 + 0.004\text{Pv} \quad (4)$$

2.1.2 Land Surface Temperature (LST) Calculation

The LST calculation was performed using the Plank Function inversion method formulated as follows (Ndossi and Avdan, 2016):

$$LST = \left(\frac{BT}{1 + \left[\frac{\lambda \times BT}{\rho} \right] \times ln\ \varepsilon} \right) \quad (5)$$

2.2 Fault Fracture Density (FFD) Map Construction

DEM data were processed with ArcGIS using the Hillshade tool qualitatively and quantitatively. Qualitatively, straightness was analyzed on each hillside with the direction of irradiation N 050° E, N 100° E, N 200° E, and N 315° E. Quantitative results in the form of Line Density values were obtained by combining the qualitative analysis of the straightness of each irradiation direction.

2.3 Hydrothermal Alteration Analysis

Hydrothermal Alteration was analyzed by creating an Alteration Map of the Study Area using Landsat 8 OLI/TIRS data, using Sabins's Band ratio Method. Using RGB Bands of 4/2, 6/7 and 6/5, to detect areas with hydrothermal alteration zones.

2.4 Manifestation Point Determination

Geothermal manifestation points are obtained from areas of high surface temperature anomalies at night. Then, the land cover was adjusted by removing the value of each pixel indicating settlements. Furthermore, the points that are outside the area with medium-high (FFD) are removed. Thus, the distribution points of geothermal manifestations can be identified.

3. REGIONAL GEOLOGY

3.1 Geological Condition

Mount Slamet is located in Central Java and is part of the Quaternary Sunda volcanic arc as a result of the subduction of the Indo-Australian Plate under the Eurasian Plate (Hamilton, 1979). This volcano arose at the boundary between two Miocene sedimentary basins in the North Serayu Mountains and the Bogor Zone. Both sedimentary basins were uplifted to form an east-west trending fold. This trend is more or less parallel to the which lies in the southern part of Java. The Bogor Zone extends from Slamet Volcano to the west, while the North Serayu spreads eastward from Slamet Volcano.

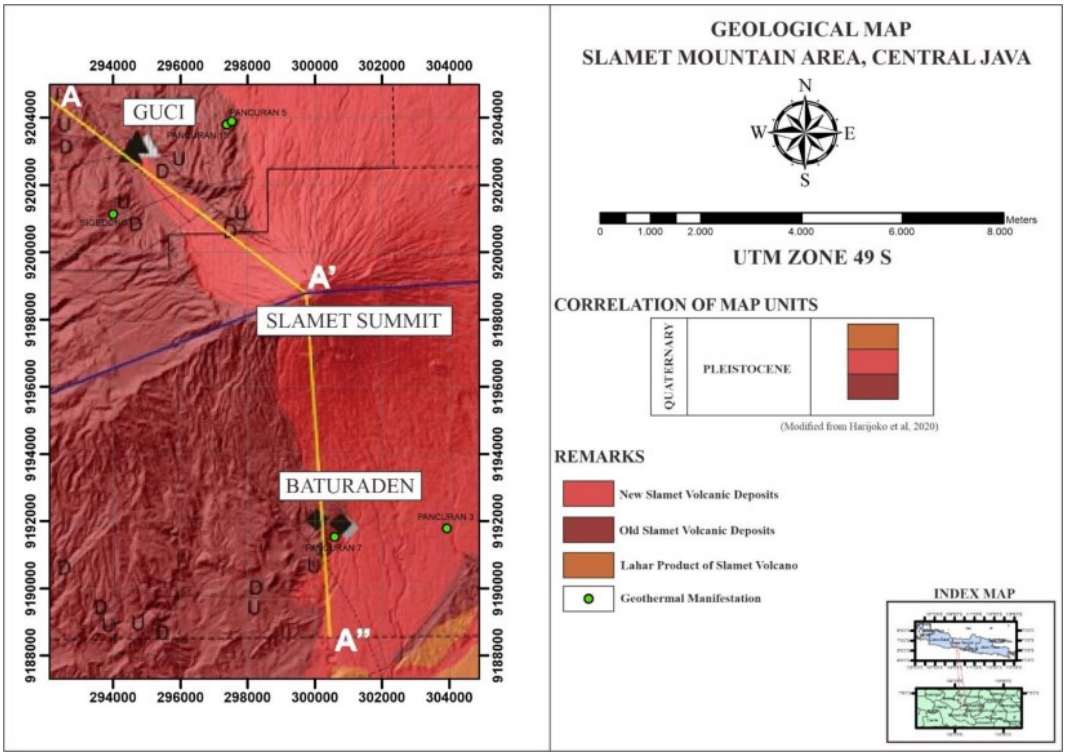

Figure 2: Geological Map (Modified from Harijoko, 2020; Kastowo, 1975; Sutawijaya et al., 1985; and Djuri et al., 1996).

Djuri et al. (1996) proposed that the substrate-tum rocks of the Slamet Volcano were sedimentary rocks of Rambatan, and the Halang Formation was part of North Serayu Mountain. Those sedimentary rock formations outcrop around the Slamet Volcano. Rambatan Formation was formed in an unstable back-arc basin flank (Husein et al., 2013), producing calcareous sandstone and conglomerate interbedded with shale, marl, and tuff (Djuri et al., 1996: Kastowo, 1975). During the sedimentation of the Halang Formation, the North Serayu region received a supply sediment of volcanic products indicated by the volcanic composition of the Halang Formation such as andesitic sandstone, tuffaceous conglomerate, and marl with intercalations of sandstone (Djuri et al., 1996).

3.2 Geological Structure

The regional geological structure assists in the interpretation of the faults. It is interpreted that there are two local faults right lateral fault. However, there is no evidence of a slicken side in the field except for the evidence on the ground except for fractures. There is a main fault structure that formed in the northeast of Mount Slamet, according to the Geological Map of Purwokerto-Tegal Sheet (Djuri, M. et al, 1996) are left and right horizontal faults with a southwest-northeast oriented. On the east, a horizontal fault structure develops on the left and northwest-southeast trending folds and west-east trending folds. This fold consists of two synclines (Mendelem and Majakerta) and two anticlines (Gombong and Karangmanggu). Most of the folds are relatively elongated from west to east except for the Majakerta syncline which runs northwest-southeast. Faults in the study area can only be observed from maps or satellite images.

Fractures are located in sandstone and no fractures are found in shale and igneous rocks. Field observations show fracture directions azimuths in two different dominant orientations, namely northeast-southwest and northwest-southeast. The fault direction from stereographic projections is interpreted as being dominated by the principle of transitional stress.

3.3 Alteration Condition

In the Gunung Slamet area, there are several types of alteration that develop due to fluid influence characterized by secondary minerals in the form of chlorite, quartz, pyrite, and calcite veins. Whereas in the area near the igneous intrusion, secondary minerals such as sericite, quartz, and pyrite are found, which are interpreted as subpropylitic alteration based on the alteration mineral graph (Prawiranegara et al, 2015).

There are polymictic breccia rocks with fragments consisting of tuff, basalt, metamorphic rock, and sandstone. The matrix has undergone oxidation and alteration to argillic (montmorillonite and halloysite) and silica in the Baturaden area (Indarto, 2017)

3.4 Geothermal

Geothermal manifestations around Mount Slamet appear as hot springs at several points in the study area. In the Baturaden area on the southern slope of Mount Slamet, there are Pancuran 3 and Pancuran 7 hot springs. In the Guci area on the northern slope of Mount Slamet, there are Pancuran 5 and Pancuran 7 hot springs, and on the northwestern slope, a hot spring manifestation also appears, known as Sigedong.

In general, geothermal manifestation points in the Gunung Slamet area are present in the breccia-lava-tuf unit (Qvs) which is a product rock of the Old Slamet volcano. Geothermal manifestations in the Mount Slamet area follow a northwest-southeast trending fault pattern.

According to research by Iswahyudi, et al (2020), hot water manifestations located at the five manifestation points in the research area are in immature water conditions. This condition indicates that there has been a process that causes the geothermal fluid to be unbalanced. This condition causes hot springs to be difficult to use in determining reservoir temperature with the geothermometer method. Based on the results of geoindicator analysis, there are three geothermal systems working in the study area, namely the Baturaden, Guci, and Sigedong systems or reservoirs. The recalculation of geothermal reservoir temperatures in the study area for Batudaren, Guci, and Sigedong using the silica-enthalpy method is 204°C - 220°C, 187°C - 196°C, and 181°C.

Table 3: Water Sample Types Used in this Study and the Types of Wall Rock Where the Springs Discharge (Modified from Harijoko et al., 2020).

Type	Location	UTM Coordinate		Elevation (m)	Sample Code	Temperature (°C)	pH	Estimated distance from Slamet summit (km)	Wall rock at the discharge point
		mE	mN						
Hot Spring	Baturaden, Pancuran Telu	304534	9191298	698	HP3	50	7	7.53	Basaltic lava
	Baturaden, Pancuran Pitu	303810	9191933	762	HP7	46	6	7.66	Basaltic lava
	Guci, Pengasihan	297197	9203712	1236	HPN	40.5	8	7.39	Volcanic breccia

4. RESULT AND DISCUSSION

4.1 Geomorphological Condition

In geothermal system modeling, geomorphology is important to determine the characteristics of the geothermal system, recharge areas, and source components. Geomorphological analysis of the Mount Slamet area using DEMNAS data, then hillshade analysis and slope calculation for landform interpretation.

The landform of the study area is a volcanic landform in the form of a crater, Old Volcanic Cone, Young Volcanic Cone, Foot Slope, and Lava Plain. The manifestation of the research area is associated with morphology in the rocks of the old Slamet volcano, especially in the morphology of the lava plain and Foot Slope. Areas with geothermal potential are usually associated with structures, and the volcanic regions are associated with foot slopes.

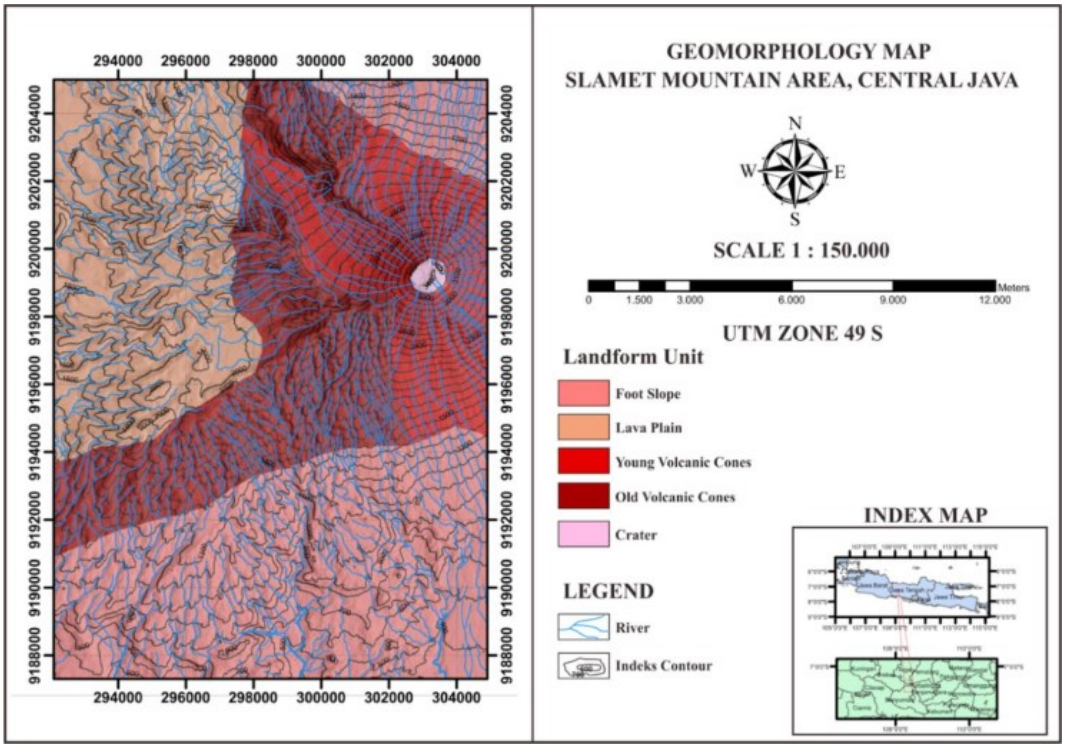

Figure 3: Geomorphological Map.

4.2 Land Cover Map

Land cover in the study area is classified into several objects, namely primary forest (dark green), secondary forest (light green), plantation (light orange), shrubs (dark orange), residential (red), agriculture land (yellow), paddy field (mint green). The results of the land cover map interpretation are used to make corrections to the results of data analysis from the land surface temperature (LST) map because it is likely to produce surface temperature anomalies influenced by residential areas.

4.3 Fault Fracture Density Map

In the Research Area, the previous manifestation point was associated with a high fracture density value, so the determination of a new manifestation point must also be associated with a high fracture density value. The manifestation point can also be associated with low fracture density values, so the point closes the possibility of a new manifestation point but additional data is still needed in the form of direct field checks in the field (Khoirunnisa et al., 2024).

4.4 Normalized Difference Vegetation Index

In the Research Area, the Vegetation Density Value is classified into 5 classes (Hakim et al., 2017). The NDVI value that dominates the research area is class 4 with a dominant distribution in the west, center and northeast of the lot. class 1 is associated with volcanic cone. Class 2 is dominantly distributed in the Southeast of the map due to clouds and west of the map due to settlements. Classes 3 and 5 do not dominate.

The purpose of this NDVI classification is to delineate geothermal hotspots by class. Areas with high vegetation density will have lower surface temperatures and low vegetation density will have higher surface temperature values (Hakim et al., 2017). In addition, it is also to help the calculation of land surface temperature values and regional corrections for hydrothermal alteration maps, because high vegetation density values will also produce inappropriate alteration maps.

The difficulty of using this NDVI map is the data used, if the image data used is a lot of clouds, the results will not be suitable. In addition, to help determine geothermal prospects, there has not been much research for areas with high vegetation density values, because they are prone to errors. However, it can be used because the previous manifestation point is associated with high NDVI values, so researchers concluded that NDVI is one of the determination parameters but the percentage is small. Table 3. NDVI Value Classification for Vegetation Density (Youhao, 2007)

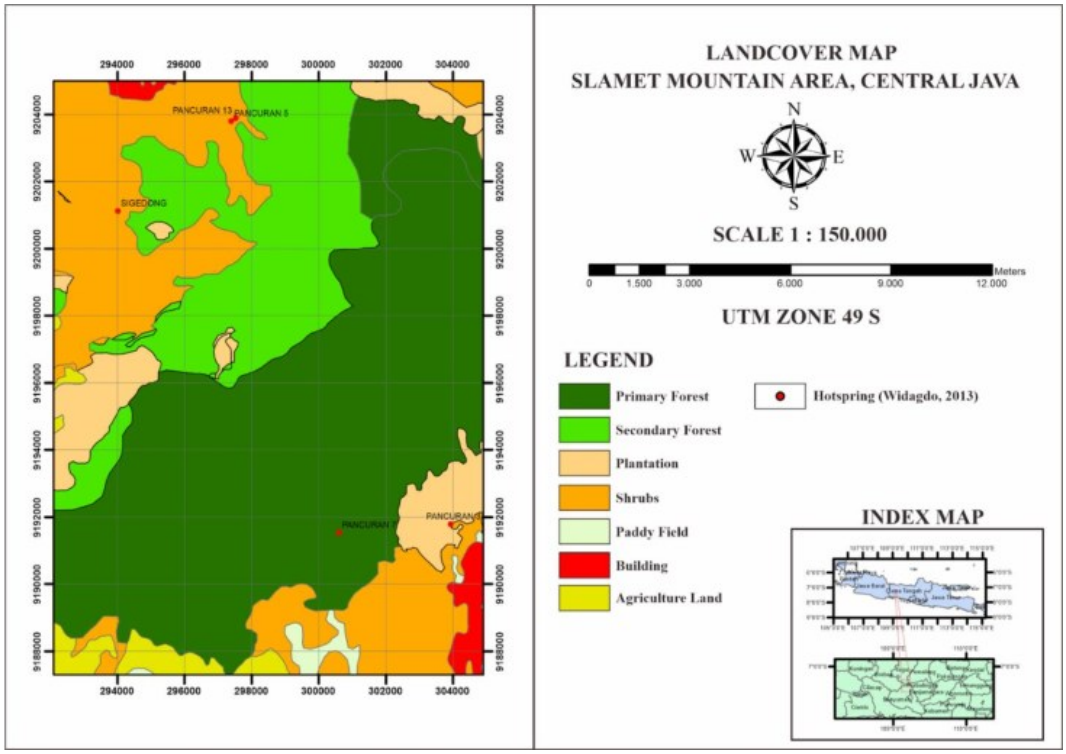

Figure 4: Land Cover Map.

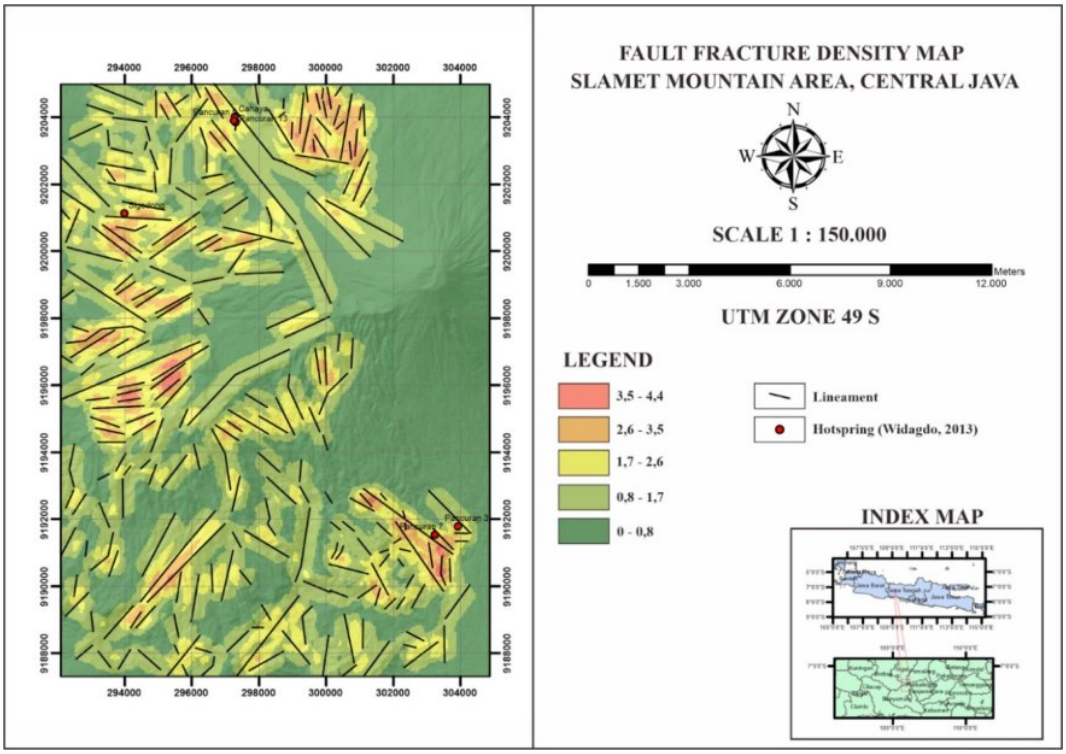

Figure 5: FFD Map.

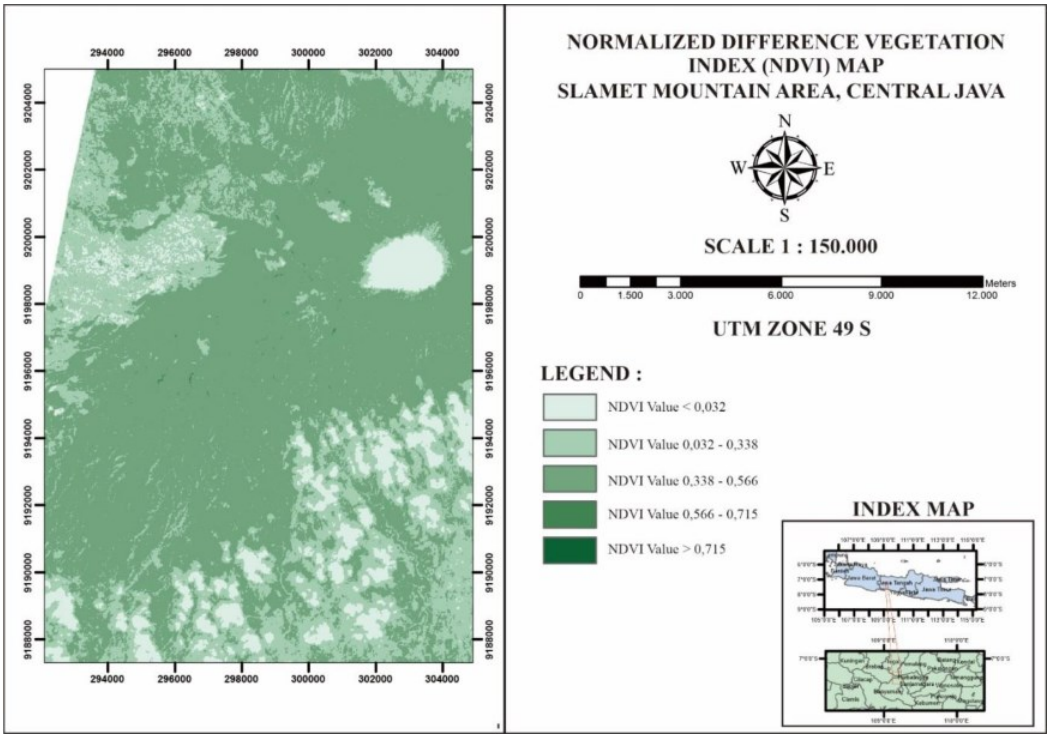

Figure 6: NDVI Map.

Table 4: NDVI Classification (Hakim et al., 2017).

No	NDVI Value	Classification
1	< -0,032	Aquatic, No Vegetation
2	-0,032 – 0,338	Clouds, Settlements
3	0,338 – 0,566	Rarely
4	0,566 – 0,715	Medium
5	> 0,715	Thick

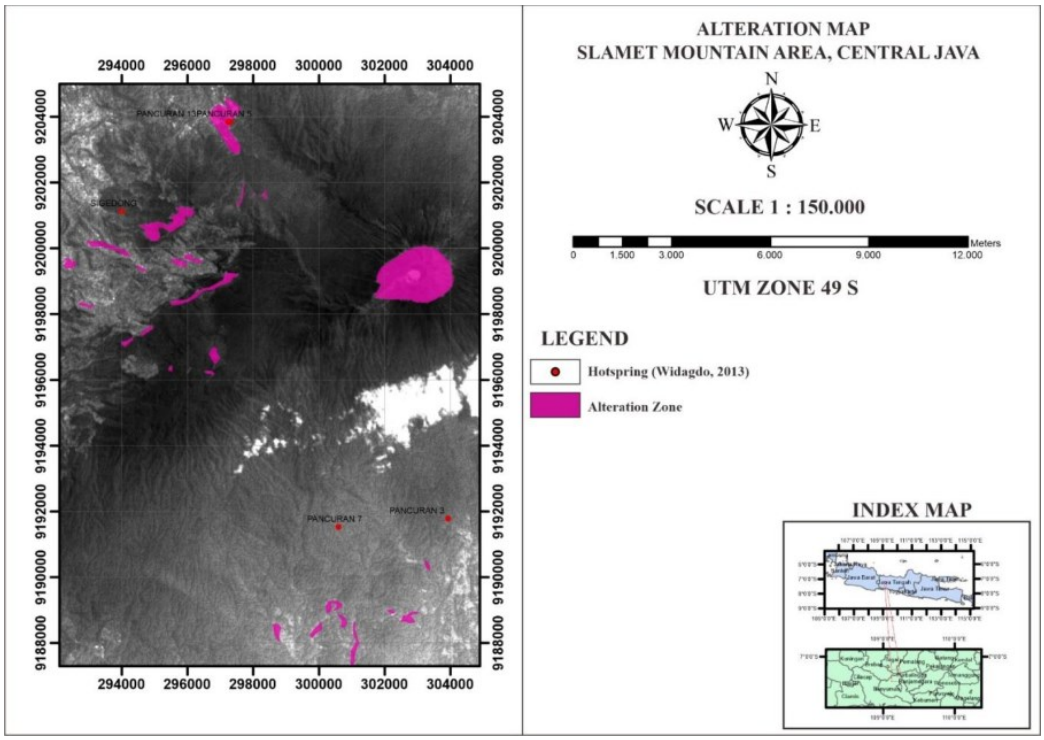

Figure 7: Alteration Map.

4.5 Hydrothermal Alteration Map

Hydrothermal alteration is an important component of a geothermal system. Because areas with geothermal potential usually have hydrothermal alteration zones. In this study, remote sensing analysis was carried out to determine the alteration zone, but it was not used as the main parameter in determining potential because of the high level of vegetation density that made it difficult to detect in remote sensing.

The Alteration Map of the Study Area was created using Landsat 8 OLI/TIRS data, using the Sabins's band ratio method. Using RGB bands of 4/2, 6/7, and 6/5, to detect areas with hydrothermal alteration zones. Band 4/2 - iron oxide, Band 6/7 - clay mineral, Band 6/5 - ferrous mineral. The distribution of alteration was also eliminated by NDVI map, high NDVI values cannot be used for zone determination due to the high failure rate.

4.6 Land Surface Temperature

LST Calculation Processing results from ASTER Night images, with a minimum temperature of 9.2°C and a maximum temperature of 30.4°C and an average temperature of 23.07°C. the temperature distribution in the volcanic cone area is relatively low because it is still influenced by higher elevations. The distribution of hot temperatures spreads around the foot slope to the north, south and west of the map.

Temperature anomalies are seen based on the characteristics of the area; the crater has the highest temperature because there is still active volcanism. Vegetation also affects temperature distribution, areas with high vegetation density tend to have lower temperatures, while low vegetation density tends to have higher temperatures, elevation also affects temperature distribution, the higher the elevation the lower the surface temperature.

The use of land surface temperature analysis results is very influential in determining geothermal prospect points, but it must be compared with other parameters to determine the location of new geothermal manifestations.

4.7 Temperature Determination

Based on the results of FFD Analysis, Geomorphology, NDVI, Land Cover, Geology, and LST Night and Hydrothermal Alteration as supporting data, Determination results are carried out qualitatively, with 5 data point locations of manifestations that have been previously identified as initial corrections marked with red dots in Figure 9.

Determination results obtained 8 new manifestation points marked with yellow dots in Figure 9, the manifestation point is included in the old Slamet volcanic deposit (Qvs) formation, and its geomorphology is included in the foot slope landform, old volcanic cone and lava plain. Determination results have 100% accuracy from previous manifestation data because 5 out of 5 initial manifestation points matches.

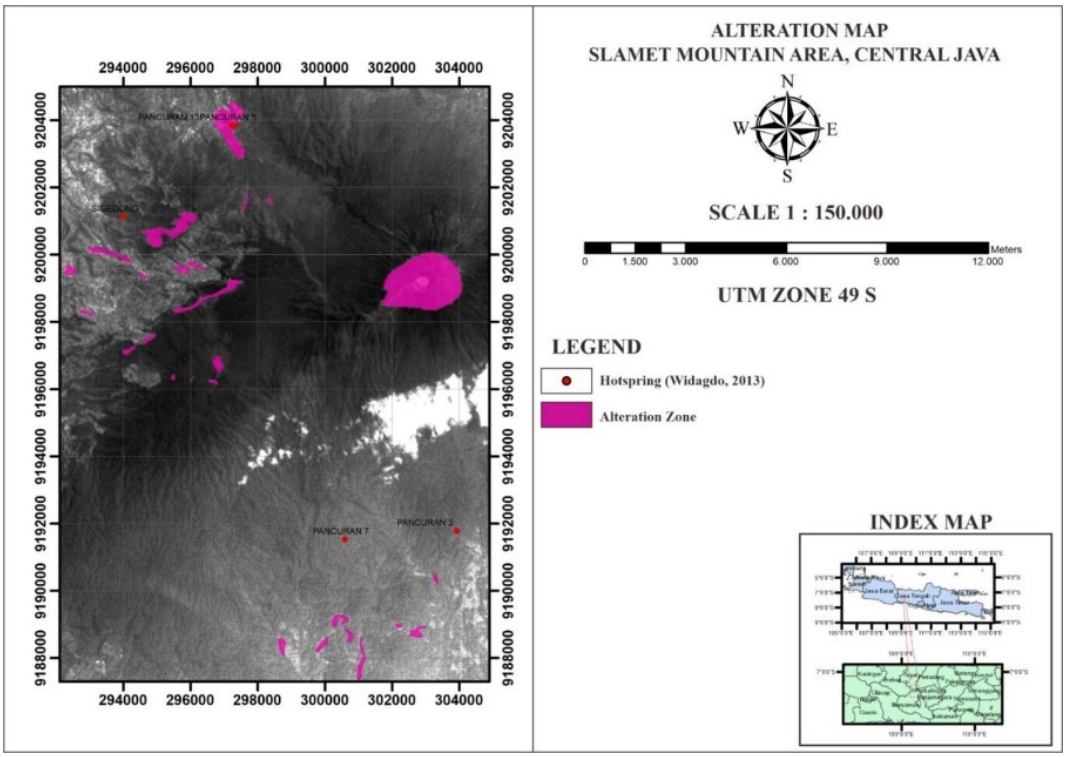

Figure 7: Alteration Map.

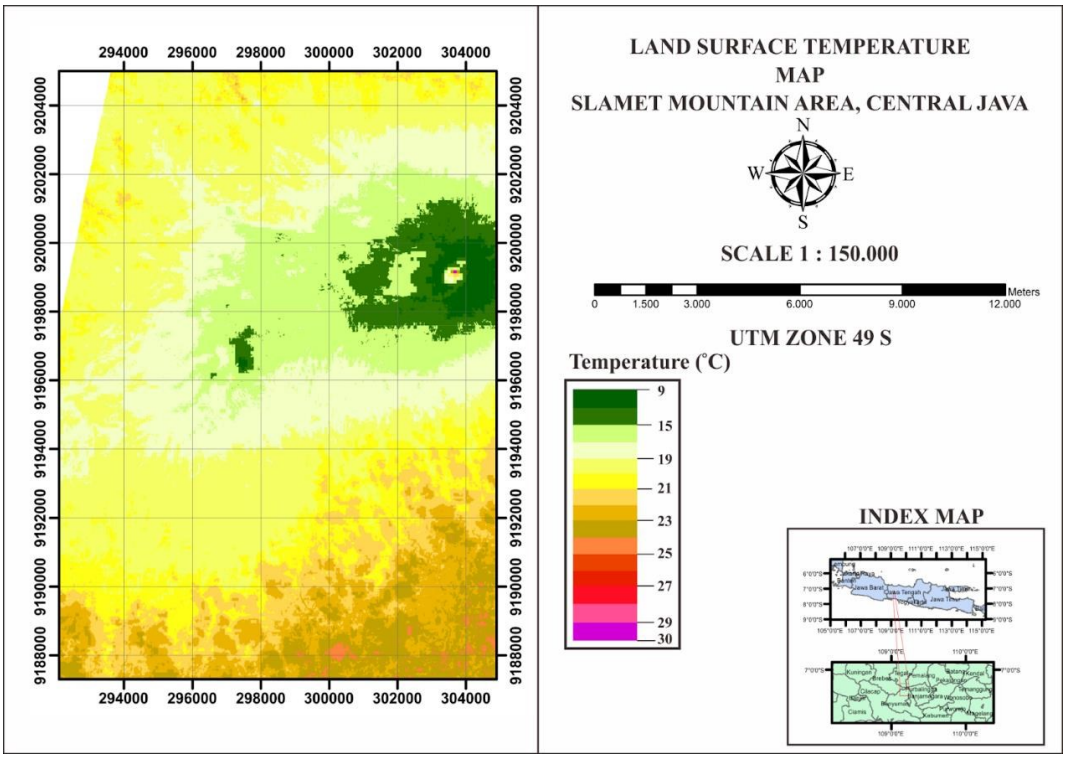

Figure 8: LST Map.

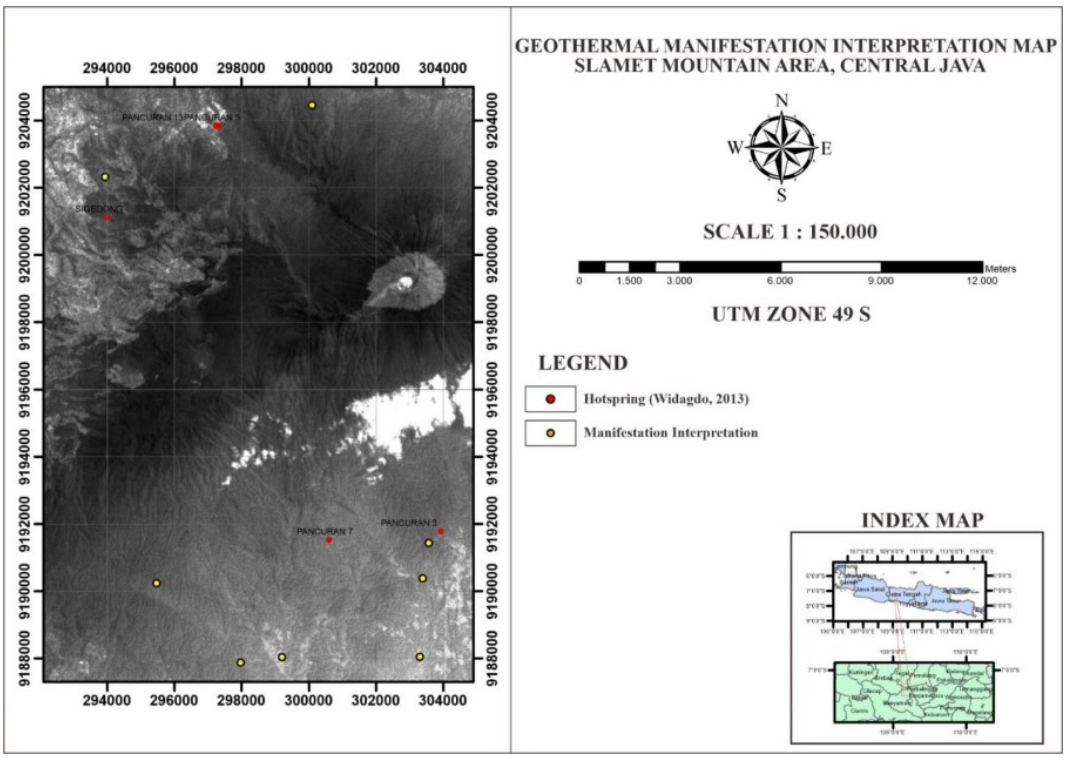

Figure 9: Geothermal manifestation interpretation map.

5. CONCLUSION

Identifying potential geothermal manifestation points in the Slamet Mountain area and its surroundings using remote sensing methods has proven to have a very good level of accuracy. This research can be used as a reference in determining geothermal manifestation points, especially in this study the identified geothermal manifestation points are in accordance with the location of the manifestations that have been found previously. From this

research, 8 new geothermal manifestation points were identified in the research area obtained from the analysis of Fault Fracture Density, Landcover map, Land Surface Temperature Night, and Hydrothermal Alteration map with 100% accuracy based on previous data. However, field mapping, subsurface analysis, and geochemical data are still needed to validate the research results and create a geothermal system.

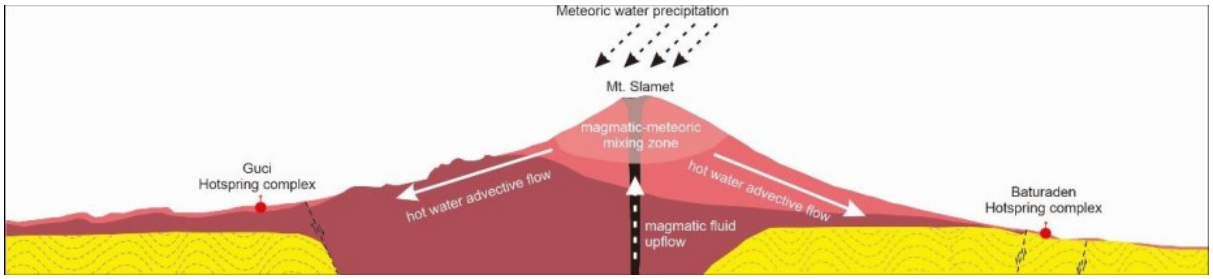

Figure 10: Geothermal Model (Modified from Harijoko, 2020).

Keywords: Geothermal Energy, Massepe Geothermal Field, Numerical Reservoir Modelling, Uncertainty Quantification

ABSTRACT

The Massepe Geothermal Field in South Sulawesi, Indonesia, presents promising geothermal energy potential. This study outlines a three-dimensional (3D) digital conceptual model and a numerical reservoir model of the Massepe field. A 3D digital conceptual model was developed utilizing geological, geophysical, and geochemical data. The model incorporates key formations, fault lines, and structural features, with a particular focus on the North-South Massepe fault. The integration of magnetotelluric data helped delineate the alteration zone, while surface manifestation data defined the model's temperature distribution.

A numerical reservoir model compatible with AUTOUGH2 and Waiwera geothermal simulators was subsequently developed. This model represents the temperature distribution, fluid flow, and heat transfer processes within the reservoir. The grid setup and boundary conditions were carefully designed to simulate the natural state of the geothermal system. Rock properties were assigned based on lithology, faults, and alteration zones. The natural state simulation was calibrated using estimated temperatures and the locations of surface manifestations.

The results indicate a geothermal upflow through the North-South Massepe fault, with lateral migration effectively restricted by adjacent geological structures. This study provides a robust understanding of the geothermal system's natural state, enhancing the knowledge necessary for strategic geothermal resource development in Indonesia.

1. INTRODUCTION

The Massepe Geothermal Field, located in South Sulawesi, Indonesia, is a promising site for geothermal energy development. Geographically, the field is situated between 119°44'15.5" - 119°51'17.25" E and 3°56'41" – 4°4'30.6" S in the Sidenreng Rappang (Sidrap) Regency, approximately 194 km from the provincial capital, Makassar City (Figure 1). The region, characterized by non-volcanic geothermal systems, offers significant opportunities for renewable energy exploration. Indonesia has substantial geothermal resources, with Sulawesi having the third-largest geothermal potential after Java and Sumatra, boasting approximately 3229 MWe identified across 76 locations, primarily in non-volcanic environments (Risdianto et al., 2015). Developing geothermal resources, particularly in greenfield sites like Massepe, is essential for diversifying energy sources and enhancing energy security.

This research aims to conduct a comprehensive assessment of the Massepe Geothermal Field using numerical reservoir modeling techniques. The study focuses on constructing a 3D digital conceptual model that integrates geological, geophysical, and geochemical data to reliably identify key formations, fault lines, and structural features. Additionally, a numerical reservoir model compatible with the AUTOUGH2 and Waiwera software platforms was developed to represent the temperature distribution, fluid flow, and heat transfer processes within the field. The natural state simulation was calibrated using estimated temperatures and the locations of surface manifestations to achieve a reliable model of the geothermal system.

The outcomes of this research will contribute significantly to the strategic development of geothermal resources, supporting Indonesia's goals of sustainable energy production and reduced reliance on fossil fuels.

2. GEOLOGICAL SETTING

Based on the Geological Map of the Majene and the Western Palopo Sheets, South Sulawesi (Sudjatmiko et al., 1998) and the Geological Map of the Pangkajene and the Western Watampone Sheets, South Sulawesi (Sukamto, 2012), the regional geology includes volcanic, intrusive, and sedimentary rocks dating from the Tertiary to the Quaternary periods. Risdianto et al. (2008) describe that the local geological formations consist of 13 rock units,

including one sedimentary rock unit, ten volcanic rock units, and two surface deposit units comprising lake and alluvial deposits (Figure 2).

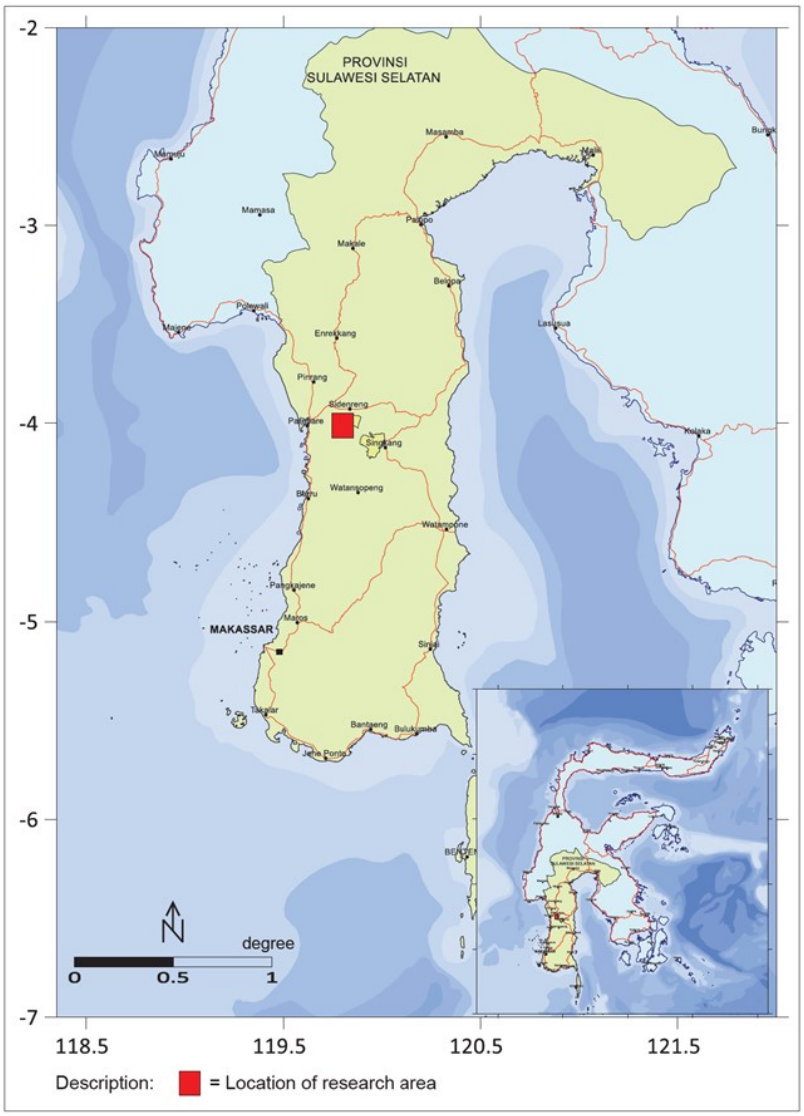

Figure 1: Map of the location of the Massepe Geothermal Field (Modified from Joni & Wahyuningsih, 2019, p. 144).

According to Risdianto et al. (2008), the oldest rocks exposed in the Massepe geothermal area are the Middle Miocene Soppeng volcanic rocks located south of the geothermal area. The Camba Formation volcanic rocks, ranging from the Middle to Late Miocene, extend from the south to the northwest. Late Miocene trachyte intrusive rocks are present in the central part of the geothermal area. The Late Miocene to Pliocene Walanae Formation, consisting of sandstone, siltstone, tuff, marl, claystone, conglomerate, and limestone, spreads from the central to the southeast of the area. The Pliocene Parepare volcanic rocks, including tuff, breccia, and volcanic conglomerate, are distributed in the northwest. Holocene-aged alluvial lake and coastal deposits, composed of clay, silt, mud, sand, and gravel, spread from the east to the north of the Massepe geothermal area.

The geological structure of the Massepe Geothermal Field is dominated by a series of faults and fractures that play a crucial role in controlling the geothermal system. The primary structural feature is the Walanae Fault, a major normal fault trending northwest-southeast, which has significantly influenced the regional geology by creating a graben (depression) that accommodates sedimentary deposits from the Tertiary Walanae Formation. Other significant faults include the Kalampee Fault, a dextral (right-lateral) strike-slip fault, and the Bulubaka Fault, a sinistral (left-lateral) strike-slip fault. The Massepe Fault, oriented north-south, controls the emergence of the Pajalele and Alakuang hot springs and is a key conduit for geothermal fluid flow (Risdianto et al., 2008).

The hydrogeology of the Massepe Geothermal Field is influenced by the area's geomorphology and the composition of its underlying rock formations. The recharge zones, where meteoric water infiltrates the ground,

are primarily in the hilly regions. The area experiences relatively high annual rainfall, significantly contributing to groundwater recharge, which interacts with the geothermal system, influencing the formation and characteristics of geothermal manifestations such as hot springs (Risdianto et al., 2008).

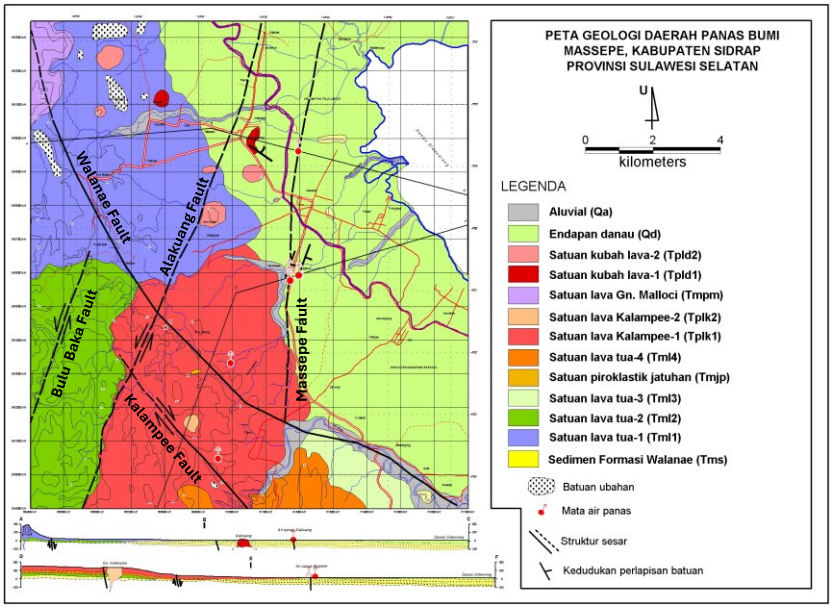

Figure 2: Local geological map of the Massepe Geothermal Field (Modified from Risdianto et al., 2008).

3. GEOCHEMICAL STUDIES

The geochemical survey of the Massepe Geothermal Field focused on analyzing the chemical composition of hot springs, geothermal fluids, and subsurface temperatures. The survey covered an area of approximately 13 x 15 km², featuring several hot spring manifestations with temperatures ranging from 29 to 68 °C, flow rates between 0.5 to 2.0 liters per second, and pH levels between 6.70 to 7.40 (Sulaeman et al., 2008).

The hot springs at Pajalele (Pajalele-1, Pajalele-2, and Pajalele-3) exhibit high concentrations of chloride (Cl), bicarbonate (HCO_3), and sulfate (SO_4), classifying them as bicarbonate-sulfate type waters and "immature waters" based on Cl-SO_4-HCO_3 triangular plots. The Alakuang hot spring, with a temperature of 45.3 °C, showed high concentrations of chloride and bicarbonate, indicating it as chloride-bicarbonate type water and "mature water" (Sulaeman et al., 2008).

Detailed ternary plots of Cl-SO_4-HCO_3 and Na-K-Mg (Figure 3) suggest that the Pajalele and Alakuang hot springs are on the borderline between immature water and partial equilibrium, indicating slight meteoric water dilution (Sulaeman et al., 2008).

High concentrations of bicarbonate and sulfate in the Pajalele hot springs indicate significant interaction between geothermal fluids and the surrounding rock formations. The elevated silica content supports a deep origin, as silica enrichment typically occurs through prolonged interaction with hot rocks at depth. The isotopic composition of the water confirms this deep origin, showing deviation from the meteoric water line and indicating geothermal fluid mixing with magmatic gases. (Sulaeman et al., 2008).

The estimated subsurface temperature for the Pajalele area using Na/K Giggenbach geochemical thermometers was around 193 °C, indicating a medium-temperature geothermal system. Soil and gas analysis showed Hg concentrations ranging from 7 to 259 ppb and CO_2 levels in the soil air from 0.03% to 6.34%, aligning with the north-south trending Massepe Fault and supporting the presence of underlying geothermal activity (Sulaeman et al., 2008). However, the reservoir temperature estimate is less accurate, considering that fluids from the Pajalele and Alakuang hot springs have been slightly diluted with meteoric water.

In conclusion, the geochemical survey highlights the potential for geothermal energy exploitation in the Massepe Geothermal Field, supported by significant ion concentrations, high subsurface temperatures, and distinct soil gas anomalies.

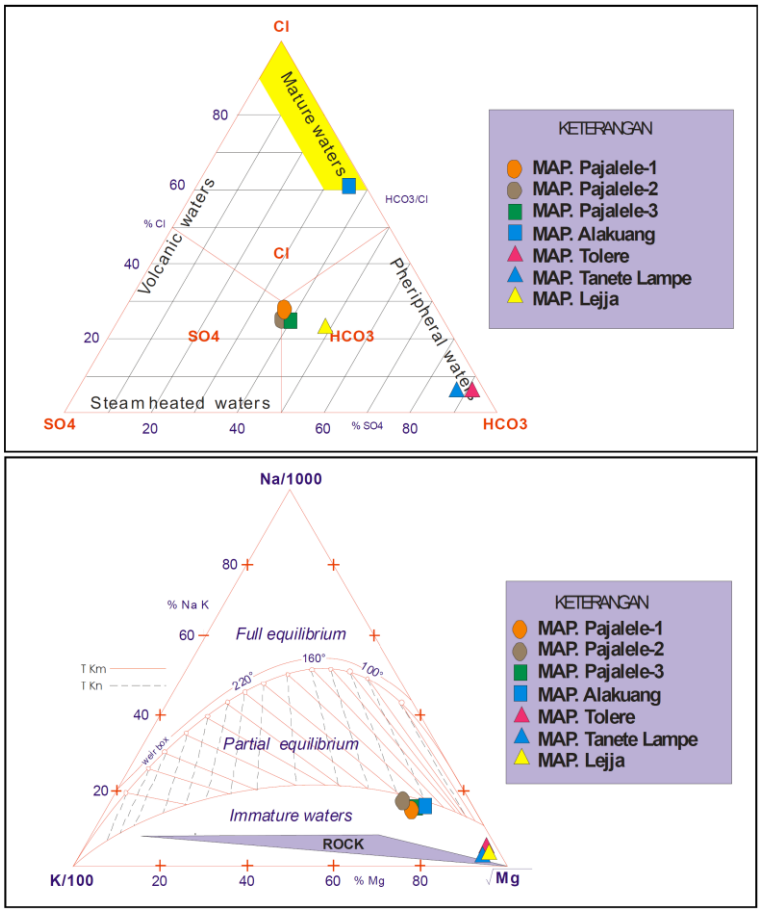

Figure 3: Ternary plots of the Massepe water sample: Cl-SO4-HCO3 (Top) and Na-K-Mg (Bottom) (Source: Sulaeman et al., 2008, p. 6,7).

4. GEOPHYSICAL SURVEYS

Advanced geophysical techniques were employed to investigate the subsurface conditions of the Massepe Geothermal Field. These techniques included geoelectrical resistivity, gravity, geomagnetic, and magnetotelluric (MT) surveys, each providing critical insights into the geothermal system.

4.1 Geoelectrical Resistivity

The geoelectrical resistivity surveys identified several low-resistivity zones indicative of hydrothermal alterations. These zones are primarily located around the Pajalele hot springs, suggesting the presence of conductive geothermal fluids. The resistivity profiles reveal a distinct contrast between the low-resistivity alteration cap and the underlying higher-resistivity zones, which are interpreted as unaltered rocks hosting geothermal reservoirs (Risdianto & Soetoyo, 2008).

4.2 Magnetotelluric (MT)

The MT surveys provided detailed resistivity structures down to several kilometers depth. The MT data delineated a prominent low-resistivity zone, interpreted as the clay alteration cap, which acts as an impermeable barrier above the geothermal reservoir. This alteration zone is primarily associated with the North-South Massepe fault. The MT resistivity cross-section (Figure 4) highlights areas of low resistivity extending from the surface to greater depths, indicating zones of intense hydrothermal alteration and potential geothermal upflow (Joni & Wahyuningsih, 2019).

4.3 Gravity

Gravity surveys revealed significant Bouguer gravity anomalies, indicating variations in subsurface density. A prominent low-gravity anomaly was detected in the central part of the field, corresponding to a graben structure filled with less dense sedimentary deposits of the Walanae Formation. Additionally, a high-density anomaly was identified beneath the Pajalele manifestation, suggesting the presence of an intrusive rock body (Figure 5). This intrusive body is likely contributing to the heat source for the geothermal system and is critical for understanding fluid flow and heat transfer within the reservoir (Risdianto & Soetoyo, 2008).

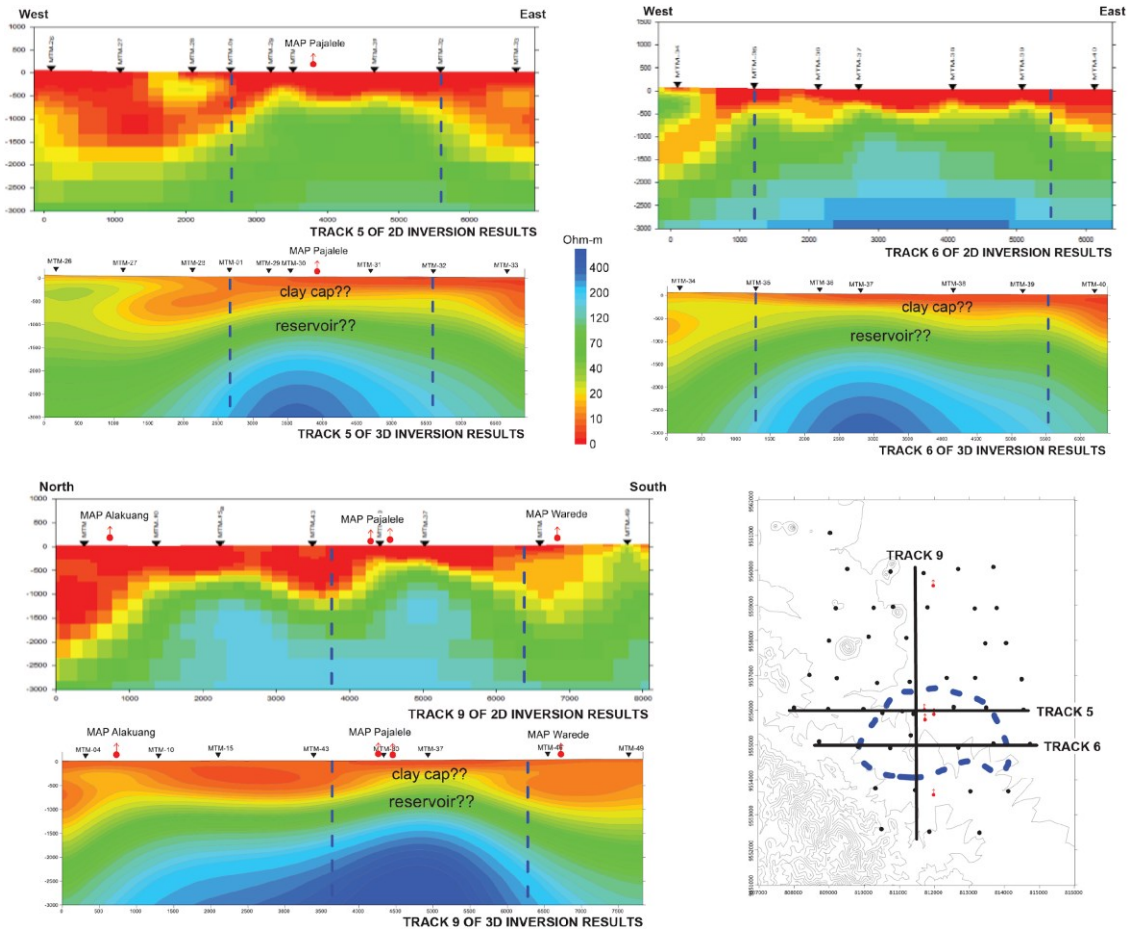

Figure 4: Cross-section resistivity results from 2-D and 3-D modeling along tracks 5, 6, and 9 (Modified from Joni & Wahyuningsih, 2019, p. 152).

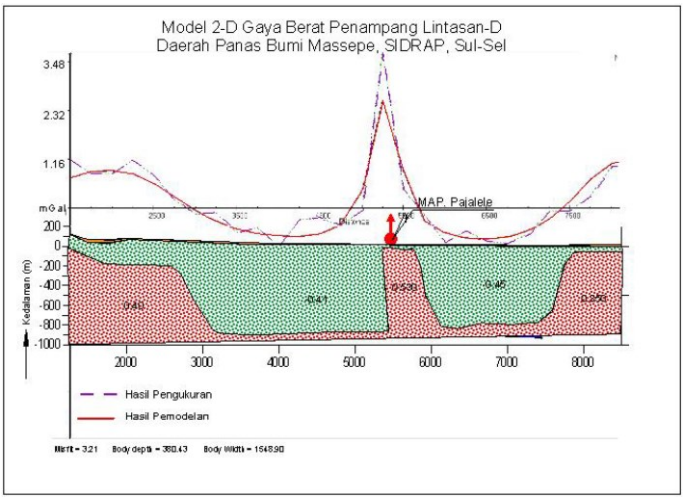

Figure 5: 2-D modeling of the gravity of the Massepe field (Source: Risdianto & Soetoyo, 2008).

4.4 Geomagnetic

The geomagnetic surveys detected notable magnetic anomalies associated with the volcanic rocks of the area. A strong magnetic anomaly correlates with the trachyte intrusive rocks in the central geothermal area. These anomalies suggest the presence of magnetically susceptible minerals, which could indicate heat sources contributing to the geothermal system. The magnetic data further delineates the structural trends and fault zones that control fluid flow and heat transfer (Munandar & Hermawan, 2008).

5. CONCEPTUAL MODEL OF THE MASSEPE GEOTHERMAL FIELD

The conceptual model of the Massepe Geothermal Field integrates geological, geophysical, and geochemical data, providing a comprehensive understanding of the subsurface conditions and geothermal system dynamics. The key geological formations include the Middle Miocene Soppeng volcanic rocks, the Middle to Late Miocene Camba Formation, the Late Miocene Walanae Formation, the Pliocene Parepare volcanic rocks, and the Holocene Alluvium deposits. The primary structural feature is the North-South trending Massepe Fault, which controls geothermal fluid flow and is associated with the Pajalele and Alakuang hot springs.

Hydrothermal alteration is evidenced by low-resistivity zones identified in MT surveys, with a prominent clay alteration cap acting as an impermeable barrier above the geothermal reservoir. Geothermal fluids ascend through the North-South Massepe Fault, driven by heat sources from intrusive rock bodies identified in gravity surveys. Geochemical analysis of hot springs shows high concentrations of chloride, bicarbonate, and sulfate, indicating significant interaction between geothermal fluids and surrounding rocks. Isotopic compositions confirm the deep origin of these fluids.

Figure 6 shows a top plan view of the conceptual model, highlighting the spatial distribution of key geological formations and structural features. Figure 7 provides cross-sections of the conceptual model, detailing the subsurface geology, hydrothermal alteration zones, and fluid flow pathways.

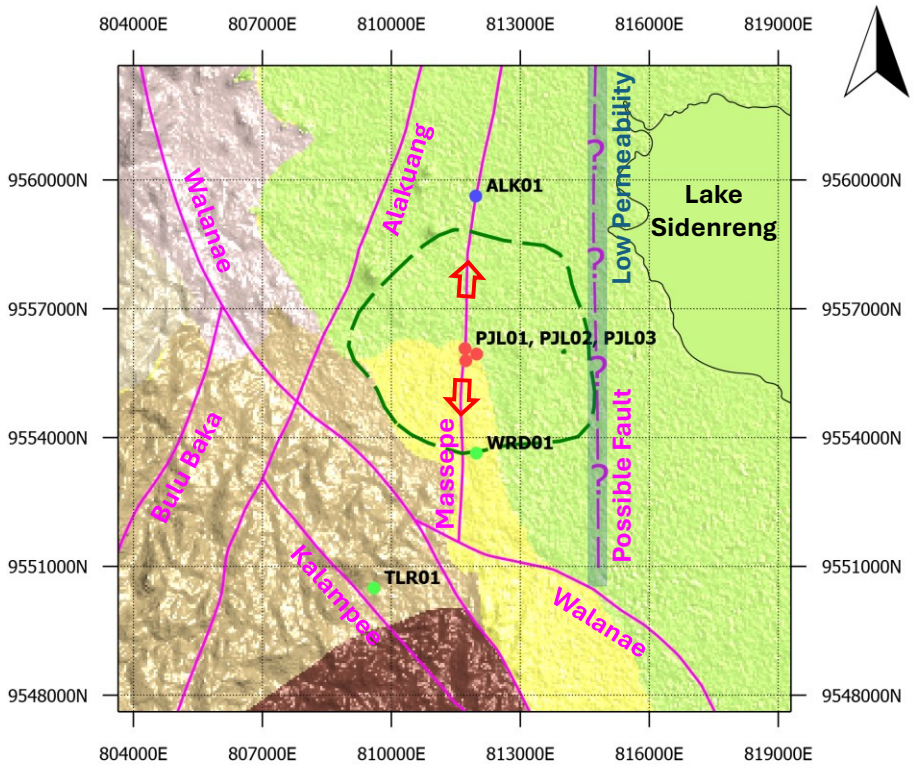

Figure 6: Top plan view of the conceptual model of the Massepe Geothermal Field. This includes faults (magenta line), bicarbonate-sulfate springs (red dots), bicarbonate springs (green dots), an alkali chloride spring (blue dots), and the boundary of the clay cap (green dashed line).

6. 3D MODELS CONSTRUCTION

The construction of 3D models for the Massepe Geothermal Field was essential to visualize and analyze the subsurface geological formations, structural features, and hydrothermal systems. The 3D geological and alteration models were developed using Leapfrog Energy software, which integrates various data sources to create a comprehensive representation of the geothermal field.

6.1 Geological Model

6.1.1 Topography Setup

The topography setup incorporated digital elevation model (DEM) data to represent the surface contours and elevation variations of the Massepe Geothermal Field. The model covered an area of approximately 44 km x 44 km around the Pajalele hot springs (Figure 8), highlighting significant elevation differences crucial for

understanding surface manifestations and recharge areas. The highest elevations are in the central and western parts of the field, influencing the direction of meteoric water recharge and surface runoff patterns.

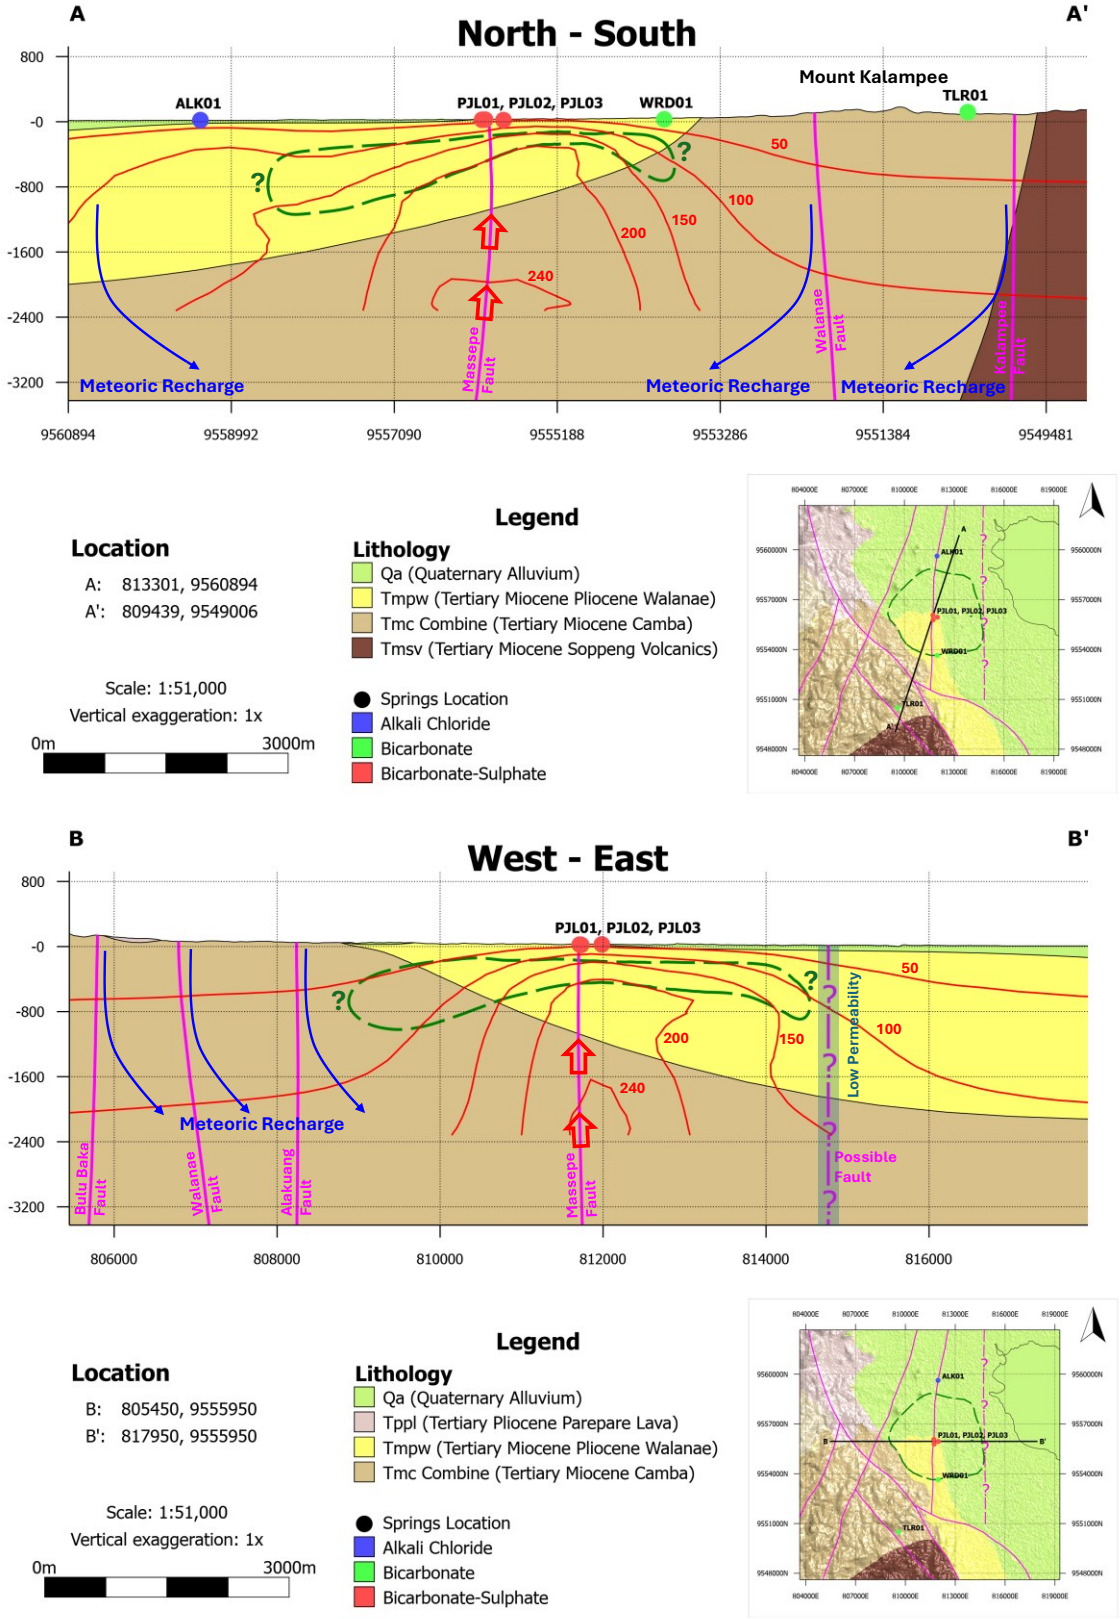

Figure 7: Cross sections of the conceptual model of the Massepe Geothermal Field. This includes the boundary of the clay cap (green dashed line) and the isotherm lines (red line).

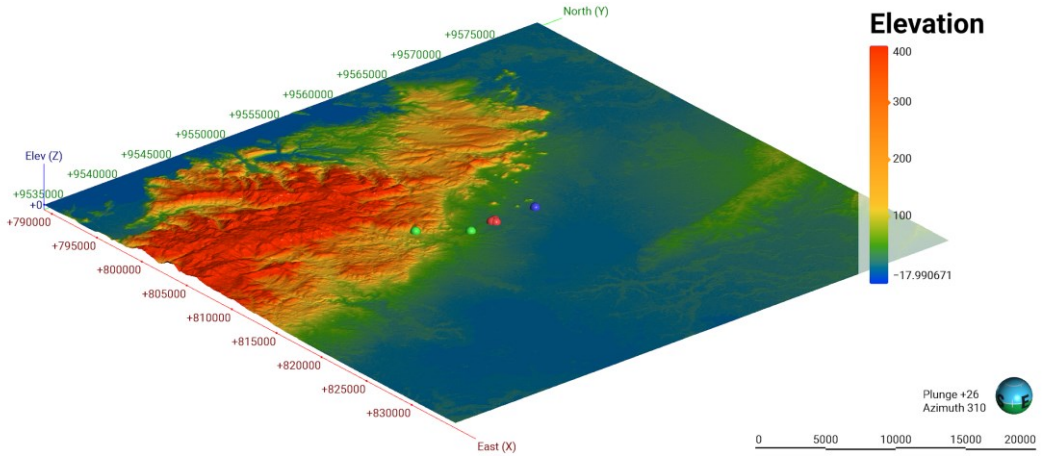

Figure 8: Topographic surface illustrated with an elevation color scale in Leapfrog. The Pajalele hot springs (Red dots) are situated at the centre of the map.

6.1.2 Lithology Setup

The lithology setup defined the spatial distribution of key rock types within the field using regional geological maps. Key formations modeled include the Middle Miocene Soppeng volcanic rocks, Middle to Late Miocene Camba Formation, Late Miocene Walanae Formation, Pliocene Parepare volcanic rocks, and Holocene Alluvium deposits. The lithology setup indicated that the Camba Formation and Soppeng volcanic rocks are predominant in the subsurface, with the Walanae Formation forming significant sedimentary layers that serve as both reservoirs and seals for the geothermal system.

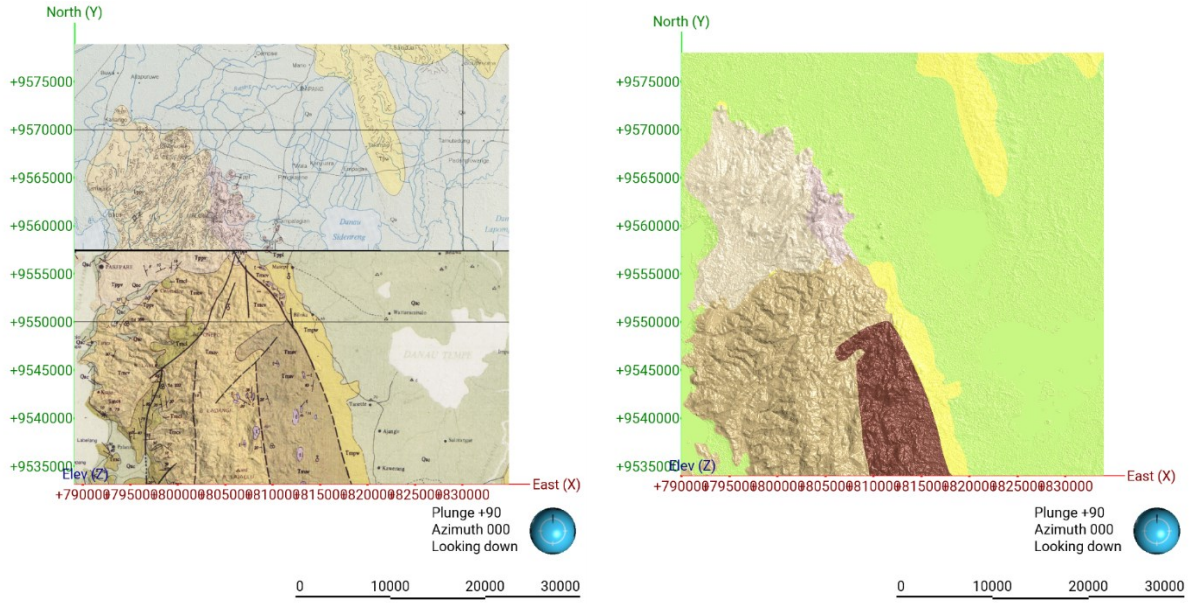

Figure 9: Lithological configuration of the Massepe geothermal system. The formation units from the newly developed digital conceptual model (left) are compared with the combined regional geological maps (right) (Modified from Sudjatmiko et al., 1998 and Sukamto, 2012).

6.1.3 Stratigraphy Setup

Stratigraphy was established using regional geological maps and cross-sectional profiles. This setup provided a detailed vertical sequence of geological formations, helping to understand the layering and thickness of each unit, which influences the geothermal reservoir's capacity and behavior. The stratigraphic sequence was developed according to the chronological age of the formations and their correlation with regional geological structures (Table 1). Figure 9 presents a comparison of the formation units from the newly developed digital conceptual model with those from the combined regional geological maps.

Table 1: Overview of the stratigraphic units within the Massepe geothermal system.

Formation Name	Abbreviation	Geologic Age	
		Period	Epoch
Alluvium	Qa	Quaternary	Holocene
Parepare Lava	Tppl	Tertiary	Pliocene
Parepare Volcanics	Tppv	Tertiary	Pliocene
Walanea	Tmpw	Tertiary	Late Miocene to Pliocene
Camba	Tmc	Tertiary	Middle to Late Miocene
Soppeng	Tmsv	Tertiary	Middle Miocene

6.1.4 Structural Interpretation

The structural interpretation involved digitizing major fault structures and fractures within the field. A total of seven active faults were identified and modeled (Figure 10). The North-South trending Massepe Fault is the primary conduit for geothermal fluid flow, controlling the emergence of the Pajalele and Alakuang hot springs. Another significant fault is the Walanae Fault, creating graben structures filled with sedimentary deposits, influencing fluid storage and migration. These faults were modeled to penetrate all geological formations with a vertical dip angle of 90°, providing possible pathways for fluid flow.

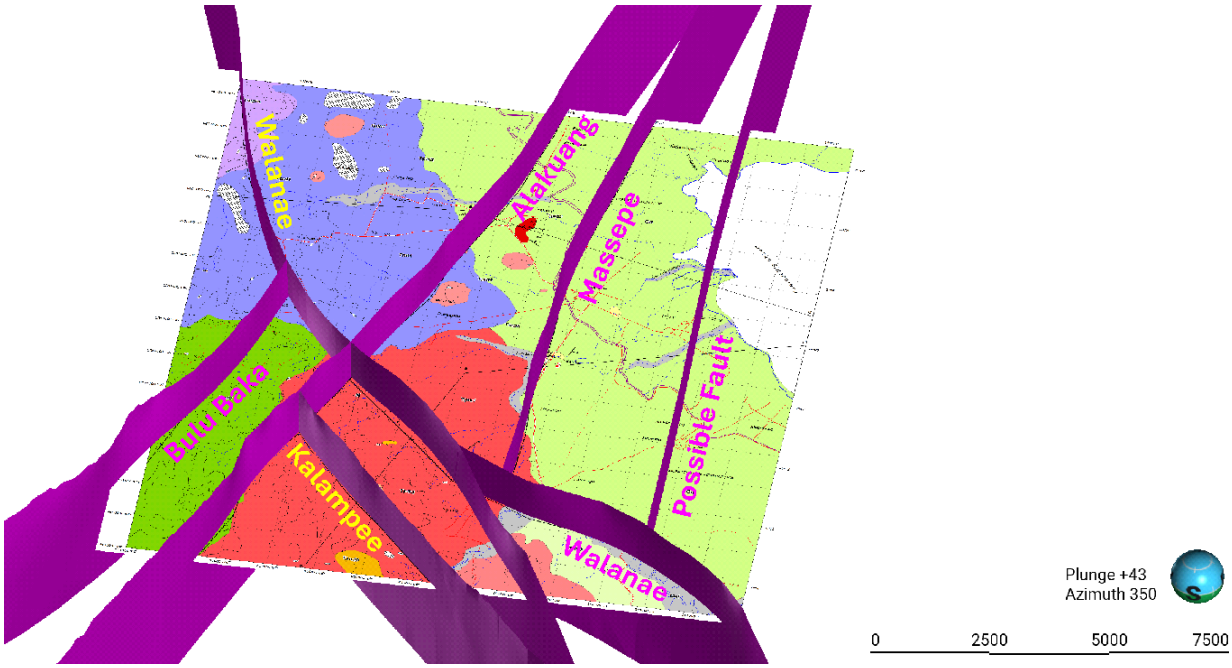

Figure 10: Fault structures in the Massepe Geothermal Field are highlighted in purple overlays on the modified local geological map (Source: Risdianto et al., 2008).

6.2 Alteration Model

The alteration model focuses on the clay cap zone, which acts as a barrier for fluid flow at the top of the reservoir. This zone was delineated using resistivity profiles from MT survey data, defining the boundaries and shape of the clay cap. The model indicates a widespread low-resistivity alteration cap, primarily associated with hydrothermal alteration processes driven by the underlying geothermal activity. The clay cap zone is delineated with a pronounced up-dome structure beneath the Pajalele hot springs, causing the clay cap to be significantly thinner in this region and thicker towards the edge of the reservoir (Figure 11).

7. NUMERICAL RESERVOIR MODEL

A numerical reservoir model is crucial for understanding the natural state of a geothermal system and forecasting its response to production and development activities. This model was constructed and executed using a geothermal simulator to represent the equilibrium conditions that existed before any exploration, production, or development took place. The reliability and accuracy of the simulation results depend on the detailed incorporation of rock parameters such as specific heat, permeability, porosity, and thermal conductivity, along with the thermophysical properties of the fluid and the fracture pattern (Franco & Vaccaro, 2014).

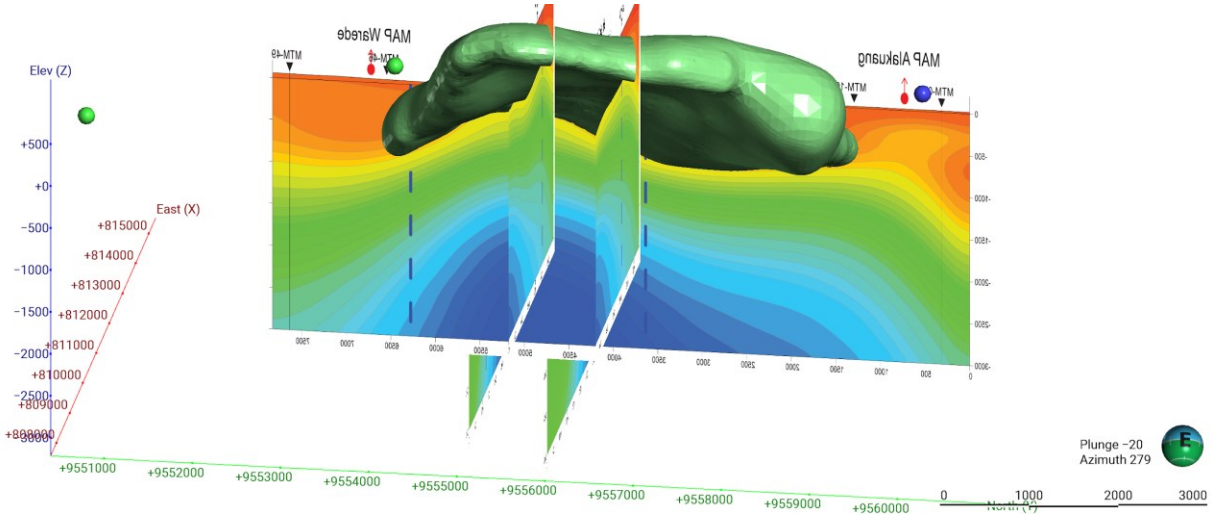

Figure 11: Clay cap zone (green volume) delineated from magnetotelluric data (Source: Joni & Wahyuningsih, 2019) and the distribution of surface manifestations. This includes bicarbonate-sulfate springs (red dots), bicarbonate springs (green dots), and an alkali chloride spring (blue dots).

7.1 Grid Setup

The grid for the model was constructed using data from the Leapfrog model. It was oriented at 0° azimuth to align with the main strike of the Massepe fault. The grid extends over an area of 16 km by 15.2 km, comprising 34,850 blocks, with the largest blocks measuring 800 m by 800 m. The vertical thickness of these blocks ranges from 500 m at the base to 20 m near the surface. To achieve higher accuracy in the zone of interest, the block size was reduced to 200 m by 200 m, providing a higher resolution in areas with significant fluid movement. Refinement in the shallow regions was also implemented to facilitate smooth numerical reservoir simulations in response to fluctuations in the water table.

7.2 TOUGH2 Model Generation

Once the grid was developed, it was imported into Leapfrog Energy to generate the TOUGH2 model input file. Leapfrog enables users to choose the geological model that will be the basis for creating the TOUGH2 model. This integration ensures that the methods available in Leapfrog for incorporating faults and alteration zones into the geological model can also be applied to the TOUGH2 model. Since the geological model in Leapfrog is dynamically updated with new data, it will be easy to implement these changes in later TOUGH2 model input files.

Figure 12 shows the TOUGH2 model that has been generated with the geological model mapped onto the grid. In Figure 13, the faults within the system are overlaid on the TOUGH2 model, with the bottom right half removed to reveal the fault blocks, which are highlighted in magenta. Similarly, Figure 14 presents the alteration model as a representation of the clay cap within the TOUGH2 model.

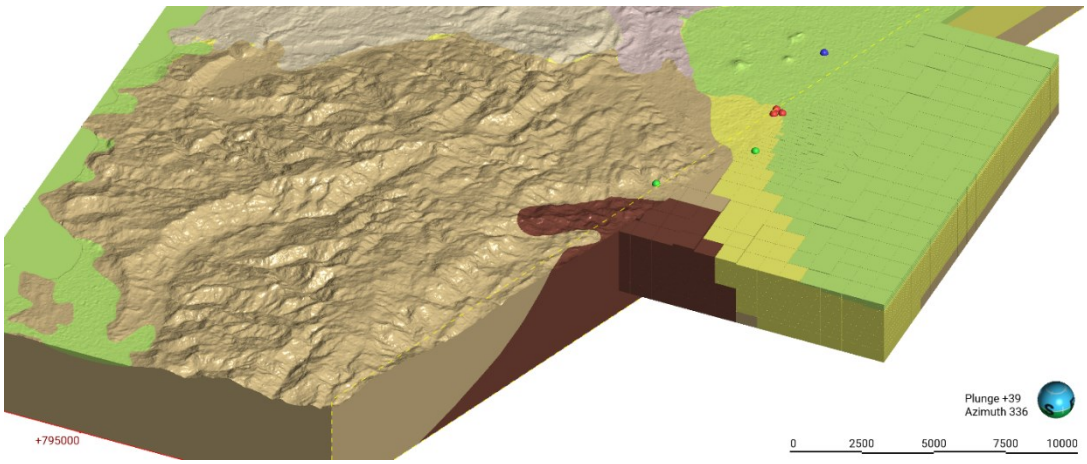

Figure 12: The Leapfrog model (top left) and the corresponding generated TOUGH2 model (bottom right), with hot springs marked.

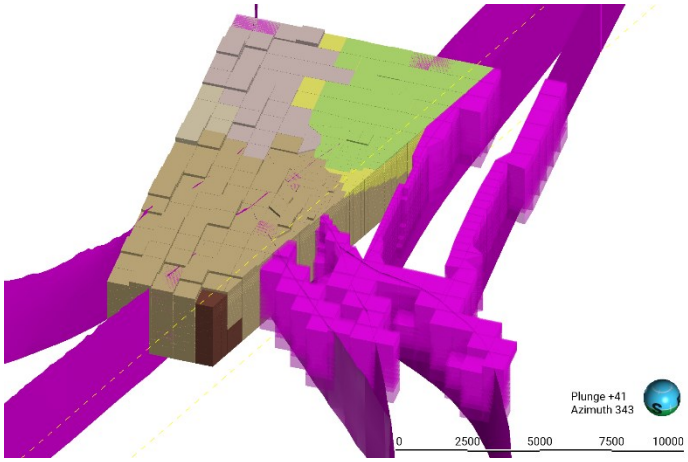

Figure 13: Visualisation of faults in the TOUGH2 model. The faults from the Leapfrog model are displayed in magenta, with the corresponding faulted TOUGH2 blocks visible in the cutaway section of the model.

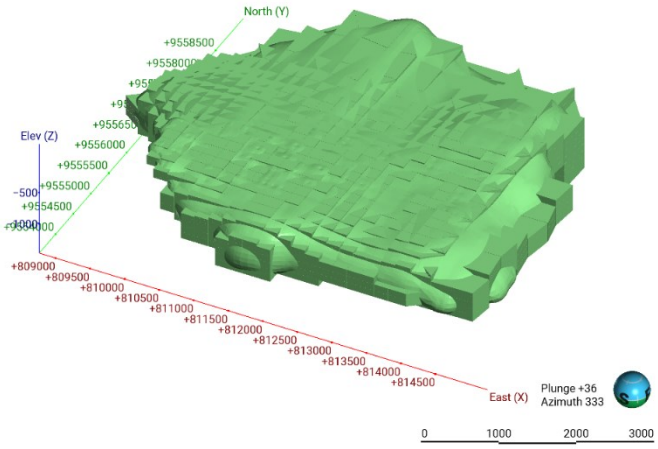

Figure 14: Visualisation of the clay cap in the Leapfrog model and the TOUGH2 model.

7.3 Boundary Conditions

Boundary conditions are essential in geothermal modeling as they define the limits and interactions of the model with its surrounding environment. They ensure that the model reasonably represents the natural physical conditions and processes in the geothermal system.

The top surface of the model simulates dry atmospheric conditions with a pressure of 1 bar and an average temperature of 26.8°C. The EOS3 module was employed to define the thermophysical properties of water and air, essential for solving mass and energy balance equations (Pruess et al., 1999). High permeability was attributed to the top surface blocks to facilitate rainwater infiltration consistent with the local topography. An annual rainfall of 1880 mm with a 10% infiltration rate was included to simulate realistic hydrological conditions.

A no-flow boundary condition was implemented on the sides of the model to encompass the entire convective geothermal system, eliminating the need for side flows. This setup ensures that the model reflects natural and induced flows within the reservoir without external influences.

The base boundary was assigned a uniform background heat flux of 80 mW/m². Additionally, as a result of the calibration process, a constant hot mass was assigned to 16 blocks with a total upflow rate of 28 kg/s and an enthalpy of 1050 kJ/kg. These blocks are strategically located along the Massepe fault to represent the upflow zone beneath the Massepe field, aligning with the conceptual model.

7.4 Rock Properties

Rock properties were directly assigned from the discretized zones of the combined model using PyTOUGH, categorized by lithology, fault zones, fault intersections, alteration, and heterogeneity. This approach resulted in up to 79 rock types with different permeabilities based on lithology, faults, and alteration, representing the geological complexities. The rock properties for the blocks were automatically assigned to align with those identified in the Leapfrog model and were set up using PyTOUGH (Popineau et al., 2018).

8. NATURAL STATE SIMULATION AND CALIBRATION

Model calibration is an iterative process used to align model outputs with measured data. Key parameters adjusted in this model include the mass of hot fluid introduced at the base and the permeabilities of various rock types affecting fluid flow. Permeabilities were modified based on lithology and fault structures, with the altered clay cap acting as a fluid barrier. The low permeability of the clay cap restricts fluid movement, directing the upflow through designated permeable zones. The natural state model was run for 5 x 10^{13} seconds to reach steady-state conditions.

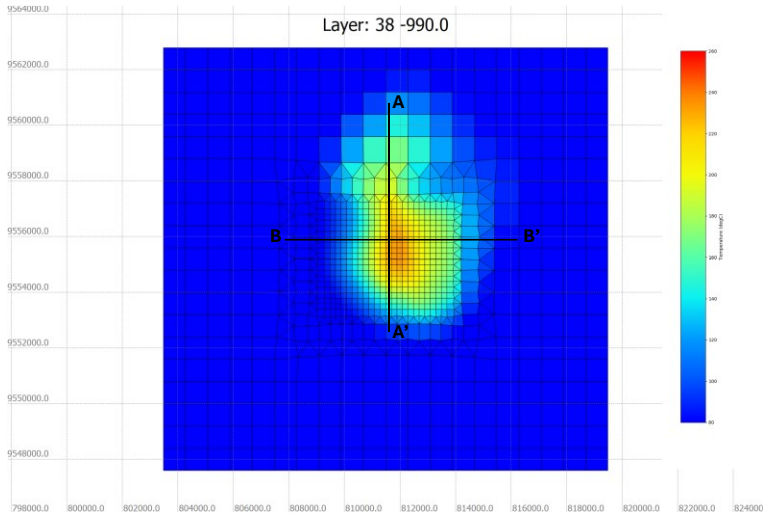

Figure 15: Temperature distribution in the natural state model at layer 38 (990 metres below sea level).

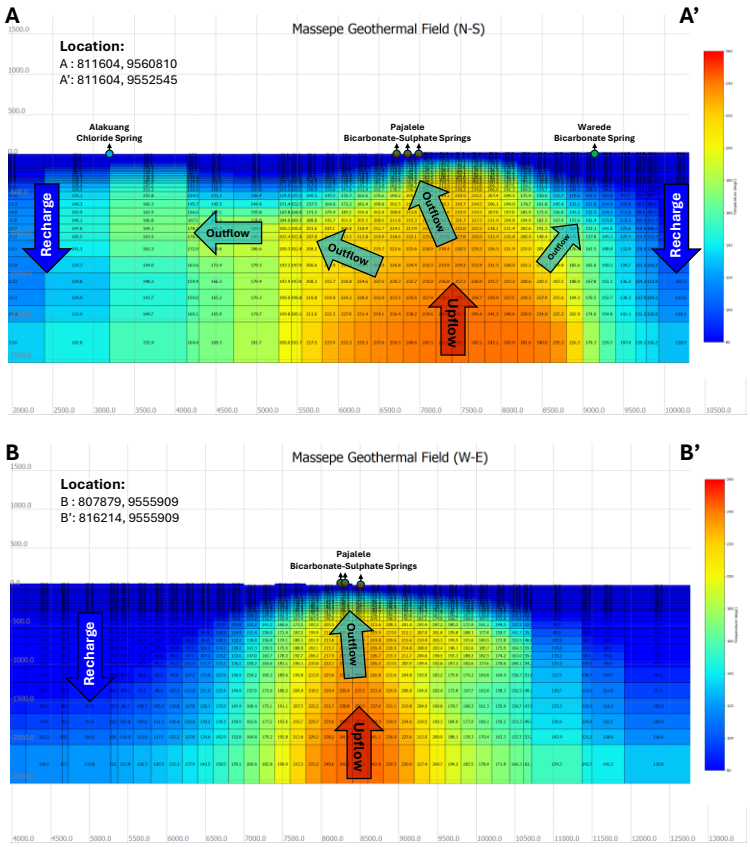

Figure 16: Temperature distribution and mass flow characteristics in the natural state model of the Massepe Geothermal Field. (A-A': North-South trajectory across the Massepe fault, B-B': West-East trajectory crosses Pajalele hot springs).

The natural state model was effectively calibrated using the estimated temperature at which the clay cap forms. The locations of surface manifestations helped in identifying upflows and outflows which can be mapped from simulation results. The presence of Pajalele springs indicates that upflow from the heat source seeps directly from the bottom, resulting in bicarbonate-sulfate manifestations. The outflow is evidenced by the Alakuang chloride spring to the north and the Warede bicarbonate spring to the south, both aligned with the Massepe fault. Figure 15 and Figure 16 show the temperature distribution resulting from the natural state calibration.

9. CONCLUSION

This study provides a detailed assessment of the natural state of the Massepe Geothermal Field using advanced numerical reservoir modeling techniques. The results indicate substantial geothermal potential, with a robust understanding of the temperature distribution, fluid flow, and heat transfer processes within the reservoir. The natural state simulation reveals a geothermal upflow through the North-South Massepe fault, with lateral migration restricted by adjacent geological structures. Continued exploration and model refinement, supported by field data and additional drilling, are essential for optimizing resource development and contributing to Indonesia's renewable energy goals.

ACKNOWLEDGMENTS

The authors would like to acknowledge the Directorate General of New, Renewable Energy and Energy Conservation (EBTKE) and the Geological Agency of the Ministry of Energy and Mineral Resources of Indonesia for providing the data related to the Massepe Geothermal Field. The authors also thank Seequent for providing a license for the Leapfrog Energy software, which was essential to this research.

Keywords: Magnetotelluric, Inversion Model, Sibayak, Bottom of Clay Cap

ABSTRACT

In 2023, PGE conducted Magnetotelluric (MT) and Gravity surveys to update the resistivity and density models of the Sibayak geothermal field. A 3D joint inversion was performed, leading to a refined understanding of the Sibayak reservoir. This study presents the updated models and reveals a significant finding: a highly conductive body (0.1-1 Ω.m) extending from deep outside the Singkut Caldera diagonally towards Mt. Pratektekan. This feature, not clearly identified in previous 2D models, underscores the enhanced image of the new 3D approach. Additionally, recent MT survey data, analyzed through 1D and 2D inversion, confirm the presence of this deep subsurface conductive anomaly. The delineation of the base of the clay cap interface with the underlying highly conductive body presents a challenge due to the absence of a distinct boundary between the two in our 3D resistivity model. Meanwhile, 1D could separate the bottom of clay cap and highly conductive body. This study emphasizes the value of updated geophysical data in understanding geothermal reservoirs and paves the way for further exploration and development in the Sibayak field.

1. INTRODUCTION

The Sibayak geothermal field, situated in North Sumatra, has been a contributing factor to Indonesia's geothermal energy production since 1996. Initially generating 2 MW, the field's capacity expanded to 12 MW in 2008 with the addition of two 5 MW units. However, an inactive steam sales contract with an Independent Power Producer (IPP) since 2012 prompted Pertamina Geothermal Energy (PGE) to re-evaluate Sibayak's potential to contribute to its ambitious 1 GW geothermal target.

Pertamina had conducted several geophysical data acquisitions. Initially, DC resistivity (Schlumberger) surveys were conducted to explore geothermal prospects with depth of investigation around 1000 meters, continued by MT survey in 1992 and Time Domain Electro-magnetic (TDEM) for static shift correction in 1997 (Mulyadi, 2000). A gravity survey was also conducted by PT. Gondwana in 1989 – 1990 using Lacoste Romberg gravity-meter (Daud, et al., 2001). In addition to the geophysical surveys, PGE undertook an update of the Sibayak reservoir model. The original model, developed in 2001, incorporated data from 10 wells drilled in the field (Atmojo, et al., 2001). Recognizing the potential impact of production history on reservoir characteristics, PGE created a new model in 2024 utilizing the available data since 2008 from the same 10 wells and incorporating a reflections of post-production conditions. (Firanda, et al., 2024).

A team of geoscientists and reservoir engineers from Pertamina Geothermal Energy (PGE) re-evaluated the Sibayak geothermal field's potential. This re-evaluation employed updated magnetotelluric (MT) data acquisition and resistivity inversion techniques to analyze the depth of the clay cap. Well cutting data from 10 wells have provided information on clay content, which will be useful in evaluating the clay cap. The updated resistivity model revealed a previously unidentified, highly conductive anomaly (less than 5 ohm.m) extending from the surface to a depth of approximately 4,000 meters below sea level (masl) with a lateral extent of about 4,000 meters. This anomaly exhibits an oval shape and trends southwest-to-northeast beneath Mount Sibayak. Notably, this anomaly was absent in previous resistivity models, However, PGE's recent MT data acquisition and resistivity model was thoroughly evaluated, resulting minor data masking for all decades above 160s (0.01 Hz) which PGE considered as satisfactory. It is also challenging to delineate the bottom of clay cap on our 3D resistivity model due to this high conductive body positions near the clay cap, resulting in a more smoothed and lower resolution view of the bottom of the clay cap (Cumming & Mackie, 2010).

Field Overview

Sibayak field is a volcanic geothermal system inside singkut caldera which formed at ~44 ka (Forni, et al., 2024) with two small conduit strato-volcano (Hochstein & Sudarman, 2015). Figure 1 visualizing two schematic conceptual model describing volcanic hosted system model and isotherm with alteration zone background derived from temperature log of the wells. The conceptual model was also used to update numerical simulation of Sibayak

Field (Firanda, et al., 2024) which consist of geothermal upflow beneath Mt. Sibayak outflowing towards Southeast and Northeast. Sibayak complex manifestations were founded in the crater of Sibayak Mountain and flank of Sibayak inside the Singkut caldera (Fahmi, et al., 2021). Figure 2 are the geological map of Sibayak with structure orientation NW-SE. Although Sibayak is a volcanic hosted system, tertiary sediments play major roles for the permeability in Sibayak reservoir.

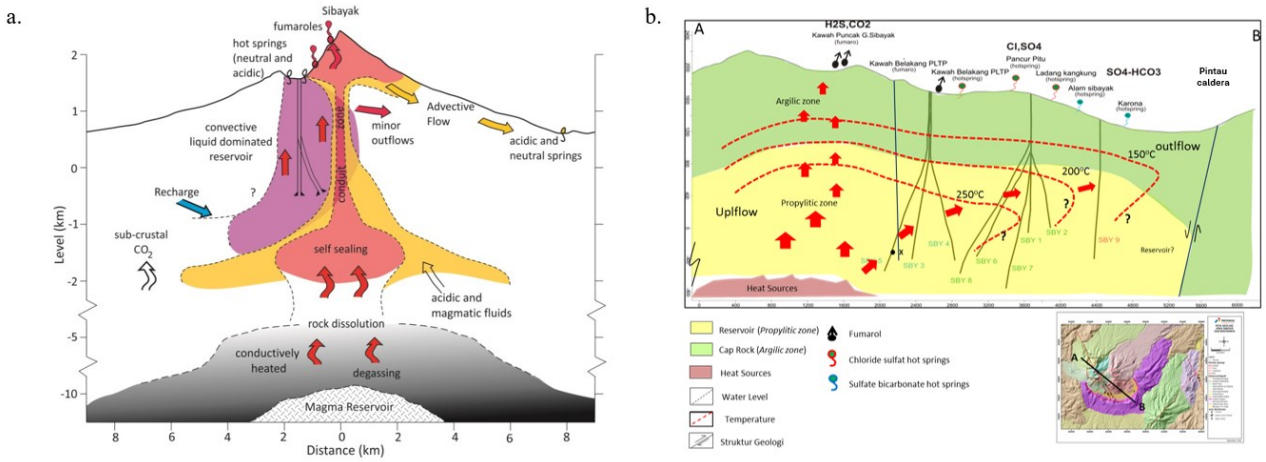

Figure 1: a. Sketch of Sibayak volcanic hosted conceptual model (Hochstein & Sudarman, 2015) and b. Isotherm conceptual model with hydrological setting of Sibayak along the alteration zone background developed from well temperature log (PT. Pertamina Geothermal Energy Tbk, 2022).

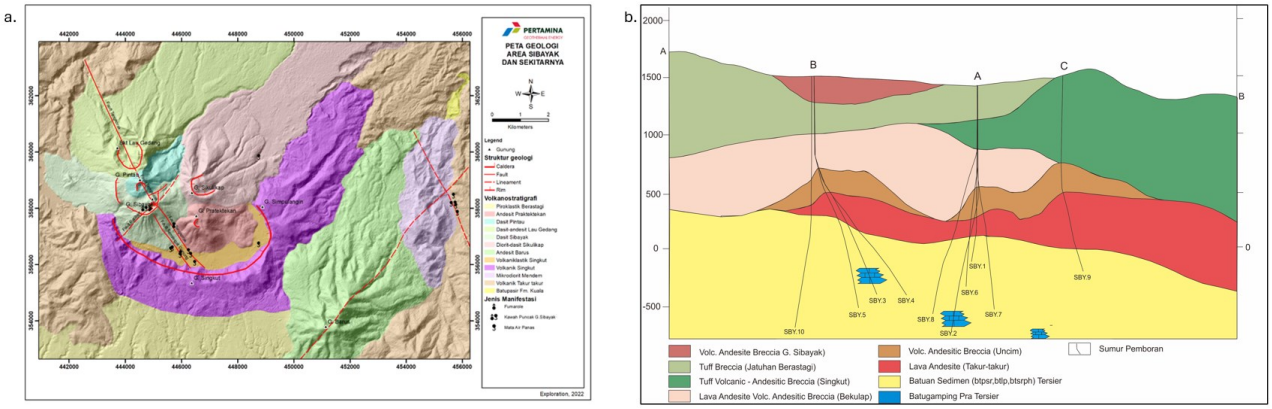

Figure 2: a. Updated geological map with stratigraphy of Sibayak field (PT. Pertamina Geothermal Energy Tbk, 2022) and b. Geological cross section interpreted from well cuttings data (PT. Pertamina Geothermal Energy Tbk, 2016).

2. SIBAYAK MT SURVEYS

Sibayak's old MT data, acquired in 1991 by PT Alico and in 1997 by PT Qodharwan Wirasta Konsultan, with total 51 MT stations, were utilized for 2D inversion techniques to verify the reservoir structure and its extent (Daud, et al., 2002). To achieve a more comprehensive understanding of the Sibayak geothermal field using modern software and technology, a 3D inversion approach was carried out. This re-modeling process aimed to enhance the three-dimensional visualization of the Sibayak Field, improving the accuracy of the geothermal resource assessment. However, limitations were encountered due to the incomplete recovery of historical MT data. To address this challenge and refine the remodeling efforts, a new MT data acquisition campaign was conducted. PGE's in-house geophysics department acquired 54 MT stations using proprietary tools and standardized acquisition procedures.

A three-receiver magnetotelluric (MT) system, including two operational units and one backup, facilitated simultaneous data acquisition at two stations per day in Sibayak. Each station utilized three MTC-80H coils with a frequency range of 1 kHz to 10,000 seconds and 4 electrode pots. Time series data processing is also run in-house using SSMT software resulting 4 excellent datasets, 48 good datasets and 2 fair datasets.

Figure 3 shows MT stations designed for capturing Sibayak reservoir. The station distributions were expected to be grid spaced or spread evenly with a target of 500 to 1000 m spacing in the inner core and 1500 m to 2000 m for the outer core with area of surveys around 100 m^2. Overall, the data acquisition was meeting the target although some part of the map such as in the North-East of Sibayak Mountain and South of Singkut Caldera cannot be acquired due to dense forest with minimum access and crowd residence with high voltage power line.

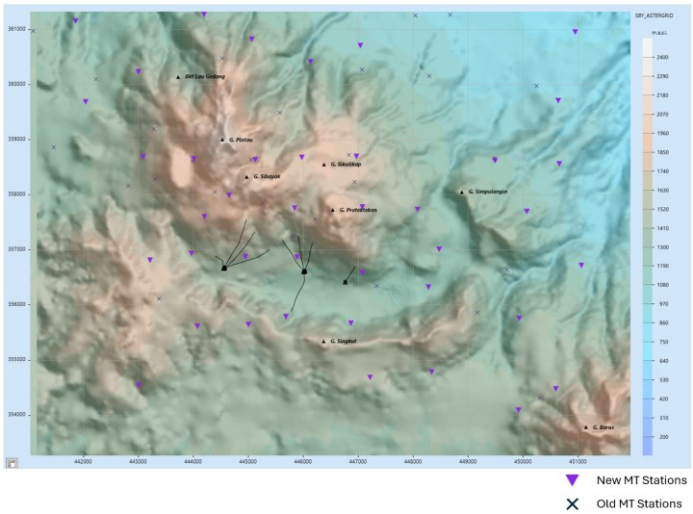

Figure 3: Distribution of MT stations from data acquisition in 2023 (purple triangle) and 1991 & 1997 (cross).

3. SIBAYAK MT INVERSIONS

Prior to this study, previous MT datasets from the Sibayak geothermal field had undergone several analyses. The first study showed that 1D inversion were used to delineate clay cap, reservoir and subsurface structure (Mulyadi, 2000). Understanding the limitation of 1D inversion, 2D inversion had been done to improve the interpretation of reservoir and basement from 1D inversion due to strong indication of 2D or 3D effects (Daud, et al., 2002). Advancements in technology have facilitated the routine application of 3D inversion techniques in recent years. Using a well-prepared MT dataset with recent technology, PGE conducted 3D inversion to create a better understanding of Sibayak reservoir.

To complement the re-evaluation, two complementary inversion approaches were incorporated alongside the contracted 3D MT inversion model. In-house 1D and 2D inversions were performed on newly acquired datasets using Geotools software. MT datasets were prepared to carry out 3D inversion. Datasets were rotated to 0-degree North, MT impedances and magnetic transfer function (tipper) were inverted. Notably, minimal data masking was only necessary for frequencies below 0.006 Hz due to anomalous behavior in the YX component at lower frequencies (Figure 4**)**. The resulting 3D resistivity model revealed a previously unidentified, highly conductive anomaly extending from the outer Singkut Caldera towards Sibayak Mountain. The validity of this anomaly was investigated through further analyses such as comparing it to the previous model, conducting 1D and 2D inversions and lastly conducting a sensitivity analysis.

3.1 Comparison of MT Inversions model

To verify the existence of the newly identified high conductive anomaly, several attempts were made to reconcile it with previous findings. As the original MT datasets used to generate the old 2D resistivity model were unavailable, the datasets of the old MT stations were plotted on the new 3D model, and the published image of the old 2D model was visually compared (Figure 5). Stations SBK-205, SBK-216, SBK-211, and SIB-128 are located within the footprint of the anomaly on the new 3D model. However, the old 2D model did not depict a conductive body at these locations. These restrictions could happen due to several reasons. First, the high conductive anomaly might exhibit a 3D effect that could not be adequately captured by the older 2D inversion algorithms. Second, due to the deep 3D nature, input data for the 2D model were restricted from 0.003 down to 30 seconds period (Daud, et al., 2002).

An additional effort to reconcile the anomaly with previous findings involved comparing published old MT curves to new MT curve nearby. Around 200 meters from SBK-211 is SBY-20 station with the same MT curve response (Figure 6). The most notable difference observed was a significantly higher initial resistivity (around 750 ohm.m) in the old SBK-211 curve (Mulyadi, 2000) compared to the new SBY-20 curve (around 40 ohm.m). This discrepancy could be attributed to the application of static shift correction using TDEM data in the processing of

the old MT data, which was not employed for the new dataset. Both curves exhibited a deflection in the Rho-YX component at a period of 1 second, while the Rho-XY component deflection occurred before 1 second in both datasets.

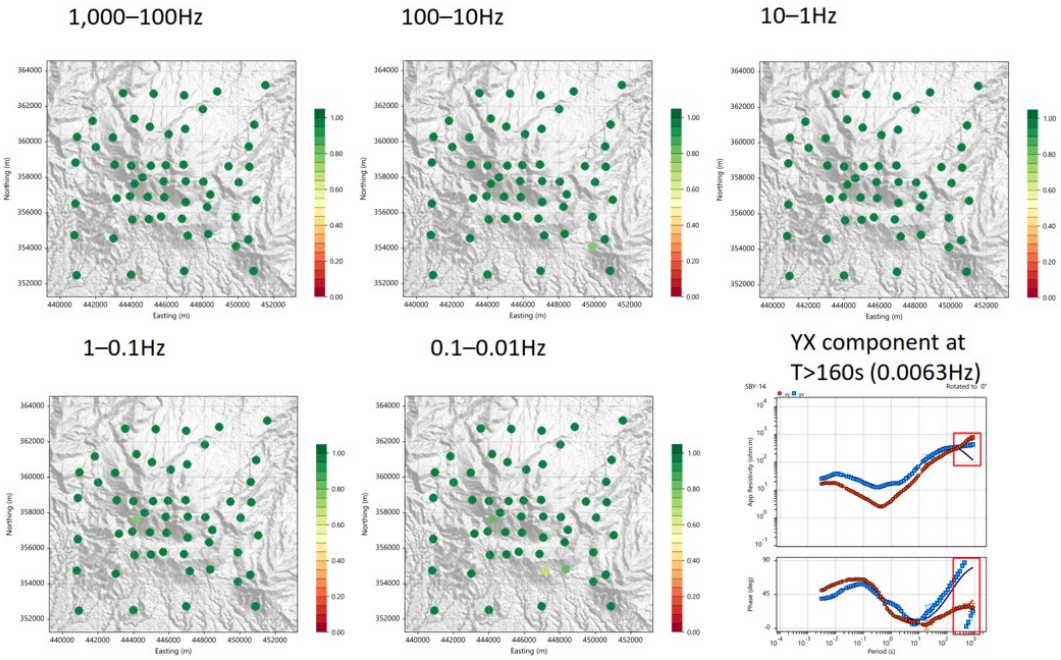

Figure 4: Data masking of MT datasets in every frequency start from 1000 – 0.01 Hz. Color bar green-red describing the percentage of data masked, value 1 or green means no data masking performed.

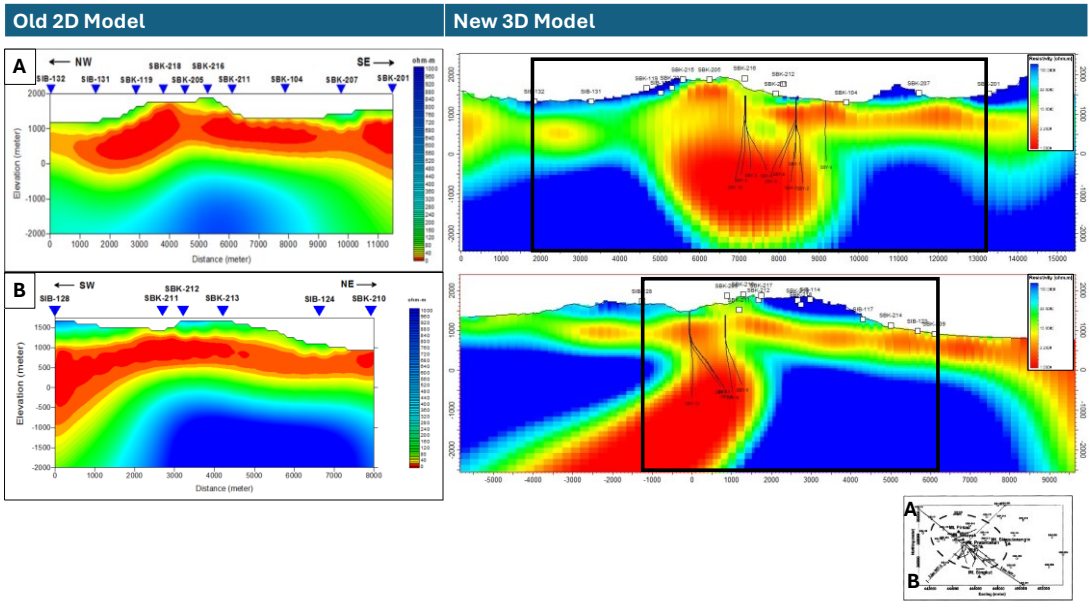

Figure 5: Cross-section comparation between old 2D model (left) and new 3D model (right). The boundary of old 2D model is visualized in a black box.

3.2 New MT Inversions of 1D, 2D and 3D Models

While 1D and 2D MT inversions using Geotools software offered a complementary approach, they presented limitations compared to 3D inversion. Unlike 3D models, 1D and 2D inversions relied on static shift correction obtained from TDEM surveys to process the MT data. This dependence on static shift correction can potentially introduce distortions in the dimensions of the geothermal clay cap as interpreted from the 1D and 2D models. However, the information derived from 1D and 2D models, when combined with alteration mineral data from wells, could still contribute to a comprehensive interpretation of the geothermal system.

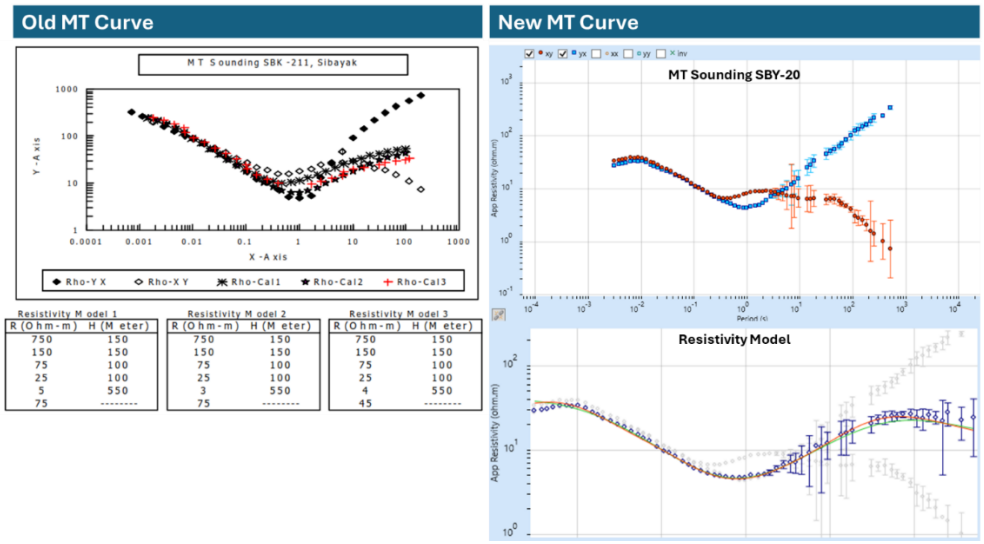

Figure 6: Comparison of nearby station between SBK-211 (old MT dataset) and SBY-20 (new MT dataset) including each 1D inversion.

To generate 1D model, smooth inversion (Occam) method were performed as it was good enough to delineate resistivity of geothermal clay cap (Cumming & Mackie, 2010). These 1D models were generated using TE and TM mode curves for all data within a frequency range of 1000 Hz to 0.001 Hz, incorporating a 5% apparent resistivity noise floor. Subsequently, the 1D Occam models were horizontally interpolated to create a cross-sectional image (Figure 7**)**. The resulting 1D model provides a clear representation of the resistivity down to a depth of approximately 1000 meters, with increased scatter at greater depths. This scattering might be attributed to the influence of 2D and 3D effect.

A 2D inversion was conducted utilizing TE and TM mode curves within the frequency range of 1000 to 0.01 Hz, as determined by data masking. Typically, 2D inversions serve as a preliminary step to refine inversion parameters before progressing to 3D modeling. However, in this study, the 2D inversion was employed to verify the presence of the high conductive body identified in the 3D model, particularly its position relative to the production wells. The 2D inversion confirmed the existence of the conductive body, although its depth was estimated to be greater than that observed in the 3D model Figure 7. This discrepancy underscores the importance of accurate static shift correction in both 1D and 2D inversions.

The 3D inversion was initiated with a uniform 50 ohm.m initial model and a 5% error floor, converging after 80 iterations to a root mean square (RMS) value of 1.08. By incorporating data from 0.006 to 251 Hz, reliable depth resolution was achieved to a depth exceeding 5000 meters. This depth coverage adequately captured the high conductive anomaly extending from outside the Singkut Caldera towards Sibayak Mountain. Notably, nine of the ten wells are located within the outer core of this conductive anomaly. However, a cautious interpretation is warranted due to the age of the well reports, which precludes further detailed analyses such as X-ray diffraction (XRD).

3.3 Sensitivity Test

To assess whether the deep conductive anomaly was an artifact of the inversion process or parameters, a sensitivity analysis was conducted (CGG Geoscience, Multiphysics, 2023). A modified 3D resistivity model (Figure 8a) was created by replacing the highly conductive anomaly with a less conductive body (50 ohm.m). The impact of this modification on the forward response was evaluated by comparing the TE-TM mode curves of the original and modified models at stations within the southwestern study area (Figure 8b). The apparent resistivity and phase curves from the original model (points) displayed significant deviations from those of the modified model (solid lines). This substantial difference in the forward responses demonstrates that the MT data possess sensitivity to the highly conductive body, suggesting its presence is required to accurately fit the observed data.

4. THE BOTTOM OF CLAY CAP FROM 1D AND 3D MT

Although the resolution of 3D model was lowered and smoothed, delineating the bottom of the clay cap using 3D resistivity models is often straightforward and typical for geothermal field evaluations. However, in the Sibayak field, the presence of a highly conductive body positioned near the clay cap in the 3D model presented a significant challenge. This proximity resulted in a blurred interface between the conductive clay cap and the anomaly, hindering clear separation. To address this limitation, 1D MT inversions were employed to provide a higher-

resolution characterization of the clay cap (Figure 7). Figure 7 illustrates a clear separation between the bottom of the clay cap (interpreted at 10 ohm.m) and the highly conductive body in the 1D model, in contrast to the ambiguity observed in the 3D model.

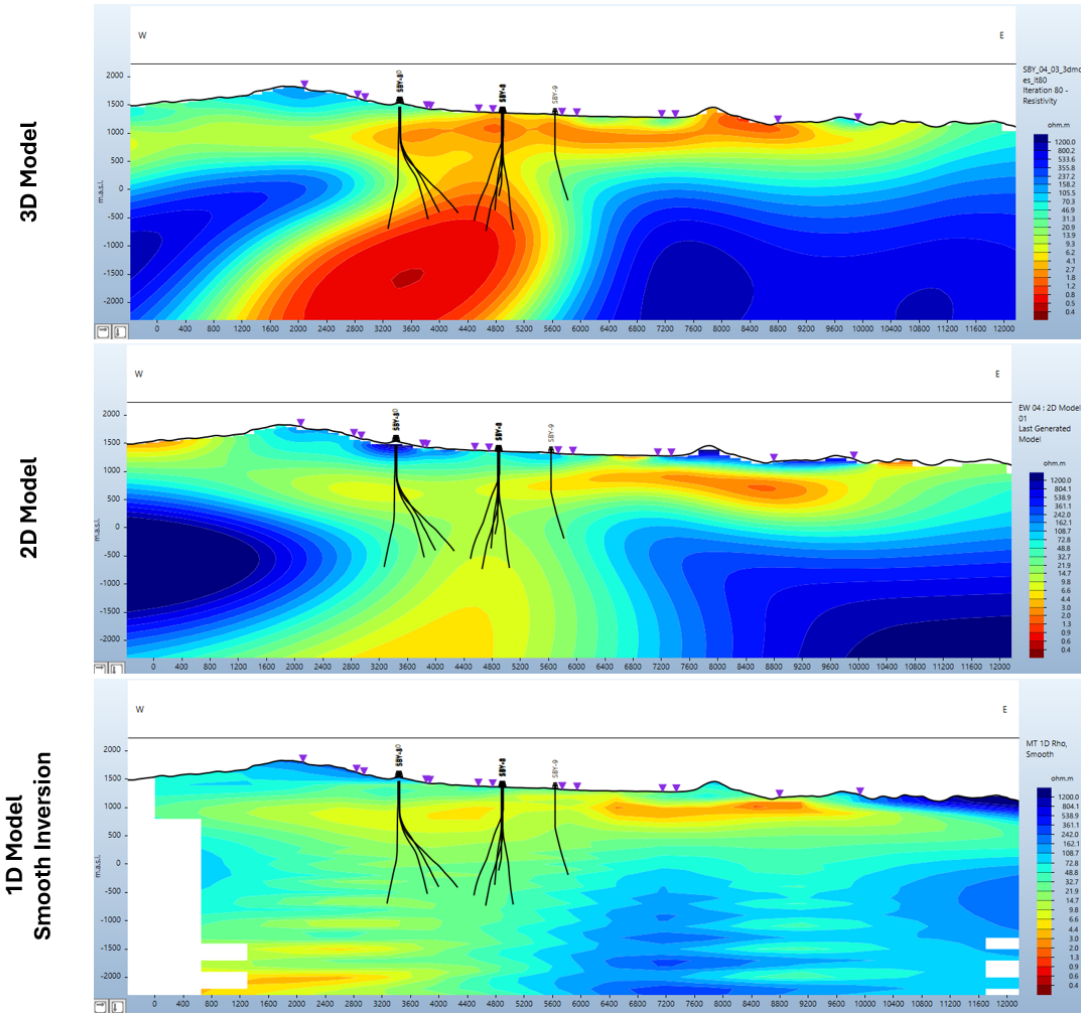

Figure 7: Three West-East Cross Section, crossing wells trajectory from 3D, 2D and 1D model sequentially.

The absence of static shift correction in the 1D model presented a significant challenge. While the integration of well data, including alteration zones, enhanced the interpretation of the geothermal system, the direct correlation between the 1D and 3D model-derived clay cap depths and well data proved to be inconsistent (Figure 9). The lack of Methylene Blue tests (MBT) in the legacy well reports, an uncommon practice at the time, hindered a more precise correlation between the clay cap and the argillic alteration zone.

To address these limitations, a combined approach was adopted. The bottom of the argillic alteration zone was used as a primary constraint, and the general trend of the bottom of clay cap from the 1D model was incorporated into the 3D model. This strategy aimed to mitigate the negative impacts of the low resolution associated with blurred resistivity value of the high conductive body and the clay cap on the 3D model at Figure 10.

5. DISCUSSIONS FOR FURTHER STUDY

While the integration of well data and 1D modeling provided valuable insights, challenges persisted in precisely defining the clay cap bottom. Moreover, the nature of the high conductive anomaly remains an open question. Potential causes for enhanced conductivity include graphite, ore minerals, saline fluids, and partial melting (Schilling, et al., 1997). However, given the likely presence of an impermeable barrier confining fluids, saline fluids are considered the most plausible explanations (Jones, 1992). Laboratory studies have established a correlation between high electrical conductivity and the presence of ore minerals, particularly sulfides. However, while this association is commonly observed, it is not universally applicable. Numerous case studies demonstrate that high conductivity can occur both with and without the presence of detectable sulfides (Lin, et al., 2023).

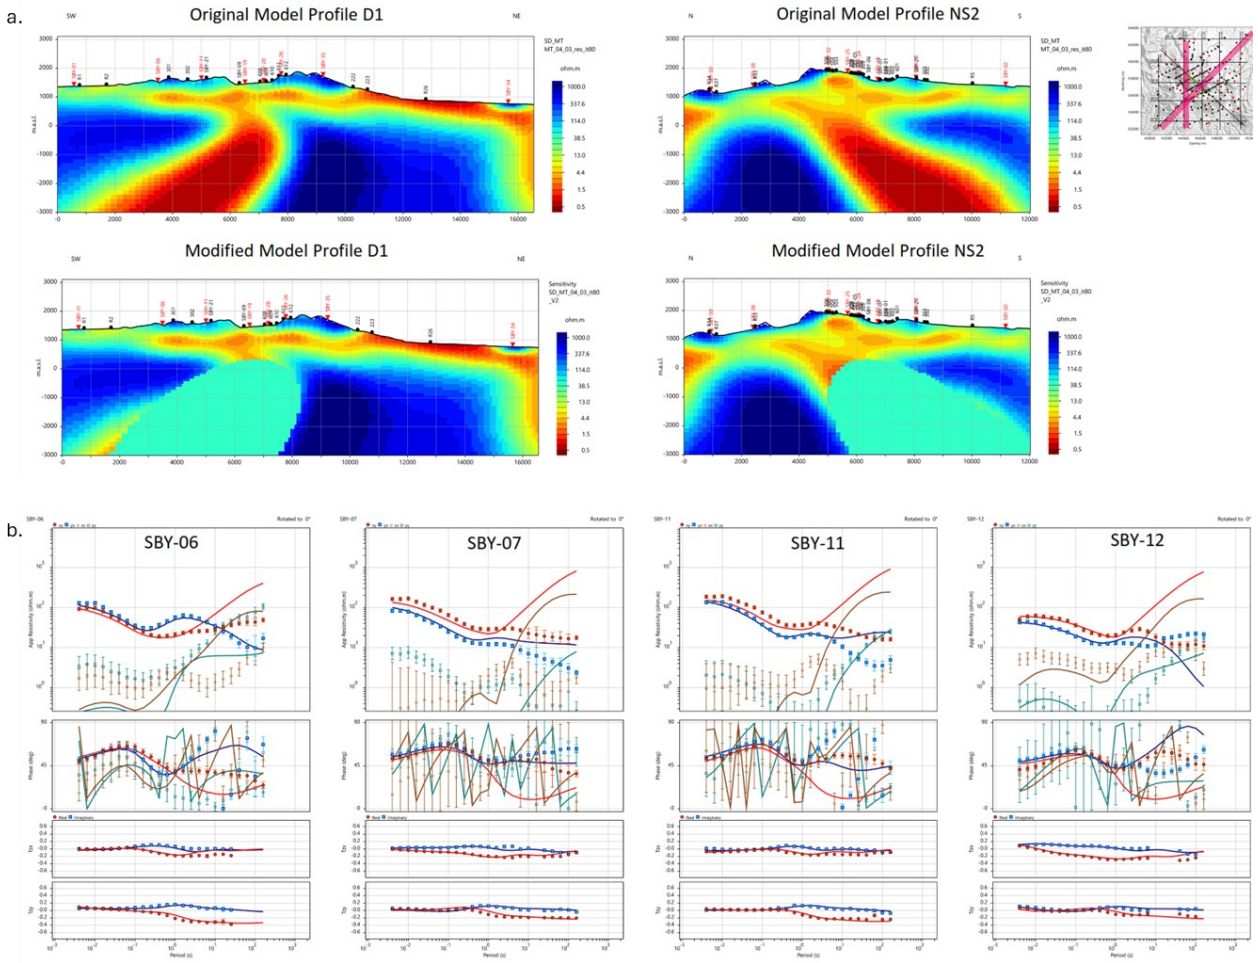

Figure 8: **a. Cross-section of two profiles comparing between modified 3D model from high conductivity into 50 ohm.m body. b. MT-curve sampled from MT stations above the high conductive body with MT curve from forward modelling of the modified body (solid lines) and original data (dots).**

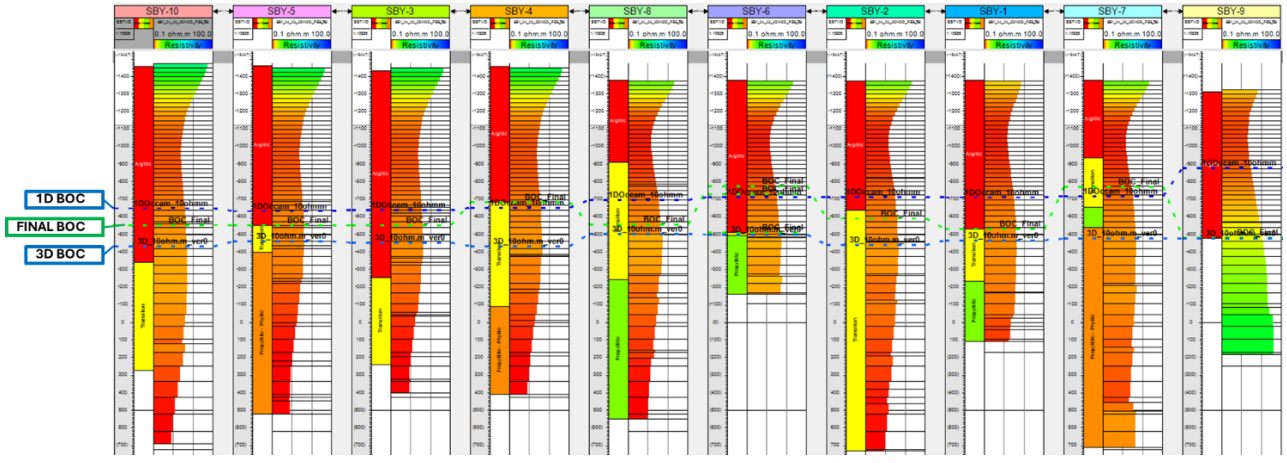

Figure 9: 1D and 3D interpreted bottom of clay cap with alteration data from Sibayak wells.

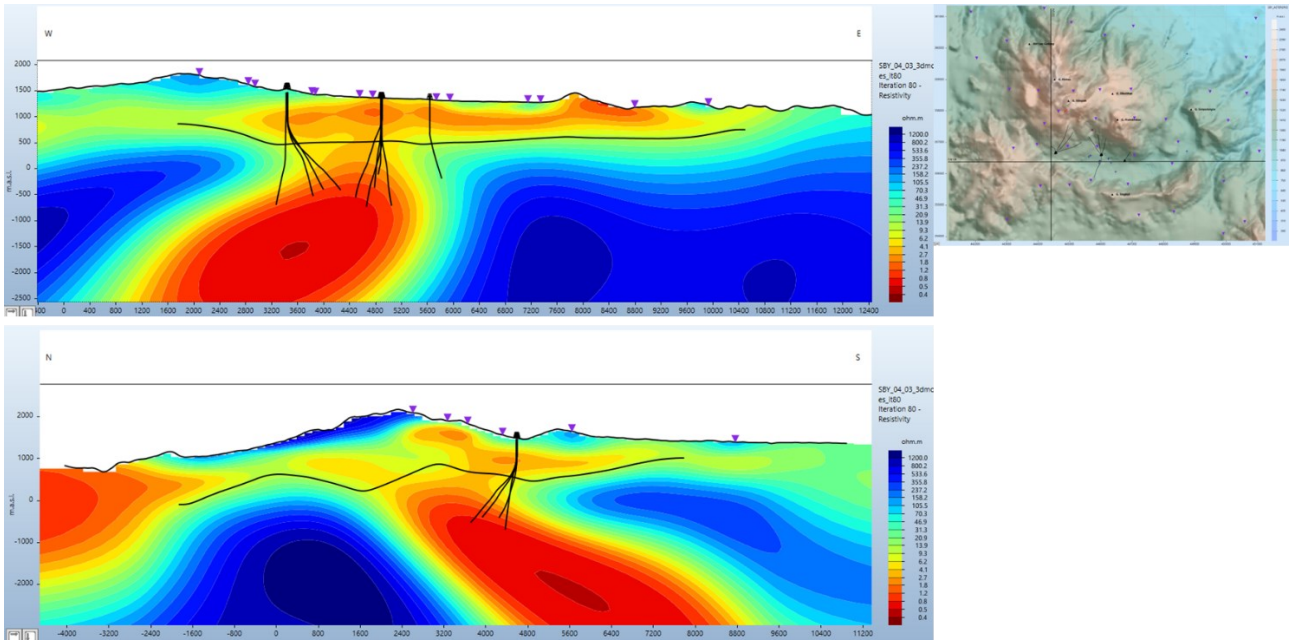

Figure 10: Cross-sections of 3D model with the interpolated bottom of clay cap from 3D interpretation BOC bound with well data and 1D BOC trends.

To discriminate between these possibilities, a comprehensive analysis of well data, including mineralogical studies and geochemical evaluations, are necessary. The characteristics of the fluids produced from the wells, combined with the spatial relationship between the wells and the conductive anomaly, will provide crucial information for determining the anomaly's origin. If the high conductivity is attributed to saline fluids, targeting this zone for future well development would be a logical strategy. Conversely, the presence of ore minerals within the anomaly might necessitate a more complex economic evaluation to assess the potential for mineral exploitation.

6. CONCLUSION

To enhance the definition of the geothermal clay cap, a combined approach utilizing 1D and 3D inversion models is recommended. While 1D inversion offers improved resolution, accurate static shift correction is essential for precise location determination. Conversely, 3D inversion captures the potential 3D and anisotropic nature of the subsurface but may suffer from reduced resolution due to smoothing effects. The resulting 3D clay cap interpretation was significantly refined, particularly in delineating the clay cap within the vicinity of the high conductive anomaly, guided by well data and 1D model interpretation.

Keywords: Geothermal System, GGMPlus, Telomoyo, Ungaran

ABSTRACT

The considerable geothermal energy potential in Indonesia is very possible to be developed and utilized, for example as a power plant and agricultural industry, because most of it has a fairly high enthalpy of the total potential of around 29 GWe. Java Island, especially in Central Java, has many geothermal potential points that can be utilized. There are geothermal potential points in Central Java that have been utilized for production, but there are also those that have not been utilized. Some geothermal potential points that have not been utilized well have some geological similarities or characteristics of the geothermal system with some points that have been utilized better. To be able to optimize other potential points, an analog study or comparison can be carried out on two or more geothermal systems to find out the similarity of the geothermal system conditions, so that later it can be maximally utilized. In this research, an analog study was conducted between the potential points of Telomoyo and Ungaran. The data used is based on the results of GGMPlus gravity satellite image processing and geological conditions in the potential point area. Based on GGMPlus data, in the Telomoyo potential point area the CBA values obtained range from low to high anomaly, where the low anomaly is located on Mount Andong and Mount Telomoyo. This is also shown in the processing results of the Ungaran potential point, where Mount Ungaran also shows a low anomaly. Furthermore, geological studies are carried out to determine the characteristics of geological conditions and validation of GGMPlus data, so that it can be used for potential development.

1. INTRODUCTION

The solo zone is formed by a complex of volcanoes that extends in a northwest-southeast direction, namely the series of Mount Ungaran - Mount Telomoyo - Mount Merbabu - Mount Merapi which is in the Quaternary volcanic geological environment. The Mount Telomoyo complex is one of the geothermal prospect areas indicated by the appearance of geothermal manifestations to the surface in the form of warm springs and rock alteration. Geothermal manifestations on Mount Telomoyo are found in the Candi Dukuh, Candi Umbul, Sepakung and Kendal Duwur areas. In addition, Mount Ungaran has geothermal prospect areas indicated by geothermal manifestations that appear on the surface in the form of fumaroles, hot spring pools and alteration rocks. Both mountains are located in the same zone, which is the solo zone, so there are indications of similarities in geothermal system conditions, geological and geochemical conditions.

Mount Telomoyo consists of several rock units, namely andesite lava unit, tuff breccia unit, pyroclastic breccia unit and alluvial unit. Manifestations that develop in this area are hot springs that have a Chloride - Bicarbonate water type and are a lateral outflow zone of the system. Furthermore, there is rock alteration that has an argillic - advanced argillic type which is an upflow zone that is above the boiling zone of a reservoir. Mount Ungaran is a quaternary volcano located in the north of the North Serayu Mountains, and is located on top of rocks and incorporated in Tertiary rock formations (Setiaji, et al, 2020). geothermal manifestations that develop in the form of warm to hot springs, including hot springs with characteristic deposits that develop in the form of sulfur and travertine. The geothermal manifestations appear to appear in the Kaligetas Formation, Gajahmungkur Volcanic Rocks, and Mount Sumbing Lava with rock distribution in the east - southeast - south of the foot of Mount Ungaran. Based on geochemical analysis, it has hydrothermal fluid types, which are Bicarbonate Water type and Chloride Water type (Trisnaning, 2021).

Geophysical methods are used in this study to find out the geothermal system under the surface of Mount Telomoyo and Ungaran. The method used is GGMPlus (Global Gravity Model Plus) satellite gravity data, which has advantages in terms of resolution of about 200 meters compared to other gravity satellites. Therefore, it can determine the geothermal system and subsurface conditions of the research area in detail.

There are several previous studies that explain the geothermal prospects of Telomoyo that can be developed and the exploration stage has been carried out. But in the Ungaran area no further utilization has been carried out, even though the two locations are still in the same zone. Hence, this research will discuss an analog study using geophysical, geological and geochemical data to determine the similarity of geological conditions and existing geothermal systems. This will help optimize the potential points on Mount Ungaran.

2. METHODS

The research used GGMPlus high-resolution gravity Landsat data, which was obtained from processing using Matlab software to obtain gravity acceleration values. To obtain the complete Bouguer anomaly value, terrain correction was carried out with Global Mapper software, then a complete Bouguer anomaly map and 2.5D modeling were made using Oasis Montaj software. The research locations are in two places, namely the Mount Telomoyo geothermal area and the Mount Ungaran area to see the potential in both geothermal development locations by looking at the similarity of geological, geochemical and geophysical conditions. Geochemical and geological data were obtained based on previous literature that has conducted previous research in the research area.

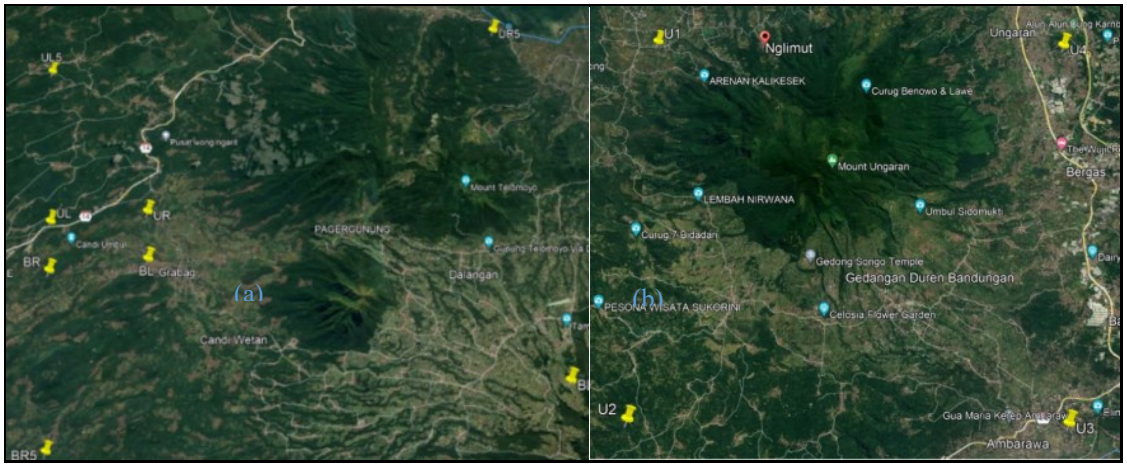

Figure 1: Location Research (a) Telomoyo Area; (b) Ungaran Area.

3. DATA AND RESULT

The Telomoyo area is a well-known geothermal area with the manifestation of hot springs from Candi Umbul and Pakis Dadu. Based on the gravity acceleration value of the Telomoyo area itself, the variation of acceleration values from high to low values is influenced by the geological conditions of the Telomoyo area. The map in Figure 4 shows that the gravity values range from 4 to 27.1 mGal, which can be classified into three zones, namely low, medium and high zones. The low zone in the Telomoyo area is in the area of Mount Telomoyo and Mount Kendil.

To ease the research, an overlay map was added between the Magelang-Semarang Geological Map Sheet and the Telomoyo Area CBA Map. Through the overlay, it is known that the lithology of the Telomoyo area comes from the Kaligetas Formation, Andong & Kendil Volcanic Rock Formation, and Gilipetung Volcanic Rock Formation, which are dominated by volcanic rocks, andesite and lava flows. The geologic map also shows the structures that control the geothermal system in the Telomoyo area.

In the previous research by Hutami, dkk in 2014 geochemical in Mt.Telomoyo geothermal Based on the analysis of the Cl - SO4 - HCO3 ternary diagram, the warm springs in the study area belong to the Chloride - Bicarbonate water type, where this water is formed due to the dilution of the chloride element by meteoric water while flowing to the surface. The presence of bicarbonate elements in the water is the result of vapor condensation below the groundwater level, which will move along the gradient of the groundwater level, the further away the influence of groundwater will be Based on the 18O and 2H isotopes of the warm spring fluid of Candi Dukuh and Candi Umbul, it shows that the fluid has experienced mixing with meteoric water. the zone of this manifestation is lateral outflow.

The Ungaran area is a geothermal area where there is a manifestation of hot springs from Gedongsongo Temple, where this area is surrounded by the Telomoyo and Guci Geothermal Areas. Based on the gravity acceleration values of the Ungaran area, the variation of acceleration values from high to low values is influenced by the geological conditions of the Ungaran area. The map in Figure 6 shows that the gravity values range from -6.8 to

19.9 mGal, which can be classified into three zones, namely low, medium and high zones. The low zone in the Ungaran area is in the area of Mount Sebangkong, which is an ancient volcano in the Ungaran area.

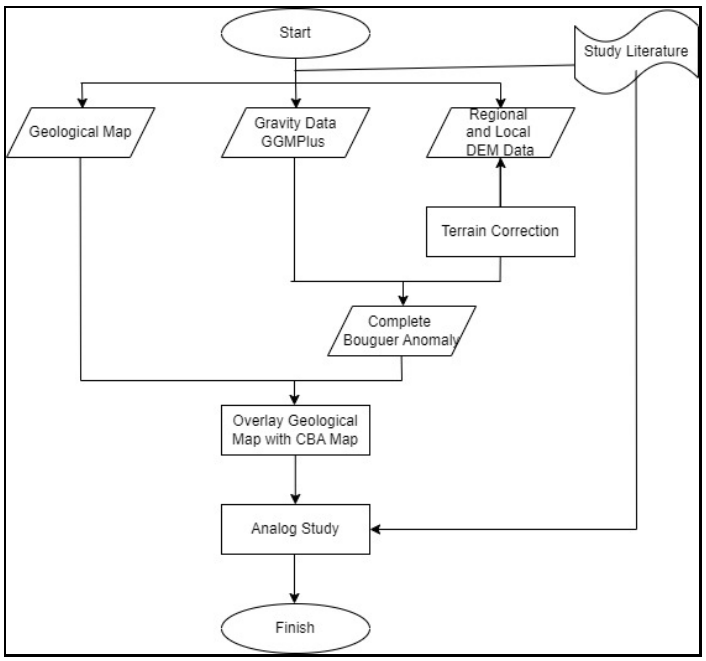

Figure 2: Research Flowchart.

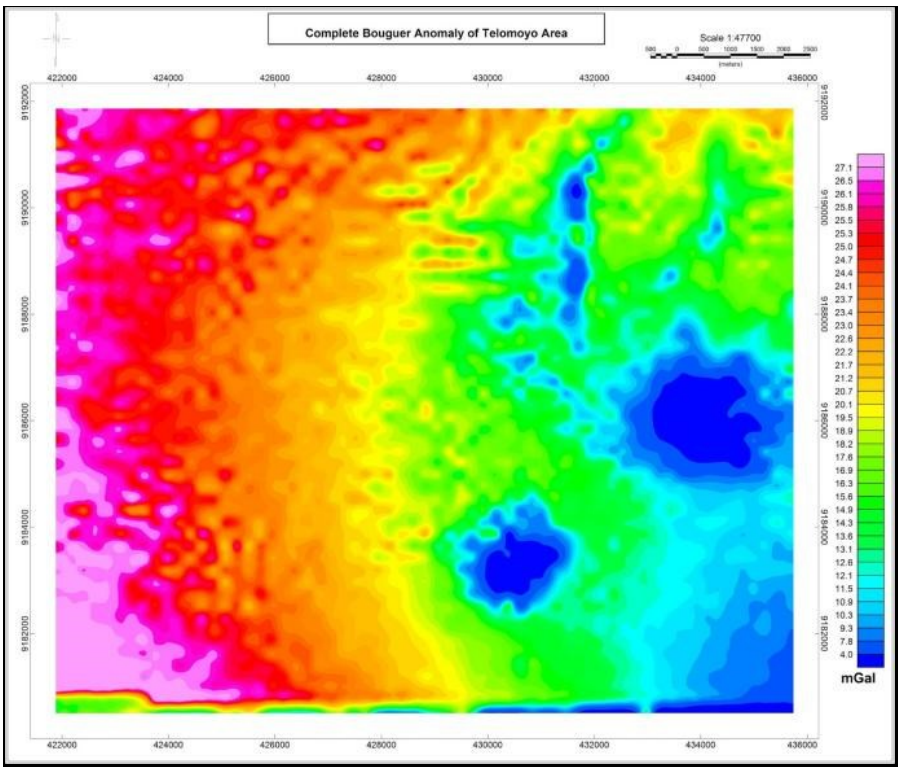

Figure 3: Complete Bouguer Anomaly of Telomoyo Area.

To ease the research, an overlay map was added between the Magelang-Semarang Geological Map Sheet and the Ungaran Area CBA Map. Through the overlay, it is known that the lithology of the Telomoyo area comes from the Jongkong Formation, Gajahmungkur Volcanic Rock Formation, and Kaligesik Volcanic Rock Formation, which are dominated by Andesite rocks with hornblende minerals and also basalt lava from the Jongkong Formation. In addition, the geological map also shows the structures that control the geothermal system in the Ungaran area.

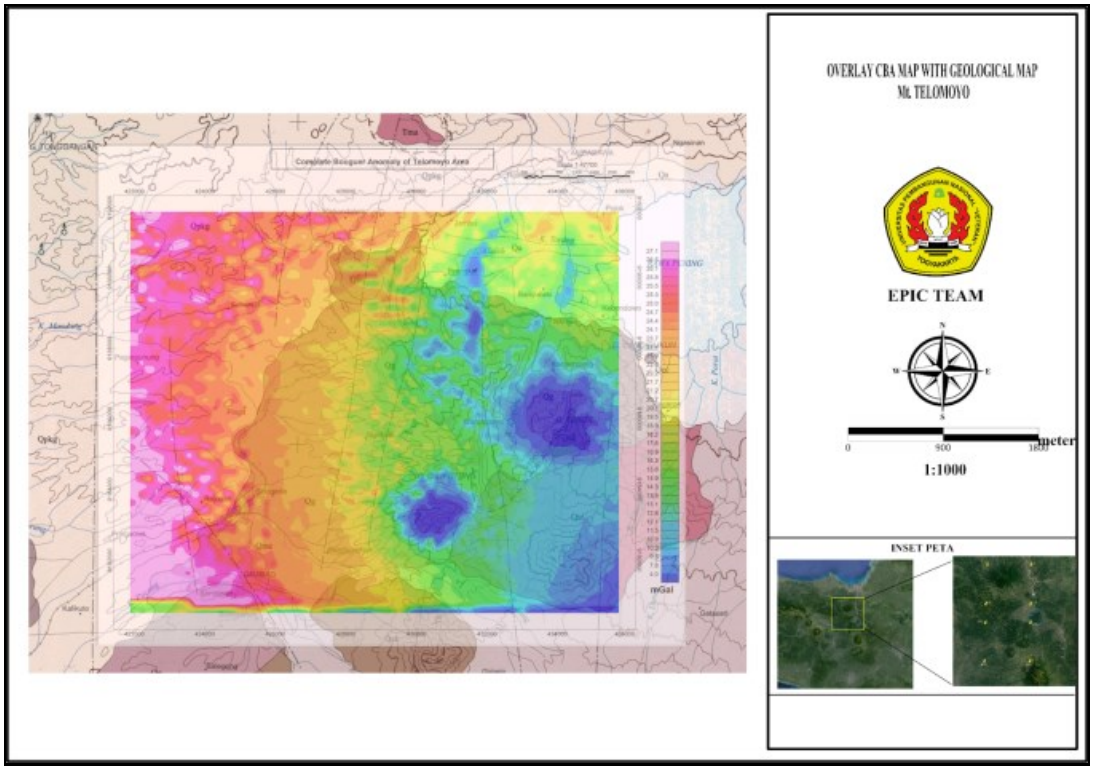

Figure 4: Overlay Complete Bouguer Anomaly of Telomoyo Area With Geological Map.

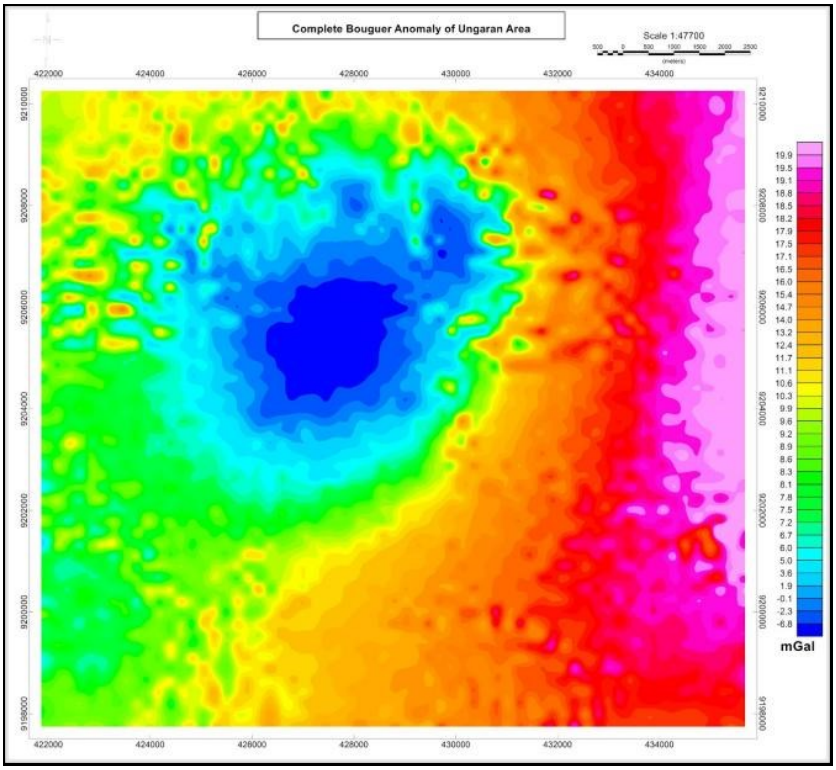

Figure 5: Complete Bouguer Anomaly of Ungaran Area.

Based on previous research by Emiyanto and Aribowo in 2011. geochemical data in Mt. Ungaran geothermal manifestation, hot water has type bicarbonate water fluid because from the results of chemical analysis, it is known that the element HCO3 (bicarbonate) is the most dominant element. This area is categorized as a steam heated water/steam condensates zone. The process that occurs in this zone is the heating of meteoric water by the underlying heat source, the water evaporates and condenses then comes to the surface with the dominant HCO3 element. Based on the plotting of the ternary diagram of the Cl-Li-B element content in hot water in Nglimut and

its surroundings. in the research area generally occurs in the edge zone (outflow). due to the less dominant Cl concentration, it indicates that the research location is quite far from the main flow of the geothermal system.

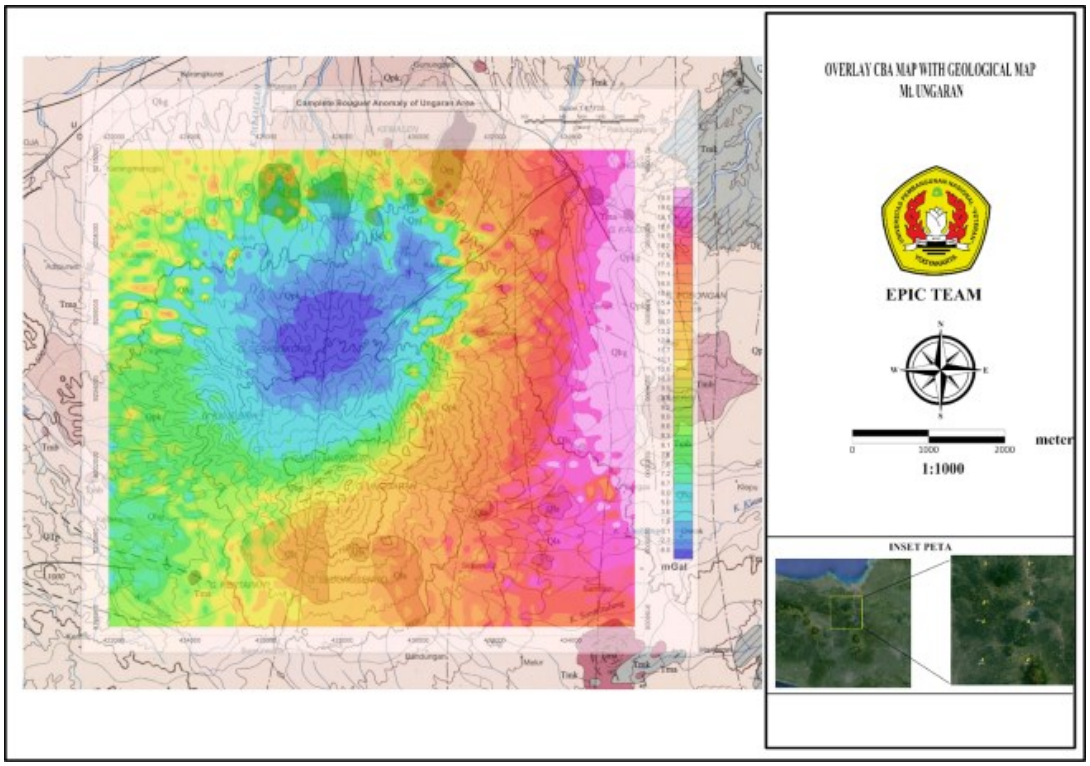

Figure 6: Overlay Complete Bouguer Anomaly of Ungaran Area With Geological Map.

3. CONCLUSION

From result and discussion above, we can know that:

1) Based on geological data Mt. Telomoyo and Mt. Ungaran have similar constituent lithology in the form of volcanic rocks. which consists of rocks as for the types of rocks that are pyroclastic rocks, alluvial, andesite.
2) Based on geophysical data It can be seen that the geothermal system in Mt. Ungaran and Mt. Telomoyo. have in common that there is a heatsource, reservoir faults and manifestations in the form of hot springs and alteration rocks on mt. telomoyo.
3) Based on geochemical data the hot water manifestation of geothermal between Mt. Telomoyo and Mt. Ungaran have a similar type of bicarbonate water. there is included as a outflow zone. but in Mt. Telomoyo Chlorine have a high domination and have higher temperature than Mt. Ungaran.
4) Based on the analog study that has been carried out, it can be concluded that Mt. Ungaran can be explored as in Mt. Telomoyo but the reservoir conditions are not mature enough and have a lower capacity compared to mt.telomoyo. so, it takes several geological years to explore and develop the uUngaran geothermal prospect.

ABSTRACT

Indonesia has non-volcanic geothermal potential that can be found in Kalimantan, one of which is located in Semolon, Malinau Regency, North Kalimantan, indicated by the presence of geothermal manifestations such as hot spring. These manifestations can surface due to the presence of geological structures such as faults. The method that can be used to identify geological structures is the gravity method. This research aims to determine the distribution map of gravity anomalies, including complete Bouguer anomalies, regional anomalies, residual anomalies, and also to identify subsurface geological structures using First Horizontal Derivative (FHD) and Second Vertical Derivative (SVD) analyses. The research was conducted using secondary data from satellite gravity measurements, specifically GGMplus and SRTM data. Secondary gravity data is useful for preliminary surveys of geological targets that are difficult to access in the field. The research results show that the complete Bouguer Anomaly in the research area is in the range of 47.7 mGal to 193 mGal. Regional anomalies in the research area are in the range of 52.6 mGal to 190.9 mGal. Residual anomalies in the research area are in the range of -18.9 mGal to 13.1 mGal. Data analyses of residual Bouguer map resulted in indication of some faults in the study area. These faults should correlate with the fluid pathways. Additional study in this geothermal prospect is needed to understand more about the conceptual model of this system.

1. INTRODUCTION

Indonesia is located at the intersection of three active world plates, namely the Eurasian, Indo-Australian, and Pacific plates, which results in Indonesia having a complex tectonic structure. Sukendar et al (2016). This strategic position makes Indonesia one of the countries with the largest geothermal potential in the world, amounting to 29 GWe. Indonesia's geothermal potential is mostly distributed along the volcanic arc, from Sumatra, Java, Bali, Nusa Tenggara, Sulawesi to Maluku (Ahluriza and Udi, 2021).

Geothermal heat sources are often associated with volcanoes. Research discussing about non-volcanic geothermal system is still limited. Non-volcanic geothermal sources can be found in the Kalimantan region of Indonesia (Yushantarti, 2020; Zarkasyi and Dikdik, 2015). Medium to low enthalpy geothermal system can be considered for geothermal prospects in Kalimantan (Ahluriza and Udi, 2021). There are 14 geothermal prospects, including Semolon, located in Malinau Regency, North Kalimantan.

Indications of geothermal system in the Semolon area is the manifestation of warm spring with temperatures ranging from 51.4° to 60.2°C (Yushantarti, 2020). According to Dahlan et al. (2011), one of the geological structures in this study area is a normal fault with a relatively northwest-southeast direction.

Geophysical method can be used to determine the geological structure of the Semolon geothermal system. The gravity method is one of the geophysical methods that can be used to identify subsurface geological structures based on variations in the gravity field caused by differences in rock density (Asniar et al., 2020; Hoerunisa and Sismanto, 2020).

In this study, gravity satellite data were used. Satellite gravity data can be used for mapping subsurface geological structures. The GGMplus data is a global gravity model with very high resolution, having data point spacing of approximately ~200 m in the north-south direction (Hirt et al., 2013, 2019). GGMplus can provide a detailed description of the gravitational field conditions in an area such as density, depth, geometric shape of structures or objects that cause anomalies below the surface (Sudrajad, 2018).

The difference in anomaly value is due to the density contrast in the subsurface. The difference in density in the subsurface can be used as a starting point to predict the presence of fault structures in the research area.

2. METHOD

This study used Global Gravity Model Plus (GGMplus) and the Global Shuttle Radar Topography Mission (SRTM). GGMplus data and SRTM data can be obtained through official online database; from this link (http://ddfe.curtin.edu.au/gravitymodels/GGMplus/). These data sources provide access to high-resolution global gravity models. Data from http://ddfe.curtin.edu.au/gravitymodels/ERTM2160/ are also used.

The SRTM data is topographic data used for gravity field correction (Hirt et al., 2019). SRTM data is in the form of full-scale gravity with spacing between data points of ~220 m. SRTM data is used to correct GGMplus data to obtain the complete Bouguer anomaly for the research area, by subtracting GGMplus data from SRTM data. The complete Bouguer anomaly value is then processed to obtain regional and residual anomalies, then further analysis is carried out using First Horizontal Derivative Second Vertical Derivative to determine the presence or absence of faults and fault types (Trimulyati and Ardian, 2022).

3. RESULTS AND DISCUSSION

The complete Bouguer anomaly value is a gravity anomaly that represents the distribution of subsurface density in shallow and deep areas. Effects originating from shallow areas are called residual anomalies, while effects originating from deep areas are called regional anomalies (e.g. on Charisma et al., 2022). Based on the results of gravity data processing, the value distribution and complete Bouguer anomaly map are shown in Figure 1. The complete Bouguer anomaly in the research area is in the range of 47.7 mGal to 193 mGal.

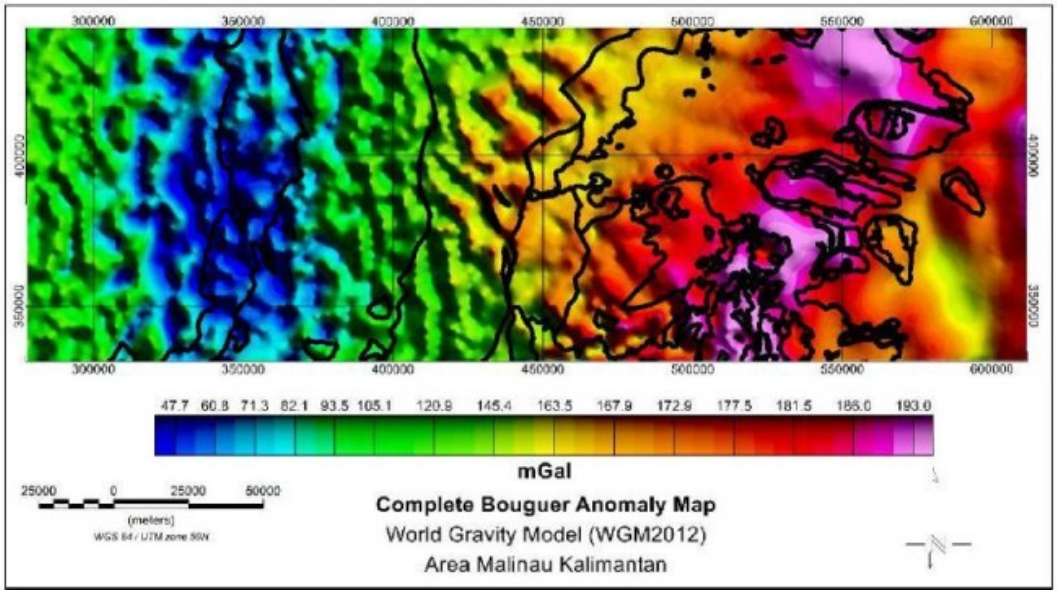

Figure 1: Complete Bouguer Anomaly Map of Semolon Geothermal Prospect Area. Red colour indicates high Bouguer anomaly.

The distribution of high anomalies in the research area ranges from 163.5 mGal to 193 mGal, depicted with color contrasts ranging from yellow to pink. The distribution of low anomalies in the research area ranges from 47.7 mGal to 145.4 mGal, depicted with color contrasts ranging from dark blue to green. The map shows that the distribution of high anomalies is on the east side of the research area and low anomalies are on the west side of the research area.

The regional anomaly in the research area is in the range of 52.6 mGal to 190.9 mGal (Figure 2). The regional anomaly pattern has a high tendency in the East with anomaly values of 164.9 mGal to 190.9 mGal and low in the West with anomaly values of 52.6 mGal to 145.0 mGal. The high value in the East indicates that the rocks in the area have a fairly high density compared to rocks in the West.

The formation of the Tarakan Basin and its deposition process cannot be separated from the existing tectonic phenomena. To the west of the Tarakan Basin lies the Kuching High, consists of metamorphic rock complexes from the Cretaceous age and a melange rock complex from Kalimantan Central Ranges of Early Eocene age (Achmad and Samuel, 1984). To the north of the study area is Sampurna Peninsula High. It consists of igneous and metamorphic rock complexes that have undergone uplift. In the southern part of the Tarakan Basin, there is the Mangkalihat-Peninsula High which is a thin sedimentary rock of Tertiary age deposited on top of uplifted bedrock. In the east, the Tarakan Basin is bordered by the Sulawesi Sea which continues to deepen and becomes the Makasar Trench.

The regional stratigraphy of the Tarakan Basin is divided into pre-Tertiary, Tertiary, and Quaternary. The oldest Tertiary rocks belong to the Danau Formation, which is composed of strongly tectonized rocks and metamorphic rocks with significant thickness. The age is still debated between Permian-Carboniferous or Jurassic-Cretaceous (Achmad and Samuel, 1984). The Sembakung Formation unconformably overlies the Danau Formation, consisting of red sandstones and conglomerates from the Middle Eocene (Achmad and Samuel, 1984).

The low regional anomalies in the western part of the research area are suspected to be caused by rocks with low density, this is in accordance with the geological data of the research area, indicating sedimentary rock deposits and geological structures such as faults or faults in the rock layers (Baharrudin , 2011; Dahlan et al (2011). In addition, there are geothermal manifestations such as hot spring, which can cause rock density to decrease due to alteration minerals produced by the circulation of hot water (Huenges, 2010).

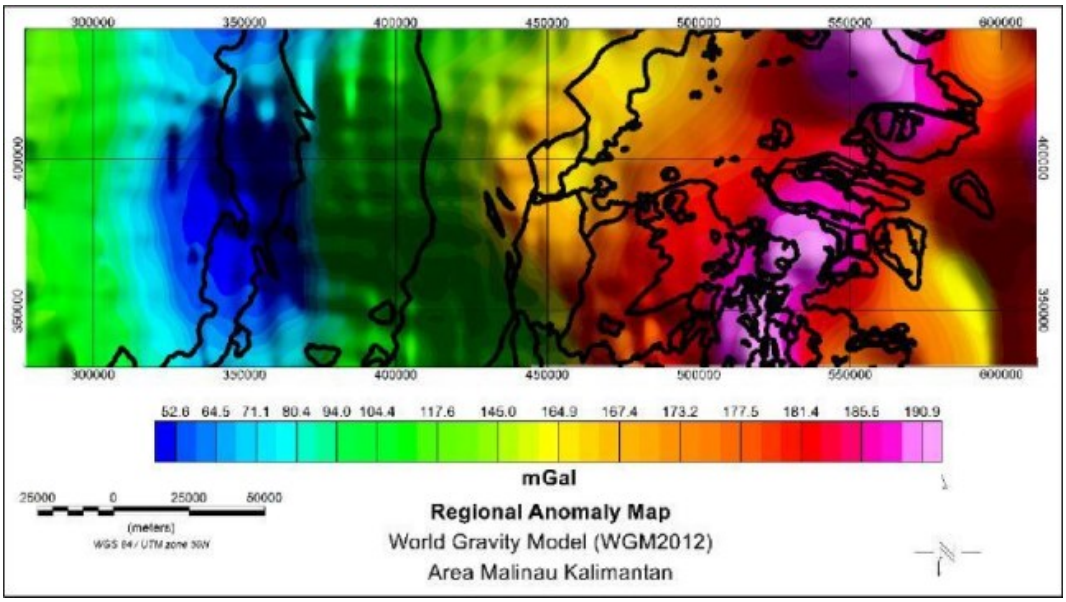

Figure 2: Regional Anomaly Map of Semolon Geothermal Prospect Area.

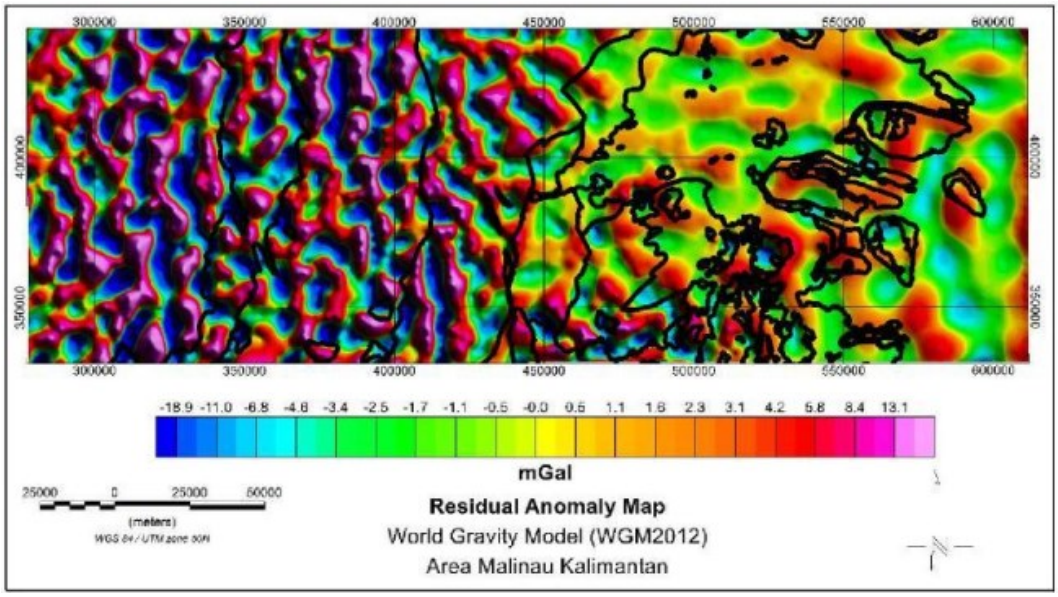

Figure 3: Residual Anomaly Map of Semolon Geothermal Prospect Area.

The results of the distribution of values and the residual anomaly map are shown in Figure 3. The residual anomaly in the research area is in the range of -18.9 mGal to 13.1 mGal. The negative anomaly value indicates that there is a much lower density value compared to the surrounding area. Low residual anomalies are in the range of -18.9 mGal to -0.5 mGal, depicted with dark blue to green color contrast. High residual anomalies are in the range -0.5 mGal to 13.1 mGal, depicted with orange to pink color contrast.

Based on the derivative analysis results, some faults were identified. These faults were identified due to maximum or minimum FHD (First Horizontal Derivative) that intersect with zero value of SHD (Second Horizontal Derivative).

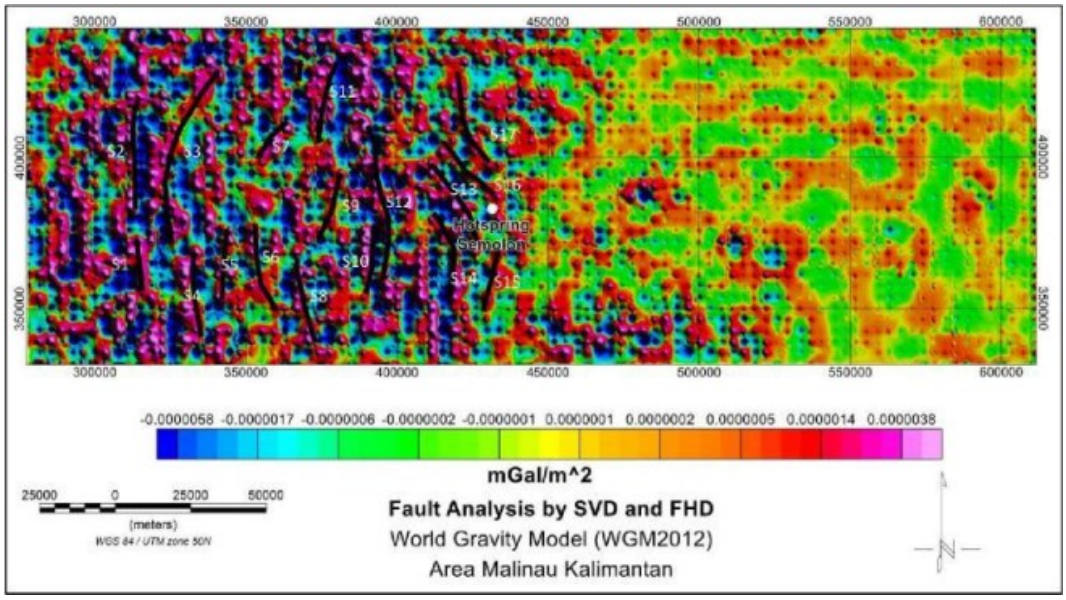

Figure 4: First Horizontal Derivative and Second Horizontal Derivative Map of Semolon Geothermal Prospect Area.

4. CONCLUSION

Gravity satellite data is very helpful to understand a geothermal prospect area in regional scale. Sedimentary layer and basement can be mapped as low and high Bouguer anomaly, respectively. Regional anomaly also displays similar result with Bouguer anomaly map. Derivative analyses shows that there are some faults indication with direction SE-NW, similar to Sampoerna Fault direction, close to Semolon warm spring.

Keywords: Cubic Interpolation, Geothermal, Interpolation, Linear interpolation, Nearest neighbor Interpolation

ABSTRACT

Interpolation in the world of geophysics has currently attracted a lot of attention because it can estimate unknown values at a certain time or location. Many interpolation methods have been developed in geophysical software such as Oasis Montaj, Surfer, Arc-GIS, and many other programs. In this research, we try to make Python programming using the Python Geophysics library and perform interpolation techniques with a focus on cubic interpolation techniques, linear interpolation, and nearest neighbor interpolation, and at the end, analyze the results of interpolation in the Cisolok-Cisukarame geothermal field. The data used is in the form of gravity data that has been measured in the field at 75 points and has undergone data processing to achieve a complete bouguer anomaly (CBA). Cubic interpolation analysis produces smooth estimates, can capture more complex variations in data and provides high accuracy but is computationally very intensive and requires a lot of memory and processing power. Linear interpolation is simple, easy to implement and suitable for linearly varying data but may not be accurate for non-linear and produces less accurate estimates. The nearest neighbor is like linear interpolation in its advantages but does not provide smooth estimates and produces a ladder-like appearance to the interpolated data. The Cubic technique produces excellent results over linear and nearest and maintains good value positivity.

1. INTRODUCTION

Geophysical data is often interpolated to generate a spatial data representation that can be described in the form of contour maps. Interpolation plays a crucial role in geophysical data analysis, especially when data points are unevenly scattered across the study area. In geophysical surveys, data are often collected at irregular intervals due to practical limitations or varying survey conditions. However, many analytical techniques in geophysics, such as fast Fourier transform for signal processing or equivalent layer methods for inversion, require regularly arranged data to allow efficient computation and interpretation (Gunn, 1975; Oldenburg, 1975). In geophysical interpolation, a lot of research has been conducted. Crain and Bhattacharyya (1967) introduced qualitative criteria to evaluate the balance between accuracy and computational time. The least-squares method with orthogonal polynomials generated through the Gram-Schmidt process showed the highest quantitative accuracy. Later, Bhattacharyya (1969) developed an interpolation method using cubic surfaces, which he stated was more accurate than using orthogonal polynomials. Several other studies followed this approach and proposed variations of the algorithm (Thomson, 1970; Heissing et al., 1972; Rasmussen and Sharma, 1979). Crain (1970) classified interpolation methods into two categories: (1) mathematical surface methods, and (2) numerical surface methods. The first method produces an analytical surface that passes through the observation points, while the second method develops interpolation points based on the distribution of neighboring observation points. Casanova P., and Alvarez R., (1985) presented a classification of Splines that featured the use of fast cubic spline algorithms operating on dense grids in an irregular area bounded by a rectangle.

Li W., et al. (2010) proposed a linear interpolation method by transforming rectangular coordinates into polar coordinates. owever, the algorithm error was high, and the operations were complex. W. Y., et al. (2012) proposed an improved method with a comparative point interpolation algorithm based on 8 directions, through maximum interpolation error analysis, analytical solutions, numerical comparisons, and computer computations, an error calculation method was obtained. This method demonstrated advantages in high interpolation precision, stable computation, and high computation speed. Zeng Min et al., 2016, found linear interpolation to be very promising for industrial applications due to its fast and promising calculations. Guilin (2020) presented missing data, and when experimental tests were conducted, linear interpolation showed good computational performance and efficiency. Dunlop, G. R. (1980) presented nearest neighbor interpolation, which had limited accuracy and was time-consuming. The presented interpolation methods are also used in many software applications such as Oasis Montaj, Surfer, Arc-GIS, and many other interpolation programs. In this study, we attempt to create Python

programming using modules that can perform interpolation techniques, focusing on cubic, linear, and nearest neighbor interpolation techniques.

2. METHODOLOGY

In this section, we will explain a little understanding of cubic, linear and nearest neighbor interpolation theory.

2.1 Cubic Interpolation

Bicubic interpolation is the simplest two-dimensional interpolation method that preserves the continuity of the function and its first derivatives (both normal and tangential) across cell boundaries (Russels W., S., (1995). It is a mathematical technique frequently used to generate new points within the range of a set of existing points. These new points represent function values of an interpolation function, known as a spline, which is composed of several cubic piecewise polynomials. This article describes the mathematical process behind this computation.

In the process of constructing the spline $\boldsymbol{f}$: $[x_1, x_{n+1}] \rightarrow$ R, where n consists of polynomials of degree 3 referred to as $\boldsymbol{f_1}$ to $\boldsymbol{f_n}$. The resulting function has the following structure:

$$f(x) = \begin{cases} a_1x^3 + b_1x^2 + c_1x + d_1 & \text{if } x \in [x_1, x_2] \\ a_2x^3 + b_2x^2 + c_2x + d_2 & \text{if } x \in [x_1, x_2] \\ \dots & \\ a_nx^3 + b_nx^2 + c_nx + d_n & \text{if } x \in [x_n, x_{n+1}] \end{cases} \quad (1)$$

Note that each polynomial is valid only within a specific interval; together, they form the interpolation function. While extrapolation predicts values beyond the range of the data, interpolation operates solely within the data boundaries $[x_n, x_{n+1}]$. With appropriately selected coefficients for the polynomials a_i, b_i, c_i, d_i, the resulting function passes smoothly through the points. To determine these coefficients, several equations are established, forming a system of equations that can be uniquely solved.

To solve the system of equations, two more pieces of information are needed. Arbitrary constraints, like setting the third derivative at a chosen point (for instance, the fourth point), to zero can be used. However, a commonly used method involves selecting boundary conditions, which consist of a pair of equations. Detailed explanations of four conditions—natural spline, not-a-Knot spline, periodic spline, and quadratic spline—are elaborated below.

2.1.1 Natural Spline

A natural spline is characterized by setting the second derivative of the initial and final polynomials to zero at the boundaries of the interpolation function.

$$\begin{aligned} 6a_1x_1 + 2b_1 &= 0 \\ 6a_nx_{n+1} + 2b_n &= 0 \end{aligned} \quad (2)$$

Visually, this means that the rate of change of the function approaches zero at both the beginning and end points.

2.1.2 Not-a-Knot Spline

For the not-a-knot boundary condition, the third derivatives of the first two polynomials are equal at the point where they meet (x_2). Similarly, the last two polynomials meet (x_n) at another point, with their third derivatives also being equal, resulting in

$$\begin{aligned} \frac{d^3}{dx^3}f1(x) &= \frac{d^3}{dx^3}f2(x) \quad |x = x_2 \\ \frac{d^3}{dx^3}f_{n-1}(x) &= \frac{d^3}{dx^3}fn(x) \quad |x = x_n \end{aligned} \quad (3)$$

After calculating these derivatives, this can be resolved by

$$\begin{aligned} a_1 &= a_2 \\ a_{n\text{-}1} &= a_n \end{aligned} \quad (4)$$

that is making the a -coefficients equal.

2.1.3 Periodic Spline

In periodic interpolation, the first polynomial's first and second derivatives are set equal to the last polynomial's corresponding derivatives. Visually, this ensures that the function can seamlessly repeat or tile. This helps if $\boldsymbol{f}$ $(x_1) = \boldsymbol{f}$ (x_{n+1}) but should work equally well with functions y where the first and last point values are different.

$$3a_1x_1^2 + 2b_1x_1 + c_1 = 3a_nx_{n+1}^2 + 2b_nx_{n+1} + c_n$$
$$6a_1x_1 + 2b_1 = 6a_nx_{n+1} + 2b_n \quad (5)$$

2.1.4 Quadratic Spline

The quadratic boundary condition specifies that both the first and last polynomials are quadratic, making this method the most straightforward. Mathematically, this means that the first coefficient of both polynomials is equal to zero:

$$a_1 = a_n = 0 \quad (6)$$

2.2 Linear Interpolation

In python programming, linear interpolation is constructed using triangulating inputs where each performed triangle uses barycentric linear interpolation (Gommers, R., (2022)). Given a sample sequence $f_n = f(nT)$ which is derived from a sample of uniform functions $f(x)$ taken in steps of T, the standard method of linear interpolation constructs a function $f_T(x)$ with the following process: for $x \in [(n-1)T, nT]$, $f_T(x) = a_nx + b_n$, where a_n and b_n are chosen such that $f_T((n-1)T) = f_{n-1}$ and $f_T(nT) = f_n$. This can be shown to be equivalent to (Blu, T., et al., 2024):

$$f_T(x) = \sum_{n\in\mathbb{Z}} f_n \, \mathrm{A}\left(\frac{x}{T} - n\right) \quad (7)$$

Where A is the 'hat' function, or linear B-Spline: A $(x) = |x|$ for $|x| \leqslant 1$ and A $(x) = 0$ for $|x| > 1$ (M. Unser, 1999).

2.3 Nearest Neighbor Interpolation

Xi, Yi are expressed as training samples for $i = 1, \ldots, n$. Given a data point x for testing, determine $R_{k+1}(x)$ to be the distance between x and its (k+1) nearest neighbor. Without loss of generality, let $X^1(x), \ldots, X^k(x)$ denote the unsorted k-nearest neighbor of x, and write as $X^1, \ldots, X^k$ for simplicity. Denote $\{R_i(x)\}_{i=1}^k$ and $\{Y^i(x)\}_{i=1}^k$ ($\{R_i\}_{i=1}^k$ and $\{Y^i\}_{i=1}^k$ in short) as distance between X^i and x and the corresponding responses. For regression models, the goal is to estimate $\Rightarrow(Y|X = x)$. Denote $\eta(x)$ as target the function, where $\eta(x) = \Rightarrow(Y|X = x)$, and $\sigma^2(x) = Var(Y|X = x)$. A Nearest Neighbor regression estimator at x, based on nearest k neighbors, is defined as

$$\eta k, n(x) = \sum_{i=1}^{k} W_i(x)\, Y^i, \quad (8)$$

Where $W_i(x)$ indicate the weight for each neighboring data point. For weight scheme $W_i \geqslant 0$ and $\sum k\, W_i = 1$, and traditional $W_i = 1/k$ for all $i = 1, \ldots, k$.

Figure 1 shows how interpolation processing is conducted in Python for gravity data in the Cisolok-Cisukarame geothermal field. The input used includes Python modules or libraries such as pandas, numpy, matplotlib, and scipy. The data is separated into two parts in CSV format: gravity data containing complete Bouguer anomaly data, and elevation data containing coordinate points and elevation. These are then displayed on a map to visualize data distribution and the values of each point. This process enables us to perform gridding interpolation using three different methods: cubic, linear, and nearest neighbor interpolation maps.

3. BACKGROUND GEOTHERMAL AREA

The Cisolok-Cisukarame geothermal field is situated in the western region of Java Island, within Cisolok village, Cisolok sub-district, Sukabumi district, West Java province, Indonesia (Figure 2). Evidence of subsurface hydrothermal activity in the field is demonstrated by surface manifestations such as hot springs and geysers with high temperatures and a relatively neutral pH, and flow rates of approximately 10 L/m. Additionally, the area features deposits of travertine and silica sinter in alteration zones (Herdianita & Mandradewi, 2010). These observations led to a pre-feasibility study in 1970, which involved a detailed 3G (geological, geochemical, and geophysical) survey. In Figure 3 the Cisolok-Cisukarame geothermal field is primarily composed of Quaternary rocks, including andesitic, basaltic, and pyroclastic lavas from Mount Halimun. Additionally, there are sedimentary rocks such as limestone (Sujatmiko & Santosa, 1992).

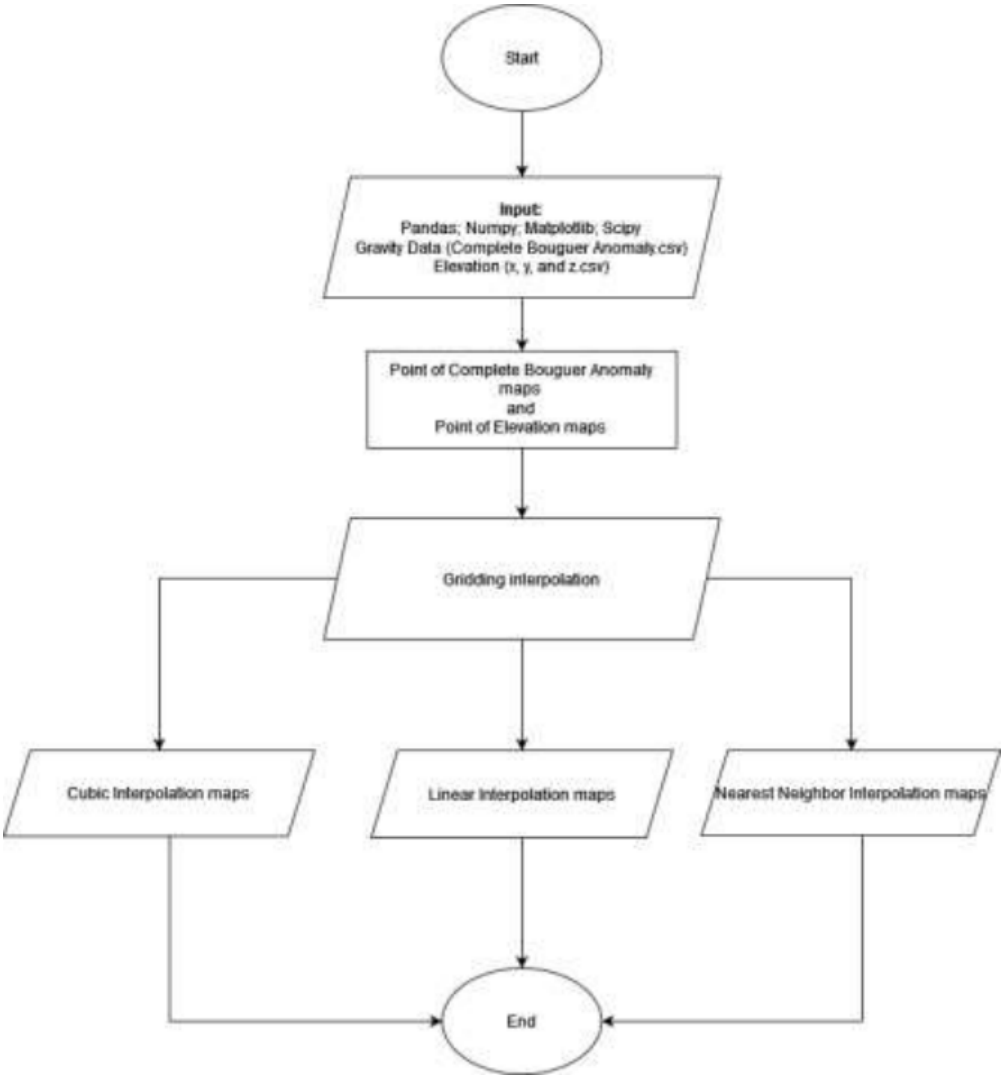

Figure 1: Flowchart of interpolation processing using python gravity data at Cisolok-Cisukarame geothermal field.

The geological structures in the study area, which trend north-south and northeast-southwest, formed during the Plio-Pleistocene period and are now covered by Quaternary volcanic deposits (Sujatmiko & Santosa, 1992; Herdianita & Mandradewi, 2010). The geothermal manifestations in the Cisolok-Cisukarame area are divided into two distinct regions: Cisolok and Cisukarame. In the Cisolok region, there are hot springs and geysers with temperatures ranging from 90 to 100°C and a relatively neutral pH of about 8 (Suryantini, 2009; Herdianita & Wulandari, 2010; Haty & Nugroho, 2013; Abdidallah et al., 2017).

The manifestations in Cisolok feature high sulfate and bicarbonate fluid types, likely influenced by limestone, as indicated by the presence of travertine deposits in the area (Sintawati, 2014; Kurniawan et al., 2018). Meanwhile, the Cisukarame region has hot springs with temperatures between 54 and 99°C and a relatively neutral pH of around 6.8 to 8.2 (Haty & Nugroho, 2013). The manifestations in Cisukarame contain sodium chloride fluid, reflecting the reservoir fluid (Sintawati, 2014). Consequently, it is believed that Cisolok and Cisukarame are characterized by different geothermal systems, as evidenced by the manifestation temperatures reaching the boiling point in both areas. The reservoir temperature in the Cisolok-Cisukarame area, estimated using a Na-K geothermometer and empirical equations from Fournier (1979) and Giggenbach (1988), ranges from 185 to 212°C (Kurniawan et al., 2018).

The geophysical survey utilized DC Resistivity, Magnetotelluric (MT), and Gravity methods, leading to the drilling of the first well (CSL-01) to a depth of 1477 meters. However, the CSL-01 well was used solely for publication purposes. DC Resistivity surveys, both 1-D and 2-D, were carried out in 1976 and 1982 by West Japan Engineering Consultants and Pertamina, encompassing 150 measurement points, with only 69 of these points deemed suitable for analysis due to data quality issues (Alhamid, 1982; Hochstein, 1988). These studies revealed a low resistivity anomaly (<10 ohm.m) in the Cisukarame area, open to the south, indicating it as the center of the

geothermal system and an upflow zone, whereas the Cisolok area is identified as an outflow zone. Kurniawan et al. (2018) concluded that MT results indicate a low resistivity anomaly zone beneath the Cisolok-Cisukarame area, forming a northeast-southwest pattern in the eastern part, associated with the clay cap zone and potential heat sources in the northeast.

Research by Lase & Soebakir (2022) identified a controlling structure through the low residual anomaly, evidenced by hot spring and spouting spring manifestations oriented NE-SW, N-S, and NW-SE. From the research of Lase et al., (2024) applying the gravity inversion model in the Cisolok-Cisukarame geothermal system, West Java, Indonesia. where there are 2 different heatsources where Cisukarame originates from the magmatic Halimun mountain and Cisolok is a cooling pluton that has a deeper depth than Cisukarame. Structures in the form of faults are identified and have directions that match the regional tectonic faults.

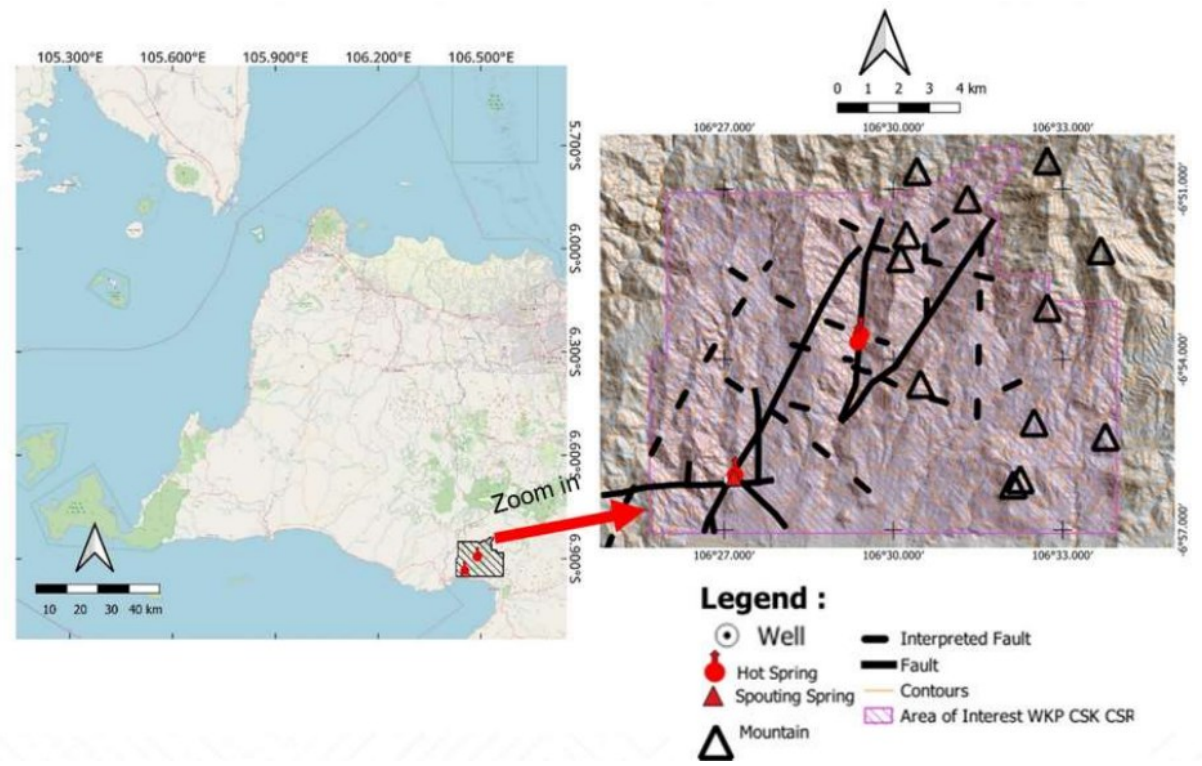

Figure 2: Location of the study area Cisolok-Cisukarame Geothermal Field in West Java, Indonesia. (modified Lase et al., 2024).

4. GEOLOGY SETTING

The Csk - Csr geothermal field is located to the southeast of Baya Mountain and consists of a large dome, Baya Dome, and several Upper Pleistocene mountains. This area is dominated by volcanic eruptions. Quaternary period with relatively steep topography ranging from 150 to 900 m above sea level. (Abdilla et al., 2017). In general, the lithology of the Csk - Csr region consists of three main types of rocks: sedimentary rocks (early sedimentary rocks); Miocene-Pliocene), acidic intrusive rocks (Miocene), and andesites (Pleistocene). Pleistocene andesite is the youngest volcanic product in the region.

Based on Figure 3, the Cikotok Formation, which consists of 12 rock units, is the oldest formation consisting of volcanic breccia, tuff, and lava. The Citarete Formation is composed of limestone and tuff, whereas the Cimapag Formation is dominated by breccia and conglomerate (Sujatmiko, 1992). Dacite occurs in the south, and in the west, granite is covered by lava and pyroclastic flow deposits (Sujatmiko, 1992). The Citorek Formation is composed of marine sediments and volcanic products deposited in the Cikotok, Citarete, and Cimapag Formations. Quaternary volcanic products are andesite and basalt, products of Mount Harimun (Sujatmiko, 1992). The alluvium is the youngest product in the region and is distributed around Cimaja and Pelabuhan Ratu in the south (KESDM, 2017).

In regional geology, the structural patterns that develop in the western part of Java Island are the Meratus pattern, the Java pattern, and the Sunda pattern. The southern part of the Leuwidamar geological map has a complex geological structure, which is caused by tectonic disturbances, resulting from the meeting between the geanthropic Java and the geanthropic Bukit Barisan in Sumatra. This area has a fault pattern with a general North-South

direction and there is also a northeast-southwest direction. There is a fold axis with a West-East to Northwest-Southeast direction. This geological structure is interpreted as a migration path for the emergence of geothermal discharges such as hot springs, spouting springs and the others in the Csk - Csr geothermal field.

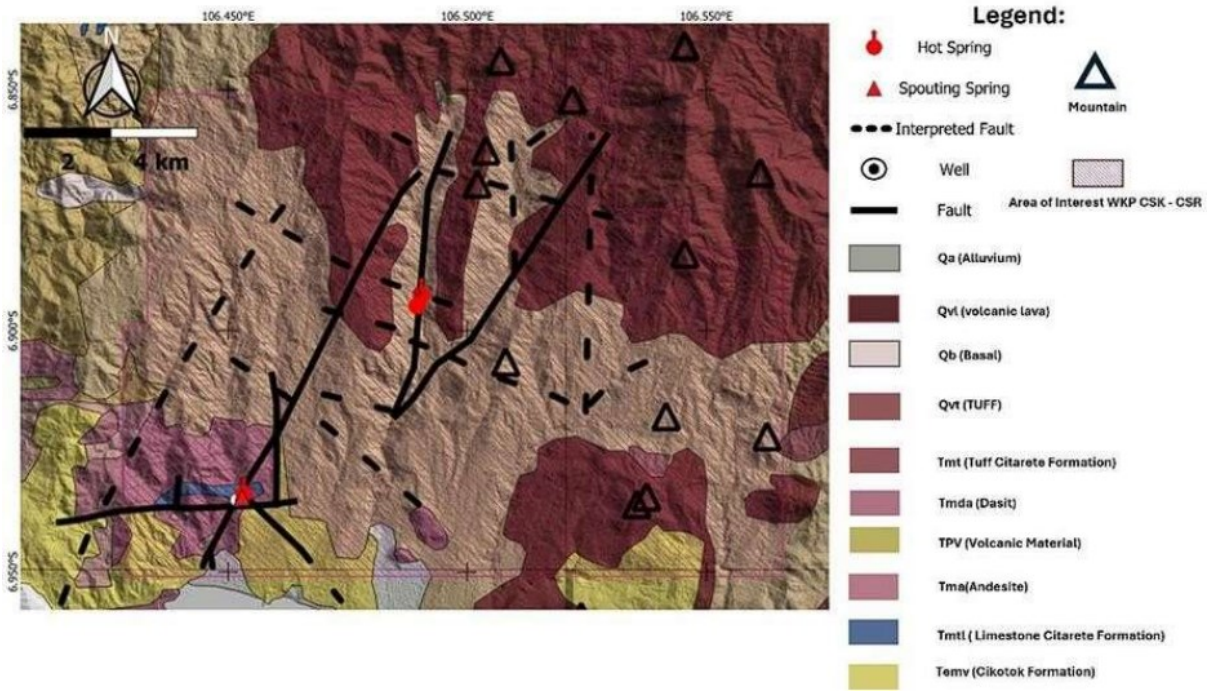

Figure 3: Regional Geology Cisolok-Cisukarame Geothermal (modified from Suryantini and Hendrasto F, 2009; Lase et al., 2023).

5. APPLICATION

5.1 Cisolok-Cisukarame Gravity Survey

The gravity acquisition in the Cisolok-Cisukarame geothermal field had 75 measurement points, with a spacing of 1 km between data points, covering an area of 100 km², and was conducted by PVMBG in 2011. Lase and Soebakir (2023) presented the GGMPLUS satellite gravity data of Cisolok-Cisukarame using minimum curvature to display CBA maps. Lase et al. (2024) presented gravity data acquisition in the Cisolok-Cisukarame geothermal field using minimum curvature to display CBA maps. In this study, we attempt to present all the data using the Python programming language, following the flowchart (Figure 1). Figure 4 shows the elevation points from the measured gravity points, where the darker purple color indicates lower elevations, and the brighter yellow color indicates higher elevations. Figure 5 shows the gravity data points, where the purple color indicates lower CBA values, and the redder color indicates higher CBA values.

5.2 Application in interpolating: Cubic, Linear and Nearest Neighbor Cisolok-Cisukarame Geothermal Field

Complete Bouguer Anomaly Maps were created using three different interpolation applications. Figure 6 shows the results of Linear interpolation, Figure 7 uses Cubic interpolation, and finally, Figure 8 shows the results of interpolation using Nearest Neighbor.

6. RESULT AND DISCUSSION

Linear interpolation (Fig. 6) offers simplicity, computational efficiency, and ease of implementation and understanding, making it well-suited for data that varies linearly. However, its drawback is its inability to accurately capture non-linear variations, resulting in piecewise linear estimates that may not represent the underlying data accurately. On the other hand, cubic interpolation (Fig. 7) provides smoother estimates and can capture more complex data variations, delivering higher accuracy, especially for data with non-linear patterns. Nevertheless, it is more computationally intensive and requires more memory and processing power, particularly for large datasets. Meanwhile, nearest neighbor (Fig 8.) interpolation excels in simplicity, computational efficiency, and preserving the original data points, making it suitable for discrete datasets or those with irregularly spaced points. However, it may not provide smooth estimates for continuously varying data and often results in a staircase-like appearance in the interpolated data.

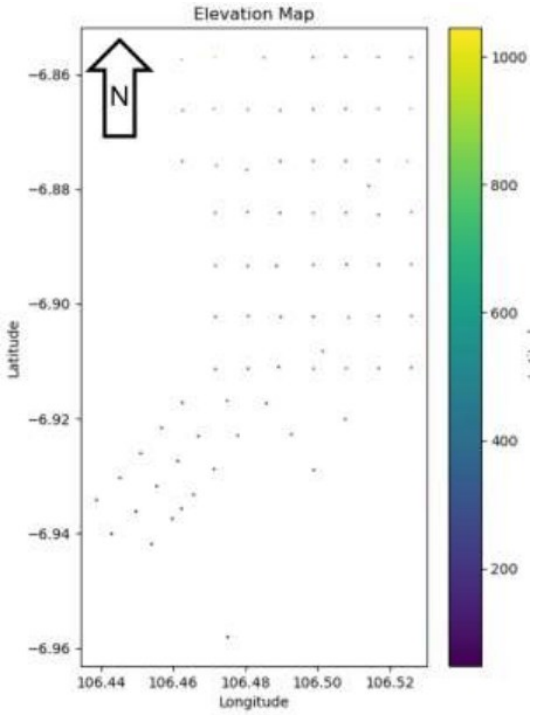

Figure 4: Elevation map from gravity station using python at cisolok-cisukarame geothermal field.

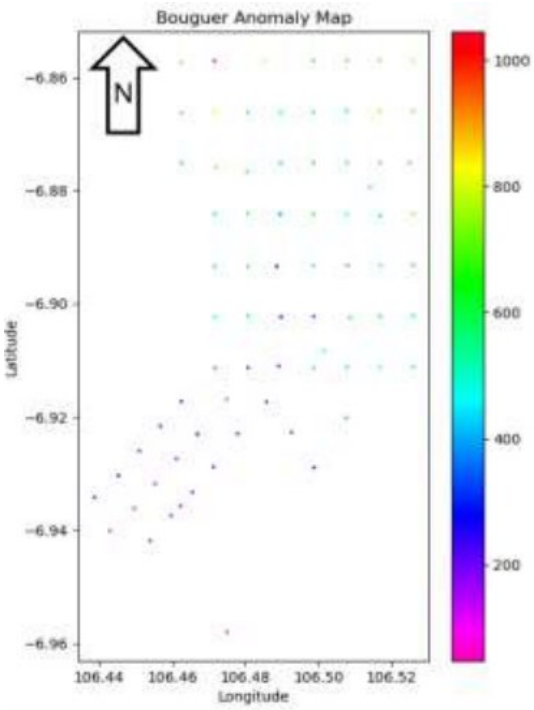

Figure 5: Complete Bouguer Anomaly map from gravity station using python at cisolok-cisukarame geothermal field.

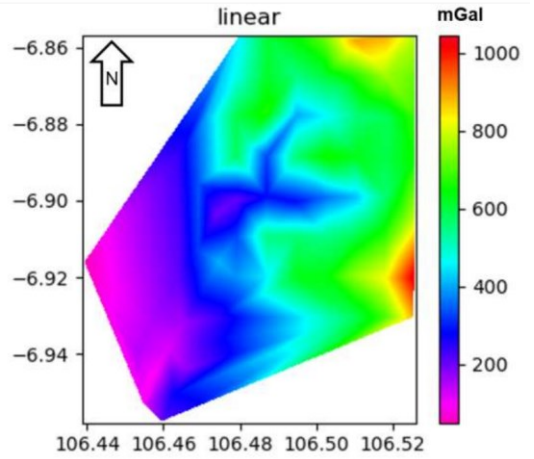

Figure 6: Elevation map from gravity station using python at cisolok-cisukarame geothermal field.

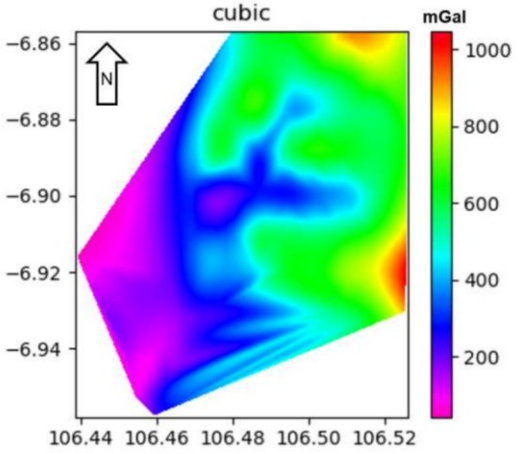

Figure 7: Complete Bouguer Anomaly map from gravity station using python at cisolok-cisukarame geothermal field.

7. CONCLUSION

We have presented a comparison of interpolation methods to test and generate interpolation performance using Python programming. The research demonstrates that there are advantages and disadvantages to each interpolation method, whether in terms of complex computations, linear or non-linear data, comprehensible learning, or using programming languages without software. Cubic interpolation yields interesting and good estimates, and it significantly has good accuracy despite the intensive and numerous computations involved. In summary, the cubic interpolation method performs better compared to Linear and Nearest-Neighbor methods.

ABSTRACT

Geothermal comes from the words Geo which means earth and Thermal which means heat, so it can be define as an energy source that comes from natural heat in the earth. Indonesia has high geothermal potential. Indonesia stores 40% of the world's geothermal reserves. Based on the Geological Agency of the Ministry of Energy and Mineral Resources (December 2020), Indonesia has total geothermal energy potential estimated to reach 23.7 GW. The research located on Jari, Samongrejo, and Sengaten village at Gondang District, Bojonegoro Regency, East Java. This area became a research location because there were indications of the potential for geothermal resources originating from Mount Pandan. Mount Pandan is a volcano in Bojonegoro Regency, East Java with geothermal manifestations in the form of mud pools and hot springs. The emergence of this manifestation can be used as data to measure the potential and existing geothermal systems. Besides that, It was discovered some alteration minerals in this area, such as travertine and pyrite. The research method used in this research was geological mapping, petrographic analysis of thin section, XRD analysis and fluid analysis. Based on the results of the geological mapping, it was found that there are several types of lithology, including mudstone interbedded with sandstone which has a gray color and this rock has carbonate cement. Then it was also found that there was andesite breccia lithology which had a brownish color, matrix supported and travertine minerals were found at some location, and also there was porphyry andesite lithology which had a grayish color dominated by plagioclase minerals and several other minerals such as quartz and biotite. Based on the results of petrographic observations, it is known that the presence of altered minerals is still very minimal, so it can be interpreted that our research area is an area with low-medium alteration intensity. Then, from the XRD results of rock samples that taken near the mud pool, it is dominated by the minerals smectite, and illite, so it can be interpreted that this location is located in the argillic zone. From the three fluid samples, located in the Keramat, Selogajah and Jari areas, it can be seen that this area has chloride fluid and it can be interpreted that this sample is included in the Mature Waters category. Based on the results found in the field, it can be interpreted that this research area is included in the upflow zone, as evidenced by the presence of chloride fluid, several travertine deposits, and clay minerals in the form of illite and smectite.

1. INTRODUCTION

Indonesia is one of the countries that has great potential for geothermal energy, because tectonically Indonesia is located at the three large plates which form a subduction zone and produce magmatism activity in the form of a row of active volcanoes (Ring of fire). The Ministry of Energy and Mineral Resources (ESDM) has estimated the total size of Indonesia's geothermal resources at 27,000 MW. However, only about 800 MW has been developed in seven locations with five of them located in Java (Setijadji, 2010).

Mount Pandan is one of the products of early Pleistocene-aged Quaternary magmatism located in the Wilis-Lasem arc segment in Bojonegoro Regency, East Java Province (Lunt et al., 1998; Smyth et al., 2005). The mountain was formed in the anticlinorium of the Kendeng Zone and is near back-arc volcanism. Mount Pandan is a quaternary mountain composed of andesite breccia and intrusions. This area has the potential for geothermal energy as indicated by several Geothermal manifestations that appear on the northern slope of Mount Pandan such as hot spring pools, mud pools and alteration rocks.

The potential for geothermal energy in Mount Pandan is associated with the volcanic environment. This research was conducted in the Gondang area, Bojonegoro Regency. The research was conducted using primary data with a geological approach such as geological mapping, petrological and mineralogical analysis of the constituent rocks of the study area, XRD analysis of altered rocks, spatial analysis, especially structures that are expected to control the appearance of manifestations on the surface. In addition, this research also using secondary data in the form of water geochemical data from the manifestation of hot springs which will later be used to determine the reservoir fluid temperature of the Mount Pandan geothermal system.

This research aims to collect detailed surface data such as the rock stratigraphy of the study area, alteration zones, and also the presence of manifestations which will later be used for zoning the geothermal system area of Mount Pandan. In addition, it is also to update existing alteration map in the research area.

2. REGIONAL GEOLOGY

The research site is located in Jari, Samongrejo, and Sengaten villages in Gondang District, Bojonegoro Regency, East Java. This area became the research location because of indications of the potential for geothermal resources originating from Mount Pandang. Bojonegoro itself is located in the Kendeng Zone or called the Kendeng Mountains, an anticlinorium with a west-east direction. The Kendeng Zone is a continuation of the North Serayu Mountains Zone that developed in Central Java. In the north, it is bordered by the Randublatung Depression, and the south is bordered by part of the mountain range (Solo Zone). The kendeng zone is composed of several formations, including:

- Kerek Formation, which is characterized by a mixture of clay, clayey marl, marl, silty tuffaceous sandstone, and tuffaceous sandstone. Also found is a typical graded bedding sedimentary structure that characterizes flysch.
- Kalibeng Formation, a formation that lies harmoniously above the Kerek Formation, is divided into two formation members namely Lower Kalibeng Formation and Upper Kalibeng Formation.
- Pucangan Formation, which develops as volcanic facies and black clay facies.
- Kabuh Formation, composed of sandstone lithology with non-volcanic materials such as Quartz, cross-bedded structure with conglomerate and tuff inserts, containing Mollusc fossils
- Notopuro Formation, composed of lava breccia lithology interspersed with tuffaceous sandstone and volcanic conglomerate.
- Undah Bengawan Solo Formation, consisting of polymict conglomerate with fragments of limestone, marl, and andesite, along with sandstones containing vertebrate fossils.

3. METHODS

This research was prepared using several types of methods, including field data collection in the form of water samples, as well as rock samples. Then further analysis is carried out on the existing data so that the results are obtained from several stages of analysis, including:

- Geochemical analysis, an analysis of the chemical composition of water to identify and determine the concentration of elements and chemical compounds contained in water, which is carried out by taking water samples in the field which are then tested in the laboratory.
- Petrographic analysis, an analysis that requires a thin section the sample rock that has been taken in the research area, this analysis requires the help of a polarizing microscope to observe the incision of a rock which is useful for knowing the minerals that make up the rock as well as the structure and texture of the rock and helps in knowing the geological history and formation.
- XRD analysis, an analytical method carried out by taking rock samples in the field then these samples are observed with an X-ray machine so that the results can be used to identify and determine the crystal structure of an alteration rock.

4. RESULTS

4.1 Surface Manifestation

4.1.1 Hot Springs

This manifestation is located in Jari Village, Bojonegoro. Where the water samples at this location have a clear color with the appearance of iron colour around the manifestation (Figure 1). Based on Ramadhani, 2018 water samples in this manifestation had a temperature of around 43^{o}C.

4.1.2 Mud Pools

This manifestation is located in Jari Village, Bojonegoro. Where the mud samples at this location have a grey color with strong scent of suplhur (Figure 2). Based on Ramadhani, 2018 water samples in this manifestation had a temperature of around 48^{o}C.

4.2 Petrology & Petrography

4.2.1 Porphyry Andesite

This rock has brownish-gray color, holocrystalline texture, where the condition of the entire rock composition consists of crystals. These rocks are usually formed where magma cools slowly. Based on the grain size, it is classified as medium to coarse. The relationship between the grains can be classified as euhedral, where the

crystals grow with a perfect shape, where the crystal boundaries correspond to the original crystal plane, growing with an ideal shape. The grain shape is classified as prismatic and granular. Prismatic is usually found in rocks that experience slow cooling, and granular where minerals have the same size. A special texture in these rocks is porphyritic (inequigranular), where minerals have grain sizes that are not the same as the texture of the rock where large crystals (phenocrysts) are embedded in a finer base.

Figure 2 : Mudpools manifestation & alteration minerals at Jari village.

If based on the petrology, there are several minerals identified. The first mineral identified is plagioclase, where plagioclase usually has a white color, with bright white, light luster, perfect cleavage, with a hardness of 6 - 6.5 Mohs. Hornblende was also found which has a greenish-black color, white spout, glassy luster, with a translucent tendency.

The mineral content found in this sample is quite diverse. By interpreting it using three different viewpoints (Figure 3) known from cutting the rock into thin sections, the following was obtained. On the phenocrysts, if based on the three identified viewpoints, this sample is composed of 37% plagioclase, with a colorless-gray-white appearance, euhedral, partly having a zoning texture. Hornblende was found at 13% with yellow-brown appearance, high relief, euhedral. In phenocrysts, sanidine is present with a percent found only in the third field of view, characterized by colorless-gray-white, euhedral. The rock mass is composed of plagioclase, hornblende, quartz and another unidentified minerals/glass.

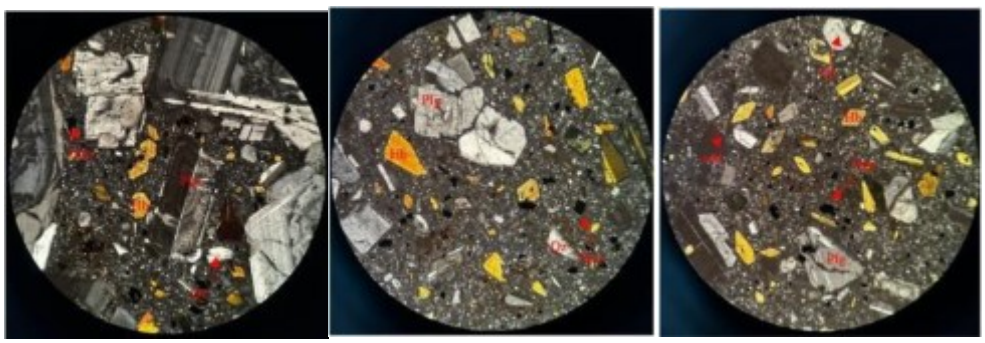

Figure 3: Petrography analysis for Porphyry Andesite (Plg : Plagioclase, Hb : Hornblend, Qz : Quartz, Opq : Opaq. Minerals, Md : Rock Mass)

From the three viewpoints and the interpretation carried out, it is known that the rock is an Porphyry Andesite (Russel B Travis, 1955). This rock has a porphyritic texture containing phenocrysts that are fused with the base mass, namely the matrix. The magma that forms porphyry andesite is an intermediate magma type. Apart from that, things that can explain that the rock is porphyry andesite, where the composition is a lot of plagioclase, pyroxene, and hornblende.

This porphyry andesite itself is interpreted to be formed from magma containing moderate amounts of silica. These magmas usually originate from subduction processes, where oceanic plates press down on continental plates, causing rock melting. When the magma reaches the Earth's surface or shallower depths, it undergoes rapid

cooling. This cooling causes crystallization of minerals present in the magma, such as plagioclase, quartz, and other minerals.

4.2.2 Volcanic Breccia

This rock has a greenish-gray color with fresh conditions. It has a grain size of gravel to sand. The mineral composition includes pyroxene, plagioclase, and hornblende with igneous rock fragments. In terms of physical properties of minerals, breccias have coarse grains, where grain size is usually > 2mm. The rock color tends to be dark blackish.

The mineral identification is known from several identification results. Pyroxene itself, has a color that tends to be dark green to black, which has a white spout, glass gloss, hardness of 5 - 6.5 Mohs, paramagnetic magnetism, with brittle properties. Plagioclase has a white color, with a glass gloss, hardness of 6 - 6.5 Mohs, with a prismatic structure, with a translucent classification. For the latter, it is hornblende with the appearance of black color, glass gloss, hardness 5 - 6 Mohs, two-way cleavage, classified as non-magnetic.

Petrographically, using three different viewpoints, the following minerals was obtained. There are porphyry andesite fragments which has some mineral such as plagioclase, hornblend and quartz. Besides that there are some minerals, such as pyroxene is subhedral in shape, the colors tends to be greenish brown. It has high relief with almost 90° cleavage and biaxial optical properties. Then there are plagioclase that has a sheet shape, with colors tending to be gray-white. Its relief is low, with a less pronounced texture when compared to other minerals. The cleavage is not clear. Hornblende has an euhedral or subhedral shape with colors that tend to be brownish green. The relief is high which means the mineral has a clearer texture and is easier to recognize.

This volcanic breccia is formed from volcanic eruptions that produce pyroclastic material and lava, which are also assisted by flow mechanisms, which then undergo a reworked process and are deposited in a marine environment.

4.2.3 Carbonate Claystone

This rock has clay grain size. It also has rounded grain shape, which causes the incision to be classified as a closed pack. The grain contact of this rock is classified as matrix Supported, where the majority of sedimentary rocks are fine-grained matrix, not clasts (in the case of conglomerates) or allochtonous (in the case of limestone). Rock porosity is classified as primary interparticle porosity, where interparticle porosity is a pore that exists between grains in the rock. Interparticle porosity is a type of porosity found in sedimentary or igneous rocks, where the spaces between larger grains are filled by smaller particles. This porosity is formed during the process of rock deposition and formation, and can affect the physical and chemical properties of the rock.

From petrography analysis (Figure 4), this rock is composed mostly of matrix at 80.6%, which is composed of microcrystalline calcite and a little quartz. The dominant matrix content has a rounded texture, good sorting and closed packing. Grains amounted to 14.3%, consisting of foraminifer fossils, one of which is Nodosaria sp. which is a benthonic foraminifera, is a type of foraminifera that lives on the seabed, which is contained between the rock matrix, and cement by 5% in the form of carbonate cement resulting from the dissolution of carbonate minerals such as calcite.

Using Embry Klovan's (1971) classification, the rock is a mudstone, which was formed through the process of weathering and erosion of other rocks. The foraminifera microfossils contained in the rock were deposited along with clay particles. These clay particles and microfossils were carried by water and deposited on the seabed then experienced deposition and formed a clay layer. This claystone underwent compaction, mineral replacement.

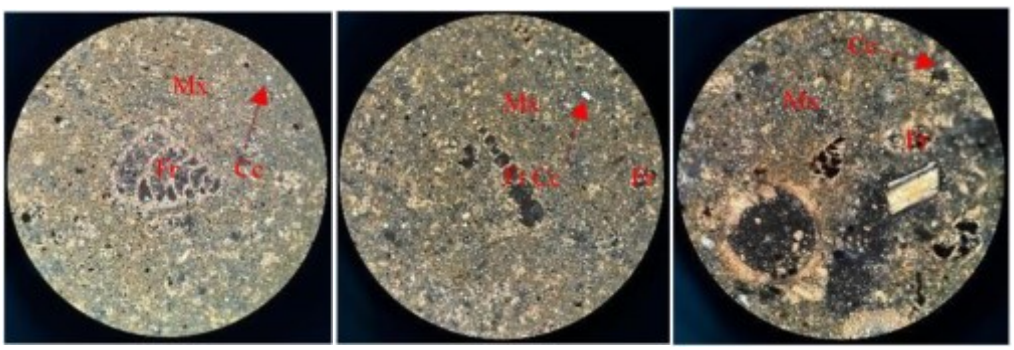

Figure 4: Petrography analysis for Carbonate Claystone (Fr : Foramnifira, Cc : Calcite, Mx : Matrix, Md : Rock Mass).

4.3 Fluid Geochemistry & Alteration

To be able to know the composition of geothermal fluids, the anion components in the form of Cl, SO4, and HCO3 are needed, which in these three anion components can help to interpret the conditions and processes that occur in the geothermal fluid source area.

In this study, there is 4 samples that we used from Hanindya's research, 2018. These included the Jari, Banyukuning, Sokogajah, and Keramat samples (Figure 1). The high Cl content of spring water can indicate that the hot water comes from a direct reservoir (minimal mixing or cooling by conduction), but water with low Cl content or that does not indicate the presence of hot spring steam is characteristic of groundwater dilution (Concentration ± <10 - >100,000mg/kg). The results obtained based on the existing fluid samples have been input into the diagram below (Figure 5):

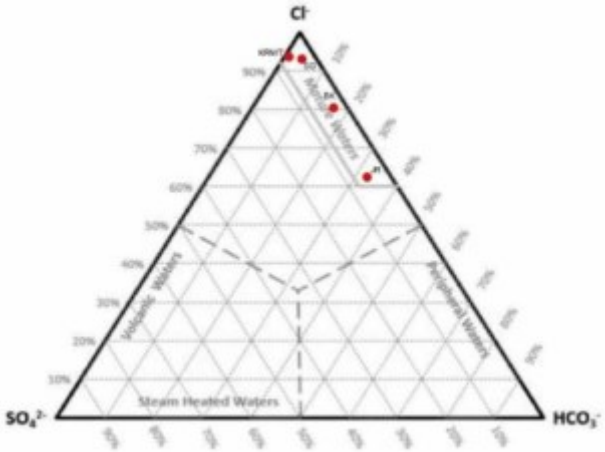

Figure 5: The results of the fluid type plot on the Cl-SO4-HCO3 diagram.

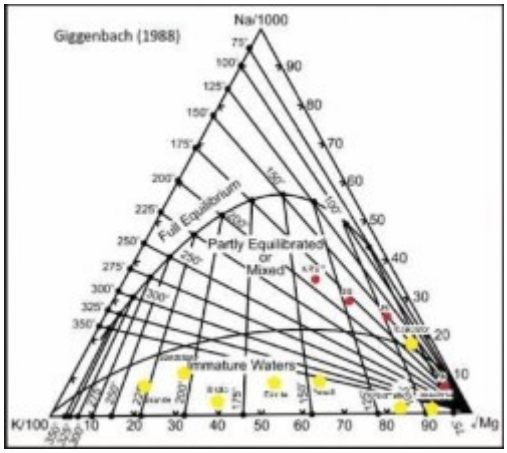

Figure 6: Geothermometer Na-K-Mg diagram.

Based on the results of data processing, it can be seen that the type of geothermal fluid in this research area is Mature Water.

In this geothermometer calculation method based on the Na/1000-K/1000- Mg diagram (Figure 6) due to the high Ca content with knowledge or theory that is classified as empirical and carried out with several literature studies. It is interpreted that the equilibrium between Na and K-Feldspar and the conversion of calcium alumino silicate minerals can become calcite. As well as the results of geothermometer calculations as follows (Table 1).

Table 1: Geothermometer Calculation Results.

Location Sample	Geothermometer Na/K/Mg (Giggenbach, 1988)
Jari	153
Banyukuning	222
Sokogajah	176
Keramat (Mud)	187

Calculations from this geothermometer have been adjusted based on the ion balance of the anions and cations, so that the data can be used is Jari's geochemical data that has a reservoir heat of 153°C (ion balance <5%).

Some alteration minerals that can be found in fields are : pyrite, travertine and clay minerals. From XRD analysis, clay minerals that can be identified is smectite. We can interpreted this area as an outflow zone, because the mineral association that can be found and also the fluid geochemistry analysis.

5. CONCLUSION

Mount Pandan has some manifestasion, such as : hot springs & mud pools. Some lithologies that can be found in this area are porphyry andesite, volcanic breccia, and carbonate claystone. From andesite & volcanic breccia thin section, there are some minerals that can be found such as : plagioclase, pyroxene, hornblend and rock mass. And from carbonate claystone thin section, there are some materials that can be found such as : foraminifera fossils, calcite and mud matrix. From water geochemical analysis at surrounding areas, it can be classified as mature water with interpretation of reservoir heat is 153°C based on geothermometer Na-K-Mg. Some altered mineral that can be found are : smectite, pyrite and travertine. So it can be interpreted this area as an outflow zone, because the mineral association that can be found and also the fluid geochemistry analysis

Keywords: Patuha, Resource Area, Drilling Campaign, Red bed

ABSTRACT

PT. Geo Dipa Energy successfully completed a drilling campaign (2021-2023) to expand the Patuha geothermal field in West Java, Indonesia. This project aimed to utilize the area's geothermal potential for a new 55 MW power plant (Patuha Unit-2). Despite challenges like complex fractures and unstable formations, the drilling reached northwest towards the Patuha Mountains, significantly expanding the proven geothermal area.

This expansion was confirmed by a separate study that analyzed geological and drilling data. The study revealed a significant increase in the usable geothermal zone, extending both north and west from previous estimates. This finding highlights the importance of a comprehensive data approach in exploring geothermal potential. By incorporating diverse datasets – including recent drilling data, geological data (lithology and structural geology), and reservoir data (pressure and temperature measurements) – we were able to create a more holistic understanding of the geothermal field. This approach not only confirmed the expansion of the resource area, but also provided valuable insights into the geothermal system itself.

The successful drilling campaign and the confirmation of an expanded resource area pave the way for further development of the Patuha field. In the next phase, understanding the behavior of the unstable formations encountered during drilling will be studied more deeply. This knowledge will be instrumental in developing more effective drilling practices, ensuring the continued success of future geothermal projects in Patuha. Additionally, these insights can be transferable, informing advancements in geothermal drilling technologies that can be applied in other geothermal fields around the world.

1. INTRODUCTION

Located in the volcanic heartland of West Java, Indonesia, lies the Patuha geothermal area. This site harnesses the Earth's internal heat to generate clean and renewable energy. Located roughly 50 kilometers southwest of Bandung, Patuha's geothermal potential stems from its unique geological setting. The area sits within a chain of volcanic mountains, including North and South Patuha, where hot molten rock heats underground water. This interaction creates steam and hot water reservoirs, a valuable resource for geothermal energy production. Surface features like fumaroles and hot springs offer a glimpse into the geothermal activity below.

Patuha plays a significant role in Indonesia's renewable energy goals. Geothermal plants convert geothermal steam into electricity, providing a clean and reliable alternative to fossil fuels. This contributes to reducing greenhouse gas emissions and fostering a sustainable future. The Patuha geothermal system is a captivating subject for scientific study. Understanding its geological structure, fluid flow patterns, and overall energy potential is crucial for optimizing its development and ensuring its long-term sustainability.

Managed by PT Geo Dipa Energi, Patuha harnesses a vapor-dominated geothermal system and has been a reliable source of clean energy since 2014, with a current capacity of 55 MW (Unit-1). In response to growing regional energy demands, PT Geo Dipa Energi commenced a project in 2021 to expand Patuha's capacity. The expansion project, designated Unit-2, involves drilling new wells to achieve a targeted increase in steam output of 55 MW.

2. SURFACE ANALYSIS RESULT

To enhance the interpretation of geological features and optimize resource development for Patuha Unit-2, a comprehensive suite of surveys and studies were undertaken:

- LiDAR Survey (2020, with MI): This high-resolution topographic survey provided detailed digital elevation data, crucial for infrastructure planning and well-site selection.
- Structure and Stratigraphy Study (2020, UGM): Geologists from Universitas Gadjah Mada conducted this study to refine the understanding of the subsurface geological structure and stratigraphy within the

Patuha field. This information is critical for identifying potential geothermal reservoirs and predicting fluid flow patterns.

- Microseismic (MeQ) Monitoring (November 2019 - October 2020, ITB): The Institut Teknologi Bandung deployed a microseismic monitoring system to detect and locate micro-earthquakes associated with geothermal activity. This data provides valuable insights into subsurface fluid movement and reservoir dynamics.
- Magnetotelluric (MT) and Gravity Survey (2020, Elnusa): Elnusa conducted geophysical surveys utilizing MT and gravity techniques. These surveys provide information about subsurface electrical conductivity and density variations, aiding in delineating the extent and characteristics of the geothermal reservoir.
- Well Surveillance (2019-2020): Continuous monitoring of existing wells during drilling and production operations allows for real-time data collection and analysis of wellbore pressure, temperature, and fluid flow. This data is vital for reservoir management and well optimization.
- Structural Model and Permeability Evaluation (during drilling): Geologists and engineers conducted ongoing evaluations of the subsurface structure and permeability characteristics encountered during drilling operations. This real-time analysis allows for informed decisions about well trajectory adjustments and optimization of geothermal resource extraction.

By integrating data from these diverse surveys and studies, a comprehensive understanding of the Patuha geothermal field was established. This information serves as a crucial foundation for the successful development of Patuha Unit-2 and the sustainable utilization of its geothermal potential.

2.1 Regional Tectonic Setting

The Patuha geothermal field, situated on the Indonesian island of Java, lies at the heart of a dynamic tectonic zone. This region is significantly influenced by subduction, a geological process where one tectonic plate dives beneath another. In the case of Patuha, the oceanic crust of the Indo-Australian Plate is subducting underneath the continental crust of the Eurasian Plate. This subduction occurs at a remarkable pace of 6-7 centimeters per year, with a N20°E subduction angle (Tregoning et al., 1994). This ongoing process plays a crucial role in shaping the regional stress patterns and geological structures that define the Patuha geothermal field.

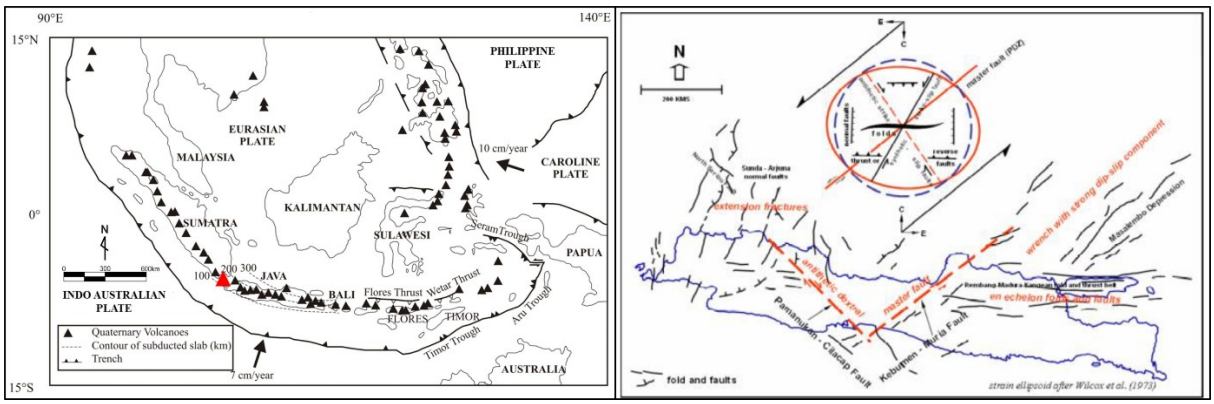

Figure 1: Java regional tectonic framework.

The island of Java, particularly its western region, is a fascinating tapestry woven by powerful tectonic forces. Three major structural trends dominate the region's geological makeup:

- N-S Trending Sunda Trend: This prominent trend reflects the influence of a large tectonic element called the Sunda Plate.
- NE-SW Trending Meratus Trend: This trend originates from another tectonic plate, the Meratus Microplate, interacting with the region.
- E-W Trending Java Trend: This trend reflects the overall east-west directionality of the vast Eurasian Plate.

Focusing specifically on West Java, Satyana (2007) have identified NE-SW, NW-SE, and E-W as the dominant structural trends (Figure 1). These trends are believed to be a consequence of a series of events related to the ongoing subduction process occurring beneath the region.

Subduction, a process where one tectonic plate dives beneath another, plays a significant role in shaping the geological landscape. Understanding the regional stress field, major plate boundaries, and faults (as depicted in Figure 1, modified from Hall and Morley, 2004 in Stingay et al., 2010) is crucial for deciphering the complex interplay of forces that have shaped West Java's unique tectonic setting.

2.2 Structural Geology Framework Update

An integrated evaluation of various data sources has shed light on the structural framework governing the Patuha geothermal field. This study incorporated field measurements, LiDAR lineament data, geophysical data, and drilling data to construct a comprehensive model (Figure 2). The analysis reveals that the Patuha field is dominated by three key structural trends:

- NE-SW Trend: This prominent trend appears to be the principal controlling factor within the field.
- N-S Trend: A secondary trend also plays a significant role in shaping the structural framework.
- Circular Patterns (Northern Gunung Patuha): Notably, the northern region of Gunung Patuha exhibits a distinct pattern of circular structures.

This structural model bears a strong resemblance to strike-slip systems as described by Woodcock and Fisher (1986). The main controlling influence appears to be a major NE-SW trending fault, with a network of en-echelon faults trending roughly NNE-SSW acting as secondary structures (Reski et al., 2023).

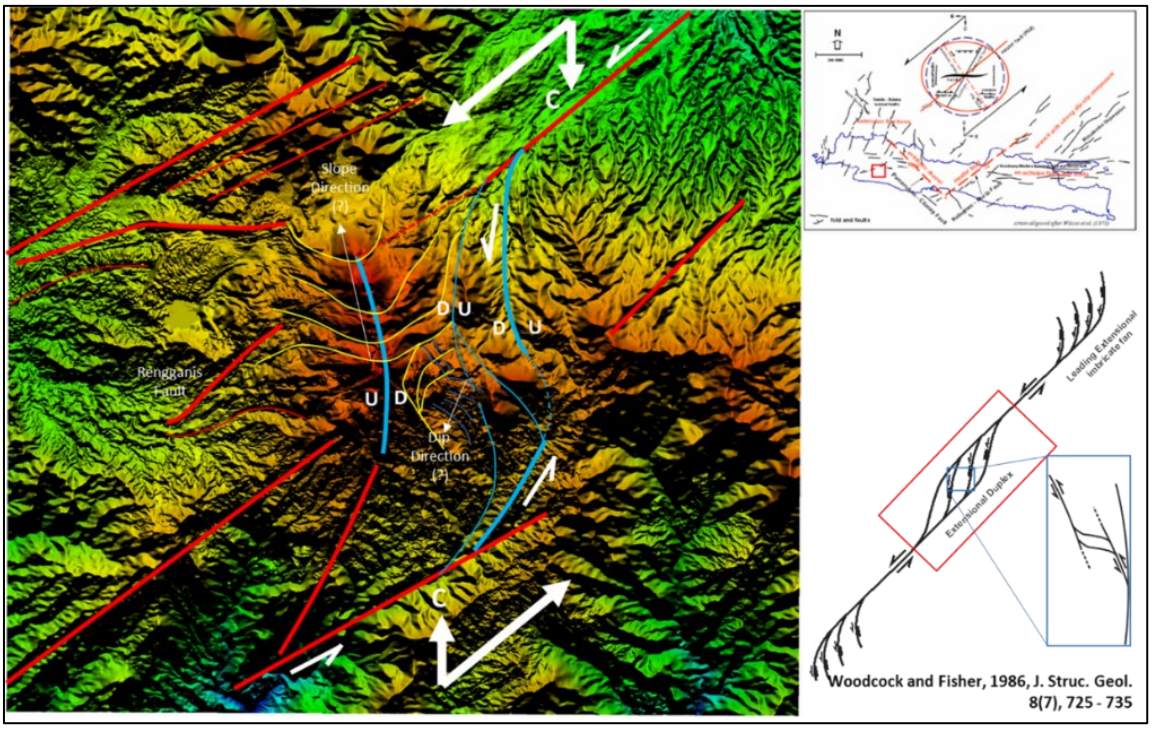

Figure 2: Patuha structural geology framework after Reski, et.al. (2023).

High-resolution image logs from wells 4X, 2Z, and 7Z, combined with permeability indicators observed during drilling and production testing, provide strong evidence for the presence of a mature fault zone within the Patuha geothermal field.

The analysis of these data sets reveals a fascinating interplay of geological features:

- Scattered Fault Network: The identified faults exhibit a scattered distribution, suggesting a complex fracture system within a relatively confined area.
- Strike-Slip and Compartmental Faults: The presence of both strike-slip and compartmental faults points towards a multi-directional stress regime that has shaped the subsurface structure.

These findings, obtained through an integrated analysis of borehole image logs and well testing results, support the established structural model for the Patuha field (Figure 3). This model depicts the field as a sinistral strike-slip system dominated by a major NE-SW trending fault. Secondary en-echelon faults trending NNE-SSW define an extensional duplex – a structural feature favorable for geothermal reservoir development.

Intriguingly, the observed presence of circular fracture patterns within this zone might not be directly related to the regional tectonic forces. As suggested by Reski et al. (2023), these patterns could be attributed to localized deformation or non-tectonic events. Further investigation into these unique features is warranted.

Well monitoring during the Patuha Unit-2 drilling campaign played a crucial role in confirming the presence and characteristics of faults within the geothermal field (Pamungkas, 2024). This monitoring focused on gas breakthroughs, specifically analyzing trends in residual gas and CO2 content.

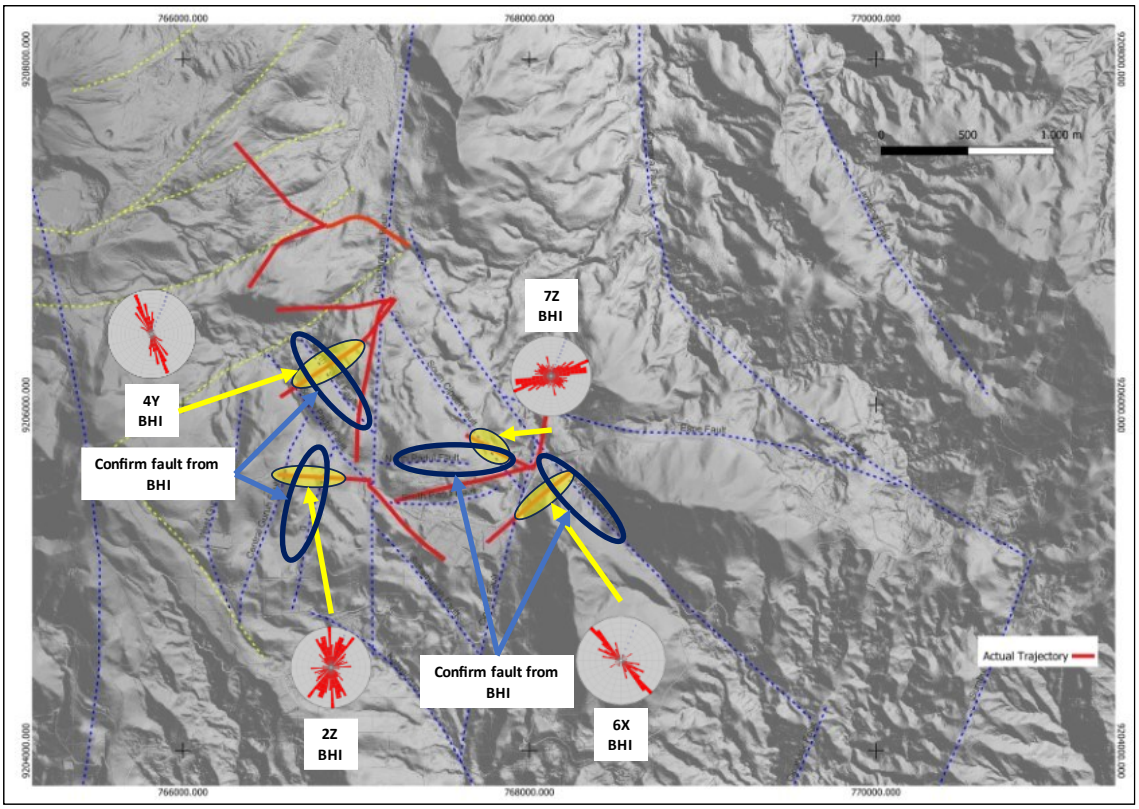

Figure 3: Patuha Bore Hole Image After Reski, et.al., 2024.

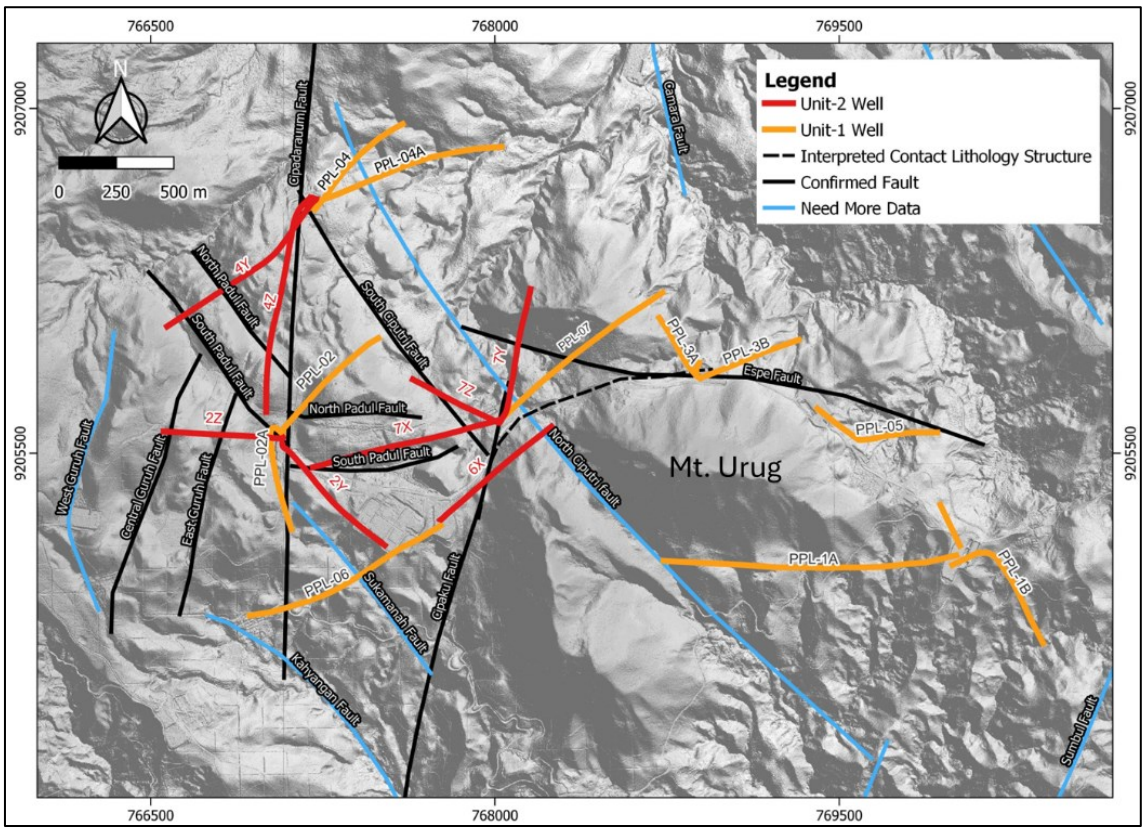

Figure 4: Map of confirmed fault by well monitoring during Patuha Unit-2 drilling campaign after Pamungkas, et.al. (2023).

When a well intersects a productive zone and utilizes an aerated drilling method, an increase in residual gas and a decrease in CO2 content are typically observed. The Patuha Unit-2 drilling campaign identified anomalies in these gas breakthrough trends, particularly in wells targeting the same fault or intersecting faults. This behavior indicates that faults act as pathways for geothermal fluids and can be used to confirm their existence within the reservoir.

The well monitoring results, along with existing geological knowledge, shed light on the interplay between regional tectonics and the Patuha geothermal field (Figure 4).

- Alignment with Regional Stress Field: The identified fault orientations, primarily NE-SW and N-S, align well with the dominant horizontal maximum compressional stress field of Java, which trends roughly N-S (Koesmono et al., 1996). This suggests a potential link between regional tectonic forces and the development of the strike-slip system governing the Patuha field.
- Local Amplification: The observed NE-SW and N-S trends in the fracture networks could be further amplified by local deformation processes associated with strike-slip faulting (Harding, 1973).

2.3 Geophysical Result

3D magnetotelluric (MT) modeling has been utilized to map the electrical conductivity distribution beneath the Patuha geothermal field. This information plays a vital role in pinpointing the boundaries of the valuable geothermal reservoir.

3D MT model show a detailed map of the geothermal reservoir within the Patuha field. This map relies on two key electrical conductivity boundaries:

- Conductive Layer Base (BOC): This boundary, identified by a significant shift from conductive layers (potentially indicating hot, saline fluids) to resistive layers (potentially drier, less conductive rocks), is interpreted as the interface between the geothermal reservoir and the underlying impermeable rock formations. Estimates suggest the BOC depth in Patuha ranges from 8-10 ohm-meters.
- Outer Reservoir Boundary: This boundary marks the transition from the highly permeable reservoir zone to the less permeable surrounding rocks. It is identified by a shift in the electrical conductivity gradient, moving from a positive value (updoming or thinning) to a flattening or thickening trend.

To account for inherent uncertainties in geophysical data and well information, two key interpretations have been employed:

- P50 Interpretation: This method merges 3D MT model data with existing well data (Top of Reservoir or TOR). It utilizes a conservative approach to define the gradient change, aiming for a balanced representation of the reservoir's extent.
- P90 Interpretation: This method relies solely on the 3D MT model and employs a more optimistic interpretation of the gradient change (focusing on a flattening trend). As a result, it potentially identifies a larger reservoir extent.

By combining these two interpretations, we can account for potential variations in data and present a range of feasible reservoir boundaries within the Patuha field (Figure 5). This information is critical for optimizing well placement and maximizing the utilization of this geothermal resource.

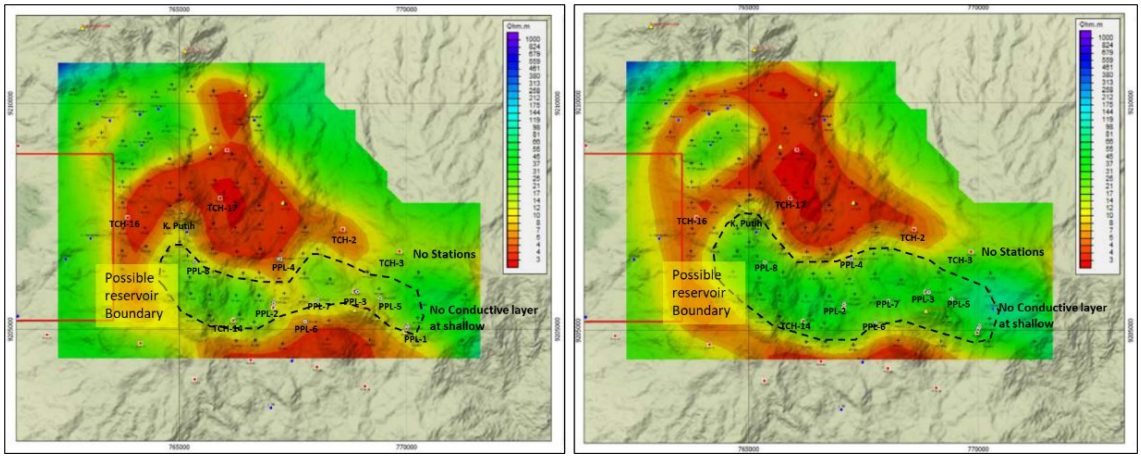

Figure 5: Outer reservoir boundary from resistivity map at 1250 mASL (Left) and 1000 mASL (Right).

2.4 Geochemical Result Update

Several wells drilled as part of the Patuha-2 campaign have been subjected to testing and sampling. Interestingly, the majority of the wells exhibited a dry steam condition with similar geochemical properties to Unit-1 wells, except for wells 4Y and 4Z which produced water condensate after the LECM.

The available gas chemistry data includes components like CO_2, H2S, NH_3, Ar, N_2, CH_4, and H_2. A ternary diagram utilizing CO_2-N_2-Ar can be used to analyze the origin of the geothermal fluids. Here, a lower CO_2/H_2S ratio suggests proximity to the upflow zone, while an increasing ratio indicates more extensive migration (Nicholson, 1993).

Wells 2Y, 7X, 7Y, and 7Z displayed low non-condensable gas (NCG) content (less than 1%wt) and a low CO_2/H_2S ratio (Table 1). This might indicate their location close to the upflow zone. In contrast, wells drilled towards the west encountered higher NCG content (1-3%wt) and a higher CO_2/H_2S ratio. This is interpreted as being caused by condensation processes occurring at shallower depths.

The majority of gas chemistry data points plotted on the CO_2-N_2-Ar diagram (Figure 6) cluster around the air zone. This suggests that the wellbore chemistry might still be significantly influenced by drilling fluids. However, well test results indicate a relatively neutral fluid with no signs of acidity, even in well 9X, which is closest to the Kawah Putih crater. Despite this initial assessment, continuous geochemical sampling during stable production conditions is crucial for ongoing reservoir monitoring.

Table 1: NCG value and the CO_2/H_2S ratio in Patuha Unit-2 wells.

Well Name	NCG (%wt)	CO_2/H_2S
2Y	0.36	19.37
2Z	0.62	31.76
4Y	1.00	56.77
4Z	2.11	49.61

3. DRILLING RESULT

The Patuha Unit-2 drilling campaign, a key milestone in expanding geothermal energy production at the Patuha field, commenced in November 2021 and completed in March 2024 with the successful completion of 12 wells. To efficiently execute this drilling program, a strategic approach utilizing five well pads was implemented. Four of these pads were existing infrastructure within the field, while a new pad was strategically positioned near the Kawah Putih area to target promising geothermal resources in that sector.

3.1 Drilling Performance

The Patuha Unit-2 drilling campaign encountered various obstacles during its execution. These challenges, arising from both equipment limitations and complex geological formations, resulted in extended drilling times compared to the initial program. The initial plan anticipated an average well depth of 1800-2000 meters and a completion time of 45 days per well, unexpected difficulties necessitated adjustments.

Drilling on well pads 4 and 9 proved particularly demanding, requiring sidetracking maneuvers in each well to bypass formation-related problems. The primary obstacle in the Production Zone was red bed formations, which presented significant drilling challenges. Figure 7 shown that the most of Non-Productive Time (NPT) in Patuha area caused by stuck pipe.

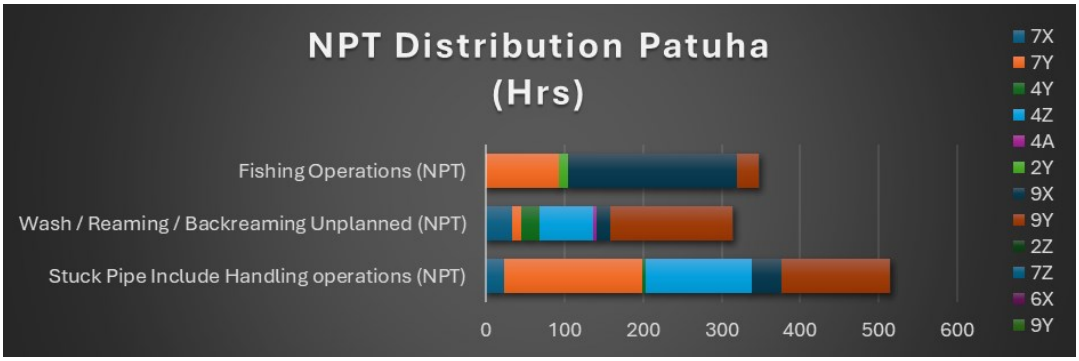

Figure 7: NPT Distribution during Patuha-2 drilling campaign.

The Patuha Unit-2 drilling campaign encountered initial challenges, but the drilling team's adaptability and collaborative approach led to significant performance improvements. Through continuous learning and close collaboration with the subsurface team to refine drilling strategies, they were able to tackle unforeseen challenges.

This resulted in a notable reduction in drilling times for later wells. These wells were completed within a timeframe of 26-30 days, with an average depth ranging from 1600 to 1700 meters. Furthermore, the team successfully eliminated formation-related issues that could have caused stuck pipe incidents. This achievement culminated in drilling a well with zero Non-Productive Time (NPT).

3.2 Permeability Update

Evaluating permeability, the ease with which fluids can flow through rock formations, is critical for optimizing geothermal well productivity. Patuha geothermal field rely on a multifaceted approach that integrates data from various sources:

- Drilling Parameters: During drilling, encountering zones where drilling fluid disappears underground (Loss Zones) or experiencing sudden changes in drilling parameters (Drilling Breaks) can indicate encountering formations with potentially high permeability. These parameters provide valuable clues about subsurface conditions. Total loss zones are particularly significant, as they directly indicate enhanced fluid movement within the rock. Drilling breaks, on the other hand, can be caused by encountering softer formations or changes in rock strength, which can be indirectly linked to increased permeability. By analyzing the depth, duration, and severity of these events, a comprehensive picture of subsurface permeability variations builds.
- Geological Hazard Indicators: The release of gases and the occurrence of kicks (sudden wellbore pressure increased) during drilling can also be associated with permeable formations. These events can occur when the drill bit encounters a zone with high pore pressure or fractures that allow pressurized fluids to flow rapidly into the wellbore. While these events can pose safety challenges during drilling, they also provide valuable information about the presence and characteristics of permeable zones.

An analysis of permeability indicators within the Patuha geothermal field has revealed a critical finding that geological structures, especially faults and fractures, exert the most significant influence on permeability. This

aligns perfectly with the established concept of Patuha being a "structurally controlled" geothermal system, where geological formations play a major role in directing the flow of geothermal fluids.

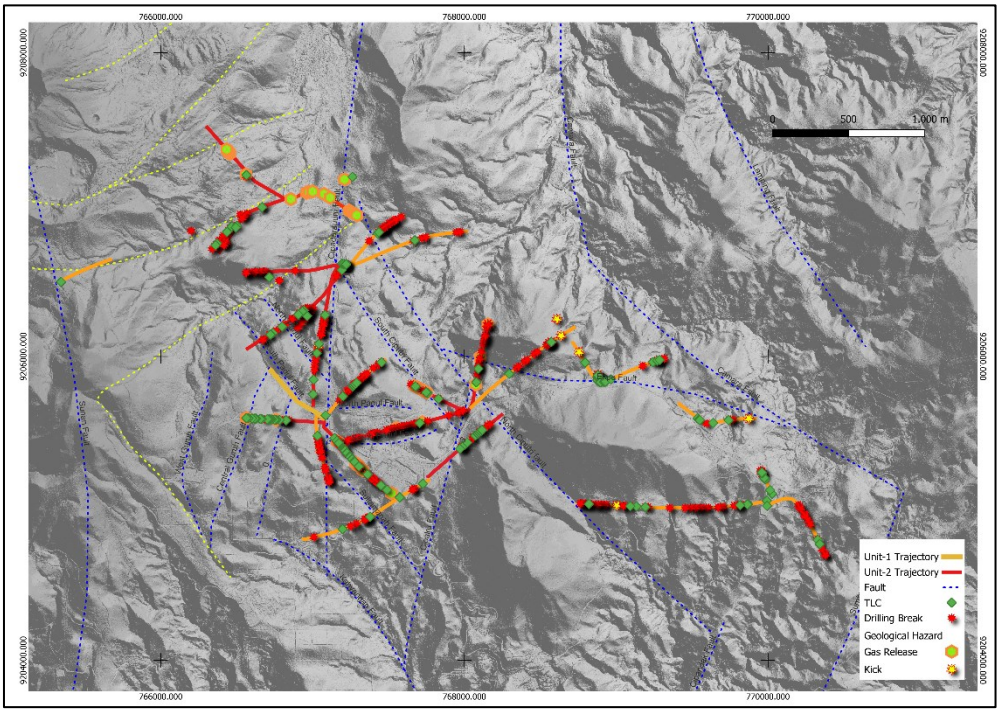

Figure 8: Patuha Permeability Indication During Drilling.

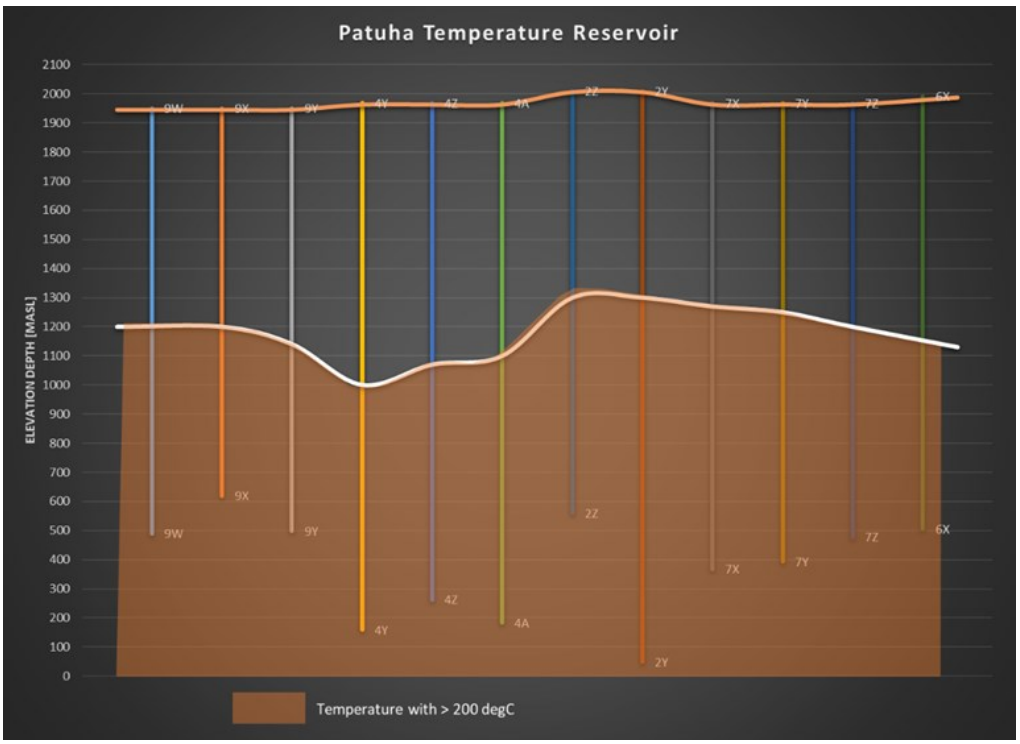

Figure 9: Patuha Temperature Distribution.

3.3 Pressure and Temperature Distribution

Following the completion of drilling for each well in Patuha Unit-2, a Pressure and Temperature (PT) survey was conducted to assess the geothermal potential of the field. This survey provides valuable insights into the presence and characteristics of geothermal reservoirs. A PT survey typically involves measuring pressure and temperature along the entire depth of a well while maintaining a consistent well condition throughout the process. These

measurements can be taken under various well conditions, including shut-in (closed wellbore), injection, or flowing conditions. In Patuha Unit-2, the PT data was acquired with the wells in a shut-in state.

For optimal results, a recommended PT survey schedule involves measurements at specific time intervals, often including 1, 3, 7, 14, 28, and 60 days after well completion. The acquired PT data can then be plotted versus measured depth, vertical depth, or elevation depth. Once the wells have reached a stable condition, plotting the PT data versus elevation depth allows for the estimation of the proven geothermal area. In this analysis, a temperature of 200°C is often used as a threshold to define the reservoir section within the wellbore.

Analysis of temperature data from the Patuha geothermal field reveals a compelling possibility for resource expansion. The central and northern regions exhibit temperatures exceeding 200°C at 1100 mASL (Figure 10), a strong indicator of the presence of viable geothermal reservoirs. This promising finding suggests that extending geothermal exploration activities towards the western and northern areas of Patuha holds significant potential. Further investigation in these regions can lead to the discovery of additional geothermal resources.

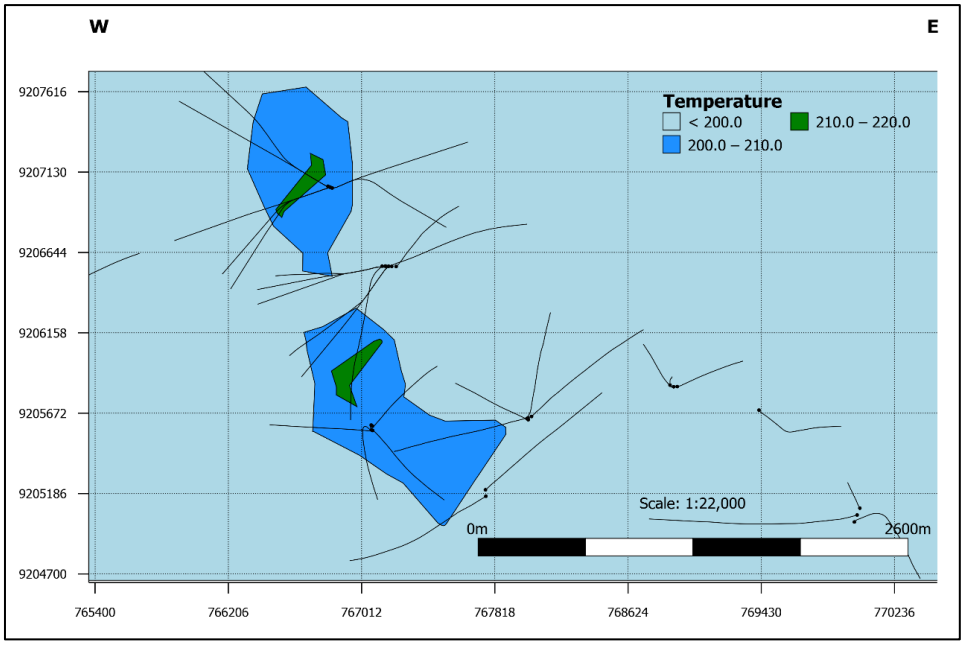

Figure 10: Temperature Distribution at 1100 mASL.

4. SUBSURFACE CHALLENGE

The Patuha Unit-2 drilling campaign encountered a multitude of challenges that demanded innovative solutions from the drilling and subsurface teams. These challenges stemmed from complex geological conditions and the need to optimize drilling efficiency while ensuring wellbore stability and safety.

4.1 Geological Hazard

Drilling operations in the Patuha geothermal field have consistently encountered a specific geological obstacle – a reddish-brown rock layer informally known as the "red bed" due to its characteristic color and oxidation evidence. This layer, in some sections, also contains elevated concentrations of clay minerals.

The red bed presents a significant challenge during geothermal well drilling due to its problematic interaction with water-based drilling fluids, particularly within the target reservoir zone. Contact with water can trigger the red bed to swell and disintegrate, leading to critical issues like stuck drill pipes. Analyses of past drilling data from Patuha reveal a concerning trend – nearly 45% of wellbore issues, including tight holes and stuck pipes, can be traced back to the red bed.

The red bed encountered in the Patuha geothermal field exhibits some internal variations, particularly in its location within the wellbore. Here's a breakdown of the key observations:

- Red Bed Above Reservoir: Commonly found above the target geothermal zone, this variant features a high visual clay content. In simpler terms, this high clay content translates to a soft, crumbly texture, and when these clays come into contact with water-based drilling fluids, they tend to become sticky. This stickiness can contribute to wellbore issues.

- Red Bed Within Reservoir: Encountered within the reservoir zone, this variant possesses a lower visual clay content but often displays a spike in the Methylene Blue (MeB) value. Despite the lower clay content, it maintains a soft and crumbly consistency. However, it visually differs from the first variant by exhibiting a shale or platy shattered appearance.

Figure 11: Type of Red Bed Occur above reservoir zone (left) and in reservoir zone (right).

Analysis of wellbore data, incorporating elevation and well correlation techniques, has revealed the presence of at least 16 distinct red bed layers within the Patuha Unit-2 geothermal field (Figure 12). These red bed layers occur at varying elevations, and interestingly, nearly every well drilled in Patuha area encountered this red bed layer. A noteworthy observation is the higher concentration of red beds encountered in wells located within the central Patuha area. This finding could be attributed to two potential factors. Firstly, the well paths in this region may have traversed a zone with a more concentrated presence of red beds. Alternatively, the central Patuha area itself might be situated within a section where the red bed formation is inherently thicker.

Research on the red bed's characteristics and impact on drilling is an ongoing process. Future studies will incorporate data from various laboratory analyses, including petrography, XRD, and Linear Swelling Tests. Integrating this data with other relevant information will contribute to the development of more robust models for understanding and mitigating the challenges posed by the red bed during Patuha geothermal well drilling.

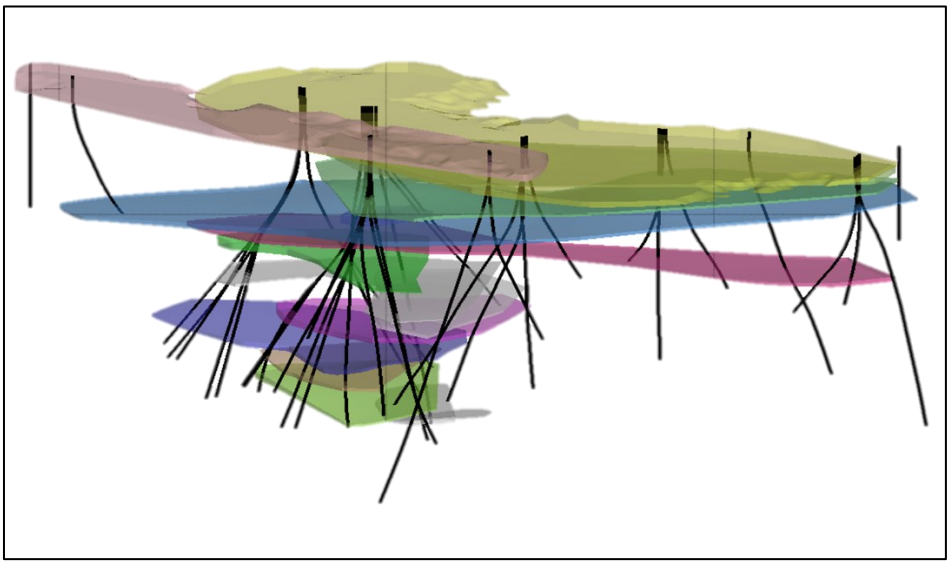

Figure 12: 16 Red Bed Layers Based on Elevation.

4.2 Drilling Challenge

The Patuha Unit-2 drilling campaign encountered a significant challenge in the production zone: unstable formations. These formations are particularly fragile when exposed to water, making them susceptible to collapse during drilling.

- Combating Formation Collapse: This presented a dilemma. Traditional drilling methods rely on water-based drilling fluids. However, with unconsolidated formations, these fluids could exacerbate the problem by further weakening the formation. The solution: a technique known as Slightly Underbalance

Drilling (SUBD). SUBD minimizes water contact with the formation by maintaining a slightly lower pressure in the wellbore compared to the surrounding rock.

- Balancing Challenges: While SUBD addressed the formation collapse issue, it introduced another challenge: high temperatures. Due to limitations with directional drilling tools that cannot withstand high temperatures, the team had to switch to a rotary drilling assembly. This compromised directional control, making it more difficult to maintain a precise well path.
- Adaptability and Innovation: The drilling team displayed remarkable adaptability. They implemented modifications to surface equipment to handle the high temperatures and extend its lifespan. This ensured continued drilling operations.
- Collision Averted: Drilling in close proximity to existing wells carries the risk of collision. However, meticulous wellbore monitoring and meticulous planning ensured no such incidents occurred during the Patuha Unit-2 drilling campaign.

Despite encountering unforeseen geological challenges, the Patuha Unit-2 drilling campaign emerged successful. The team's adaptability, collaborative problem-solving, and meticulous planning ensured efficient well construction and avoided potential wellbore issues.

5. CONCLUSION

Our exploration of the Patuha Unit-2 geothermal field, utilizing a combination of techniques, has yielded significant insights into its geological makeup, permeability characteristics, and overall geothermal potential. Geological analysis revealed a mature fault zone within the field, which may play a role in directing geothermal fluid flow. Real-time data analysis during drilling allows for adjustments to well trajectories, maximizing the extraction of geothermal resources. A specific rock layer, known as the red bed, presents a challenge due to its interaction with drilling fluids. Ongoing research is focused on developing mitigation strategies. Pressure and temperature (PT) surveys provided valuable information about the presence and characteristics of geothermal reservoirs. The encouraging discovery of temperatures exceeding 200°C in the central and northern regions suggests the potential for significant resource expansion in these areas. Continuous monitoring and data collection are essential for optimizing the development of Patuha Unit-2 and ensuring its long-term sustainability. Furthermore, spurred by the promising temperature data, further exploration of the western and northern regions holds the key to unlocking additional geothermal resources, contributing to Indonesia's clean energy goals.

ACKNOWLEDGEMENTS

The authors would like to express acknowledgment to PT. Geo Dipa Energi (Persero) for their important assistance in completing this study. We want to express our gratitude to Subsurface and Drilling Division PMU for their essential help throughout the research process. We would also like to thank the Management of PT. Geo Dipa Energi (Persero) for obtaining permission to publish this work. Their effort and teamwork were essential to the successful completion of this research.

Keywords: updated resistivity model, 3D inversion

ABSTRACT

Like most geothermal fields producing for more than 5 (five) years, XX has had problems with wells performance. This is most likely due to the result of inappropriate of subsurface data. The problem has been approached with the proper application of MT technology such as selecting and reprocessing raw data to reproduce 3D inversion. However, the analysis is frequently conflicted with the others data, primarily due to incorrect interpretation of noise and low deep resistivity.

The appropriate modelling scheme of MT data and observation of anomalous resistivity feature are interpreted as thick-conductive zone, self-sealing fracture, steep gradient of BOC, reservoir barrier at weak altered zone which separate zone between production and reinjection wells. This anomaly is strongly correlated with the temperature changes in hydrothermal minerals. This variation shows the up-dome shape of temperature contour and low resistivity zone above upflow zone. The results are confirmed from hot water and fumarole characteristics (such as altered rock and acid spring) and resistivity model.

The aim of this paper is to rebuild the resistivity model, which can be expected to analyze and integrate the distribution of alteration minerals, top of reservoir (TOR), base of conductor (BOC), hence the outflow zone and fault barrier zone that corresponds to reservoir partition at field can be identified.

1. INTRODUCTION

XX area is a volcanic, high-enthalpy resources geothermal environment, reservoir is characterized by shallow intrusion, high permeability, hosting benign fluid chemistry. The lithology setting at XX area field are composed of Quaternary volcanic rocks, both lava and pyroclastic, lahar, breccia, and tuff that comprise several formations underlying the south-western boundary of reservoir occurs to form the youngest product and high elevation (andesite) at XX area. Subtle variations in fluid chemistry allow the field to be subdivided into four distinct sectors or “cells” that are likely bounded by faults. There is clear evidence that dikes and sills have intruded into some fault zones during recent episodes of volcanism and may have either sealed existing permeability or created new pathways near the boundaries of these cells. The four sectors have been termed the three different partition.

High permeability in SW - NE profile is controlled by high temperature, presence of shallow heat source and distribution of altered mineral, while most of TOR delineation are speculatively described in large reservoir and no-barrier fluids flow. Although the distribution of clay cap spreads all over XX area, the fault / lithologic contact barrier, dike and geochemical variation divided into 3 (three) main intrusion play the significant factor in overall understanding model and how much resistivity anomaly of upflow and outflow zone can build conceptual model from previous analysis. As a consequence of disagreement between interpretation of 1D MT inversion, conducted in 2002 and improved joint inversion in 2013, also analysis of TOR (top of reservoir) or BOC (base of conductor), production and injection well can be encountered deep conductive layer and fault barrier after well completion, which for data validation needs good agreement of thickening in conductive layer and well data as the primary purpose of this publication. Proper application, quality control of magnetotellurite data and re-processing can eliminate contradiction of large prospect area with drilling data as well as mismatch of TOR and thickening of conductive layer (Figure 1 and 2).

2. GEOLOGY AND STRUCTURE FEATURE

For the compilation of stratigraphy and structure of XX site, the formations can be determined as andesite tuff – rhyodacite and lava 180,000 – 280,000 years ago, which is composed of ruptured Caldera and floored further to the west, northwest and north area and filled by the older rhyolite dome, lava and the younger tuff. In terms of the fracture zones, a major lineament is expected to exist with post-caldera units show prominent 0°~50° N to NE direction and 330°~340° NW (Figure 3 (A) and (B)).

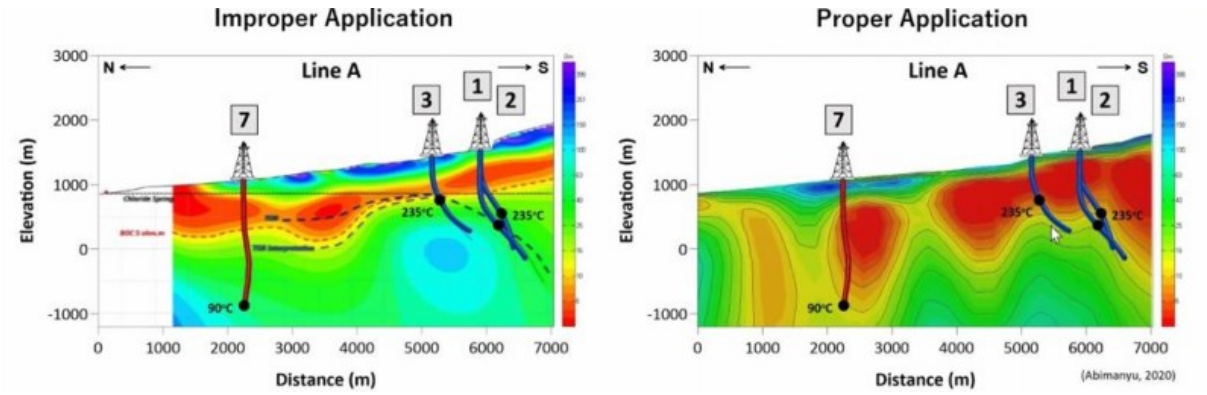

Figure 1: Application of quality control and re-processing MT data, (Daud Y. et al., 2015).

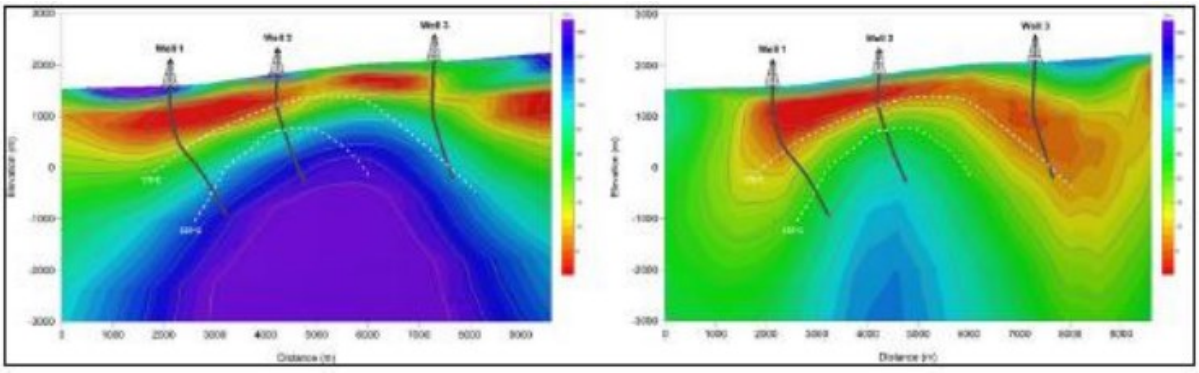

Figure 2: Correlation of MT and drilling data before (left) and after (right). Innovated application to define actual reservoir geometry and deep alteration zone (Daud Y. et al., 2017).

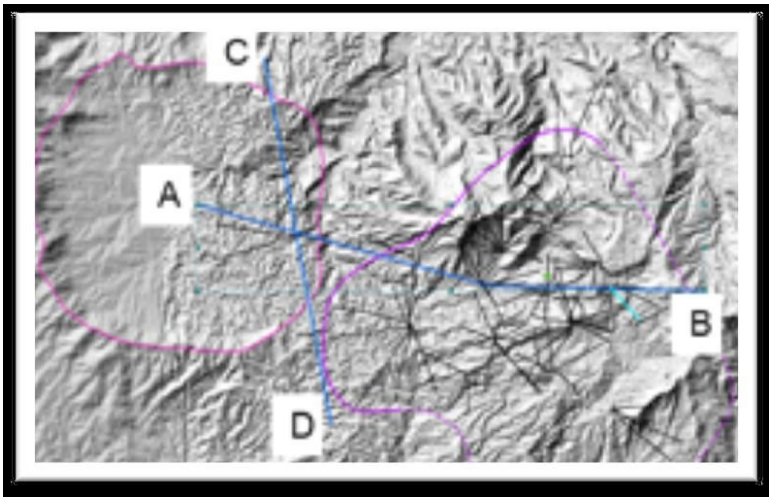

Figure 3: DEM Map shows fault lineament and surface manifestation.

The five regionally extensive basaltic–andesite to andesite volcanic centers described are the (1) the older andesite (670-1610 ka), that consists of andesitic cone that forms the rim of the caldera to the west; (2) Basaltic Andesite (420-860 ka); (3) Middle Basaltic Andesite (400-320 ka); (4) Young Andesite (180-280 ka); and (5) Rhyolite Lava (113-120 ka). Both the Middle and Upper Volcanic Formations consist of a series of dacitic (at their base) and andesitic rocks overlying each other. This new interpretation approach suggests that the separation of the volcanic rocks into ductile and brittle is impractical. Thus, the temperature and the permeability changes in volcanic altered rock interpreted as upflow and outflow zone. In addition, 3 (three) main intrusions are spread across at XX geothermal field.

NNE-trending normal faults are the dominated faults which correlated with recent volcanic vents, playing as a key indicator in forming the system, and allowing the descent of shallow fluids into the eastern, western and northern portion of the geothermal reservoir. Main fault forms an important cell boundary and it will be shown later that together with these structures bound of an fault intersection, anomalous-resistive zone, and recent

volcanism that host a thicker and highly permeable volcanic pile than the adjacent areas. Figure 3 represents the mapped faults and lineaments identified at XX area showing fault intersection, upflow, outflow and confidence on their surface feature. Thermal decrease is an evidence of boundary divided into several sectors or "cells" that are likely bounded by faults, permeability barrier or lithological contact, which are shown as an abrupt temperature change. The most common cause for such discontinuities in thermal regimes is a spatially change in permeability.

The main fault, at surface manifestations (fumarole) also main altered zone, intersect with E-W trending fault zones identified nearly parallel to the lithological contact. It serves as an outstanding example of a mapped fault zone in the area (Figures 3). The fault zone consists of a nearly vertically trending zone that is 5 m wide and that is filled with mixed of shear and broken formations. The surface formations are clay-altered tuffs that do not maintain permeable fractures. The oldest tuffs are bedded red-brown deposits that are collectively called the Lower Brown Tuff, whereas the youngest units are the Orange Tuff and a thin overlying brown ashy soil. Apparent offset on the Orange Tuff (age estimated at 8,400 to 40,000 years based on C-14 ages on overlying and underlying units) in Figure 3 (A), suggest the fault is down-to-the-north. A dip of about 75° is forming a normal fault. Slow changes in the bed dip at the fault margin may be interpreted as high permeability zone. However, no slickensides or hydrothermal alteration were observed in the fault zone or at its margins. This zone dips too steeply to represent a paleozoic channel. It is most likely to represent a young (<40,000 year old) fault with normal or oblique-normal slip.

3. 3-D INVERSION OF MT DATA

The 3-D inversion method was applied for the 123 MT soundings with a frequency range of 100 to 0.01 Hz. The overall quality of the MT data used varied from bad (20.2 %) to very good (17.5 %). The 3-D MT inversion was carried out using the MT3DInv-X software program (Daud et al., 2012). It is a user-friendly software program that utilizes the Occam's inversion data space algorithm developed by Siripunvaraporn (2011). With this software program, the 3-D inversion process was performed more effectively. The result of the 3-D inversion in this software program was integrated with the GeoSlicer-X software program (Daud and Saputra, 2010). The output of the MT3DInv-X was exported into the (x, y, z) value data format, which was used as data input in the GeoSlicer-X software to visualize the data in three dimensions.

3.1 Mesh Grid Parameter

The 3-D model consisted of blocks in the 3-D mesh-grid in the dummy coordinate system. The center of the dummy coordinate system was situated in the center of the station distribution. In the MT3DInv-X software, the x-axis was oriented from north to south (with north as positive), the y-axis was oriented from east to west (with east positive), and the z-axis was positive downwards. The 3-D MT inversion process used a 100 ohm-m homogeneous half-space as the initial model. The number of blocks was 72 from north to south and 80 from west to east, with 22 vertical layers (without air layers). Thus, the total number of model blocks was M = 72 x 80 x 22 = 126,720.

3.2 Data Input

The data input for the 3-D MT inversion process were the real and imaginary parts of the impedance tensor (Zxx.real, Zxx.imag, Zxy.real, Zxy.imag, Zyx.real, Zyx.imag, Zyy.real, Zyy.imag). To constrain the data from high errors, the error floor of the impedance tensor was set as 5% to ensure that the model response fitted well with the observed data. The total number of data (N) depended on the number of stations, frequencies, and impedance tensor elements. The total number (N) for the 3-D inversion of MT data was 110 stations, 9 periods with the frequency range of 320 to 0.01 Hz, and all eight impedance tensor elements. Thus, the total number of data (N) is 110 x 8 x 8 or 2,448.

3.3 3-D Inversion Process

The 3-D MT inversion process was run on a PC with specifications as follows: Intel Pentium core i7 with 16 GB of RAM. For one iteration, it took about 2 hours and the total time to reach the 4^{th} iteration was about 148 hours. The 3-D inversion process using MT3Dinv-X was stable and convergent before finally reaching the best fit. Thus, it produced a good subsurface resistivity structure representing the real condition. The final RMS misfit achieved was 7.3%.

4. VARIATION IN OBSERVED RESISTIVITY

In recent days, there are three (3) type of inversion as follow, inversion 1 D, inversion 2 D, and 3 D. 1D Inversion is conducted with assumption of homogenous in earth properties, thus subsurface resistivity value varies only with deep. Inversion 1D is used for simple interpretation describing complexity of subsurface condition, however 3D inversion is analyzed with time-consuming and processed using large memory database. In any special cases, which the assumption of 2D subsurface structure using valid data, 2D method could be an alternative to obtain

updated model (Baranwal V.C., 2010). Following are the stages of the research, the first step is to select 3D MT data and its interpretation of resistivity distribution, and the next step, build conceptual model by re-processing MT 3D data, others geophysical and data validation with data from previous drilling results. MT price has generally been inexpensive method compared to drilling, 123 MT stations is about 4 % of one drilling price, which can demonstrate clearly interpretation of target area than drilling data.

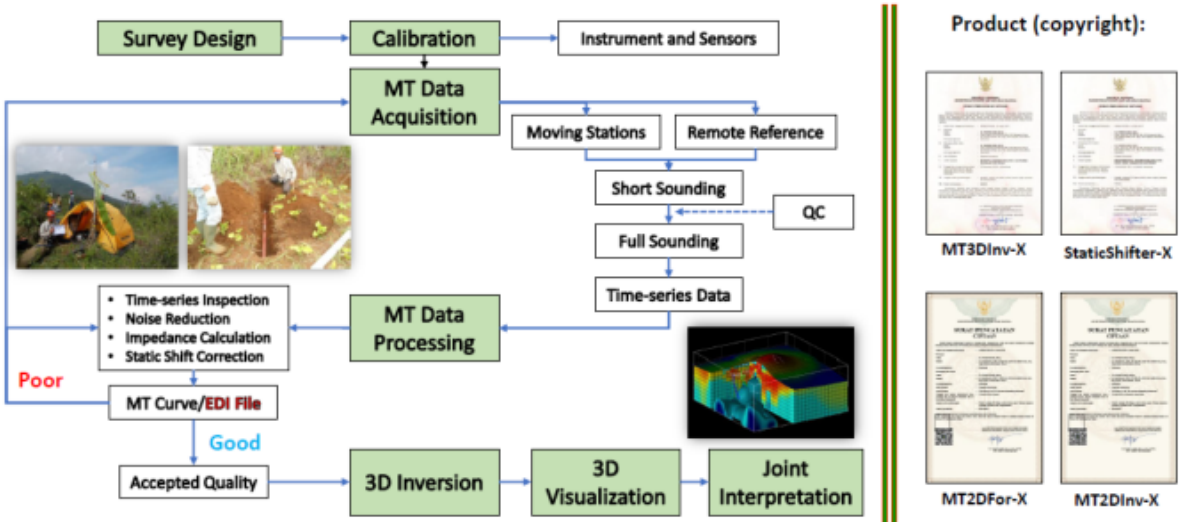

Figure 4: Workflow of MT Technology (Daud Y, 2020).

MT technology and processing program developed for various research projects are being evaluated and applied into the overall module. User documentation is being enhanced, including templates for typical application problems and improved user features. Additional time-series inspection, noise reduction, impedance calculation enhancements and applications of static-shift correction to difficult reservoir problems are ongoing. Accurate modelling criteria for MT data is essential to resemble the real 3D volcanic environment. 3D inversion method can be used in 3D complex structure area as usually correspond to volcanic formation. The MT sensitivity of conductive zone, such as clay cap, fracture zone and lithological contact, can also benefit from 3D modelling scheme based on resistivity distribution obtained from clean and genuine MT data. Proper MT technology can delineate geothermal system components such as altered rock layer (Clay cap) above the reservoir, vertical and lateral boundaries of reservoir, basement or possible heat source, well target zone (boundary of promising zone), high temperature and permeability zones.

Argillic Alteration is dominated by *smectite clay* that formed at temperatures less than about 180°C. The rocks within this alteration zone typically have resistivity below about 10 ohm-m and a conductive temperature profile indicating very low fracture permeability. The transitional argillic to propylitic zone can span up to 300 m in thickness, and is dominated by mixed layered smectite–illite clay. The propylitic alteration zone is corresponded to measured reservoir temperatures between about 220 and 270 °C.

4.1 Interpretation of Resistivity and Permeability Distribution

The update three-dimensional model shows resistivity distribution at all levels, with particularly at each elevation of 250 m. msl. At elevation – 3500 to – 1000 corresponds to the high resistivity zone as single extensive unit of resistive body and were related to the intrusion or heat source. Primary structural and stratigraphic controls on upflow system where the resistive (blue) zone extends into the sediments and lithological contact of youngest volcanic unit. Thick clay cap in the middle of prospect area is likely the barrier of two heat source and hypothesized as fault-controlled reservoir. Therefore, the upflow is interpreted to occur between the fault and deep BOC, beneath the area where the <5 ohm-m part of the clay cap (red) extends to about 2500 m depth.

Elevation – 1000 to - 500 m indicates narrowed reservoir geometry becomes 3 separated resistive zone (intrusion). Thick clay cap is found in the middle of prospect area, beneath of fumarole, and between hot spring. One important finding, believed to be interpreted for the first time: reservoir margin is described with contrast on surrounding conductive zone. This indicates that prospect area heterogeneity (and its structural details) may give a narrow and limited reservoir geometry and may explain much of the significant resistivity anomalies.

The average deep of BOC results from the resistivity mapping on a shallow deep is shown in Figure 5, elevation from – 500 to surface. It looks like a structure that hosts an upflow that extend almost 2000 m from surrounding the updome zone at about -500 m depth and dissipate near the reservoir boundary. The resulting of 3D inversion

are rich in information, illustrating a wide distribution of "anomalies" ranging from conductive or resistive class to sealed fractures and permeable fault. Importantly, the results illustrate that the three resistive zones separated by clay rich-barrier between these zones.

The three (3) main upflow zone are dominated by low permeability rocks. These intrusion may be related with heat source, fractured and high permeability zone, most likely along faults and intrusive margins (fault as conduit/vein), beneath main altered zone, barrier zone (clay rich tuff). The change of resistivity value with boiling depends on porosity and surface conduction, and was much larger for the high-permeability hydrothermal breccia and rhyolite lava from young phreatic eruption (8400 ka). Improved understanding, in three dimensions MT and correlation of well data may interpret high permeability fracture in volcanic rocks at the middle of main reservoir, such as andesite, dacite, rhyodacite, tuff, lava and breccia. Total changes in resistivity with boiling are appeared from andesite at well data and much larger for a hydrothermal breccia. Large resistivity changes associated with boiling for the highly permeable breccia (at southern kawah and thick clay barrier) suggest that a resistivity increase would correlate with high-permeability zones if steam is present.

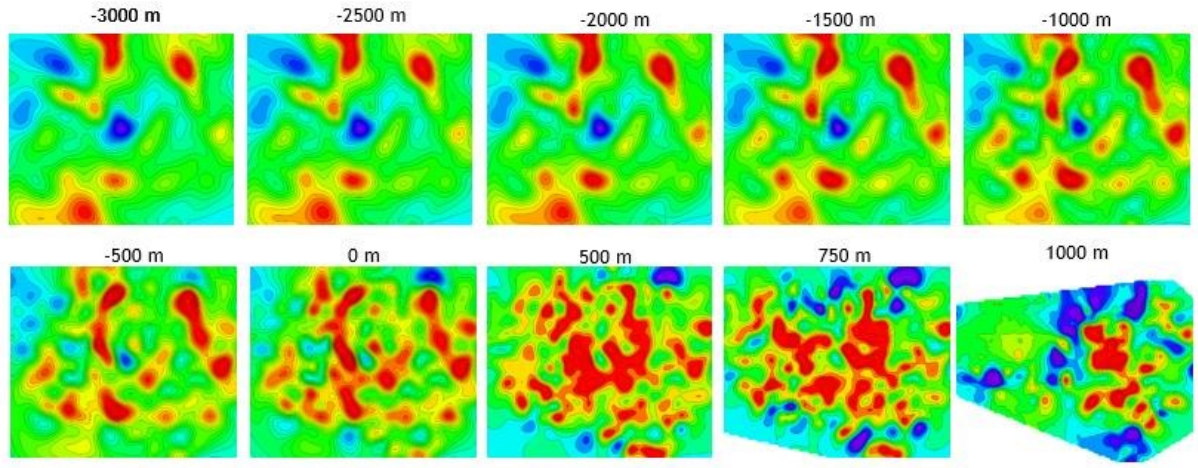

Figure 5: Distribution Map of Resistivity, shows spacious geometry of reservoir and thick clay cap in the centre (-1000 m), narrowed reservoir and three (3) main resistive zone (-500 m), clay rich tuff as barrier of the three resistive zone (0 m).

4.2 Inconsistencies of Resistivity Interpretation between 3D Inversion and 1D MT

This paper is focusing on revising the previous interpretation of 1D inversion that appear to be not exactly consistent with the real distribution of resistive zone interpretation at W - E which are speculatively described in a large reservoir from west – east . The decription of thick clay cap at W – E section and fumarole until elevation - 250 masl and no-barrier between large reservoir is not realistic to updated model. Thin conductive layer and shallow at Figure 8 is expected to represent main heat source or intrusion in 1D inversion, but in 3D model, low resistive layer is thick to nearly -750 masl. The most recent updome pattern is showed by upflow zone at updated 3D MT section and top of updome pattern (reservoir zone) at a depth of about -500 m until 500 m, which we infer to be the top of the reservoir after reviewing BOC and characteristic of upflow zone. The hotter part at conductive zone, has higher resistivity data, interpreted also as the alteration mineral product. This means a change of smectite zone into illite or chlorite with lower conductivity value. Porosity tends to decrease versus depth, so that reduce portion of fluids (Usher, Harvey & Johnstone, 2000).

Importantly, reservoir boundary is obviously determined by anomaly contrast which is analyzed using resistivity map at – 1000 until -500 m, the impermeable zone at west of the hottest production well, east of fumarole and southern hot spring. While thick, deep clay cap and sealed fractures have been known as permeability border, beneath southern hot water, 2 (two) major faults, and NW hot spring. Intrusion temperature above ~235 °C indicates a resistivity anomaly. Initial observations suggest that the resistive data could lead to reveal the occurrence of a geothermal system evidenced by discontinuous of resistivity value, at depth between - 4000 and - 3000 m. This is assumed to be the root of the igneous intrusion in the caldera area. This anomaly is present also outside the reservoir boundary but with minor presence of conductive layer.

The interpretation of revised 3D inversion is increasing the understanding of XX conceptual model. Authors suggested, based on the resistivity map layer by layer, that the reservoir margin corresponds to the sealed fault boundary; others suggested that this permeability transition occurs in areas where the conductive layer indicates greater deep than –1500 m, also explain the clay rich tuff or impermeable fracture as the barrier of reservoirs on the integrated interpretation of MT and geochemical data from production well.

Deep outflow to the northeast area (chloride spring), bicarbonate spring is supported by an extensive low-resistivity anomaly and the distribution of surface thermal features. Low permeability and temperature decline indicate outflow zone at reservoir boundary. 70 – 200^{o}C zone is represented by low resistivity (conductive, range between 1 – 10 ohm-m), characterized also by smectite mineral content (low permeability). Low resistivity at outflow zone or the presence of low resistive layer due to tertiary sediment strongly affects, compared with conductive zone identified as upflow zone. This paper suggests that the resistivity anomaly is the secondary fault filled with minerals that, in turn, intersects WE-trending fault as high permeability fractures (upflow).

The evidence for both the highest temperatures at main production well, thick clap cap as barrier, suggest that an exceptionally spacious geometry is not described in this research. This conclusion is consistent with 3D MT E-W section. The conductive layer at east area is unlikely to have been significantly thicker. In contrast, the updome pattern and temperature match and range up to 230 – 250 ºC. Previous 1D interpretation have not proven to be at shallow BOC elevation, however it is certainly thicker clay cap, at – 750 m and – 1500 m (Figure 8). The comparison here of all interpretation of MT_2004_1D-Occam does suggest that resistive and conductive layer is not similar with Top of Reservoir (TOR) from well data. 1D interpretation may not be providing appropriate elevation of high resistive value (Figure 8). Perhaps the key to intrusion feature is a lack of illustration of resistivity variation which show permeability boundaries. The images of the predictive indicator of reservoir boundary is limited because the thickening of conductive layer has no significant indication.

5. SUMMARY AND RECOMMENDATION

1. 3D MT inversion has a strong correspondence only with good criteria and interpolation/software correction of EDI file, realistic curve trend for determining resistivity distribution and deep clay cap feature instead of using fair and bad quality of EDI file.
2. Misinterpretation of geothermal conceptual model remains the potential and important issue at XX field. The result of 3D inversion improvement, lithology, surface manifestation and others data correlation can indicate reliability of the proven BOC, deep conductive zone, barrier of permeability, and upflow in reservoir as an expedient measure for revising the existing conceptual model.
3. XX is a volcanic altered zone that exhibits thick and low resistivity anomaly detected at centre of prospect area, west part of fumarole, beneath of centre barrier and feature of high resistive zone at separated region. In vicinity of clay cap or sealed fracture, heat source was mapped as well.
4. This paper outcome is improved understanding, in three dimensions MT, geological feature and surface manifestation (geochemical) in volcanic-geothermal settings. Disagreement between Base of Conductor and TOR geometry at main reservoir has been corrected with new resistivity model which produce good agreement with TOR from drilling data as well as thickening of conductive layer in unsuccessful well.
5. Comprehensive geophysical methods especially corrected timeseries/static shift of raw data can play an important role to connect and reconstruct several data.
6. This study must be able to take many lessons from the “MT vs Drilling” experiences by utilizing the valuable drilling data in order to be successful in the upcoming drilling campaign and disseminated through collaboration of university, government and operator company for further research, journal and papers or publication.

ACKNOWLEDGEMENTS

Author is very grateful and kindly thank the counselors from Geothermal Submajor, University of Indonesia for the support and guidance and PT NewQuest Geotechnology for facilitating the data processing.

Keywords: Kotamobagu Geothermal Field, Geology, Volcanology

ABSTRACT

The Kotamobagu geothermal field is located in North Sulawesi, Indonesia. Tectonically, the Kotamobagu geothermal field is on the southern side of the northern arm of Sulawesi Island, which is an active tectonic zone flanked by two NE-SW trending subductions on the northwest (Molucca Oceanic Plate) and southeast sides (Sangihe Double Subduction Zone). The tectonic processes resulted in volcanoes appearing in the Kotamobagu geothermal field.

Based on the results of geological mapping and satellite image analysis, the Kotamobagu geothermal field consists of lithology divided into four groups: tertiary rocks unit, tertiary-quaternary rocks unit, quaternary rocks unit, and the recent depositional unit. The formation of the Kotamobagu Geothermal Field is deeply intertwined with regional tectonic activities, particularly the subduction and extension phases in the northern arm of Sulawesi. These subduction processes influenced volcanic activity in Kotamobagu with the direction of the main tectonic forces acting, which are aligned with the straightness of the existing volcanic cone with the direction of northwest to southeast with the oldest volcano on the northwest, including Mt. Kolokot, Mt. Moyayat while the youngest volcano is on the southeast included Mt. Moaat and Mt. Ambang resulting in the diverse geological features observed in the field today. The extension phase, in particular, facilitated the formation of NE-SW trending structures, such as the Ambang-Makaaroyen structure, which is crucial for understanding the region's geothermal potential.

1. INTRODUCTION

The Kotamobagu geothermal field is one of the concession areas under PT Pertamina Geothermal Energy Tbk. Administratively, the Kotamobagu Geothermal Field is located in four districts in North Sulawesi Province (Figure 1). This field is tectonically located on the northern arm of Sulawesi, or approximately 200 km to the south of Manado City. In the middle of this field is the Mount Ambang complex, characteristic of volcanic activity. Geological surveys in the Kotamobagu field have been carried out since the 1980s. In 1993, three shallow wells were spread across the Kotamobagu field, and in 2010-2011, two large hole wells were drilled on the south flank of Mount Ambang.

2. REGIONAL GEOLOGY

2.1 Regional Tectonic

Based on regional tectonics, Sulawesi Island is a complex tectonic zone associated with magmatic arcs, metamorphic rocks of varying grades, ophiolites, and microcontinental fragments that formed during the Late Mesozoic and Cenozoic (Hall, 2002). This tectonic zone can be divided into five tectonic provinces (Figure 2): the western, northern, central, and eastern Sulawesi Arms and microcontinental fragments (Cottam et al., 2011). Each of these tectonic provinces is separated by major regional faults.

2.1.1 Western Arm of Sulawesi

The tectonic province of the western arm of Sulawesi extends from the north in Gorontalo Bay to the south in Makassar. This tectonic province characterizes the continental margin segment (Leeuwen et al., 2007). The western arm of Sulawesi began to form in the Late Mesozoic on the southeastern border of Sundaland (Elburg et al., 2003). The basement of the western arm of Sulawesi is composed of several metamorphic rock complexes exposed on the southern side of this tectonic province, such as the Bantimala Complex (Wakita et al., 1996 in Elburg et al., 2003). This basement was formed during the subduction process beneath Sundaland in the Late Cretaceous (van Leeuwen, 1981; Hasan, 1991; Sukamto and Simandjuntak, 1983; van Leeuwen and Muhardjo, 2005 in Leeuwen et al., 2007). The subduction process continued until the Early Tertiary when the western arm of Sulawesi rifted away from Borneo, resulting in the thinning of the lithosphere in the Makassar Strait (Calvert

and Hall, 2007). Volcanic arcs appeared continuously and intermittently until the Early Miocene and produced carbonate and siliciclastic deposits on the south and north sides of the western arm of Sulawesi.

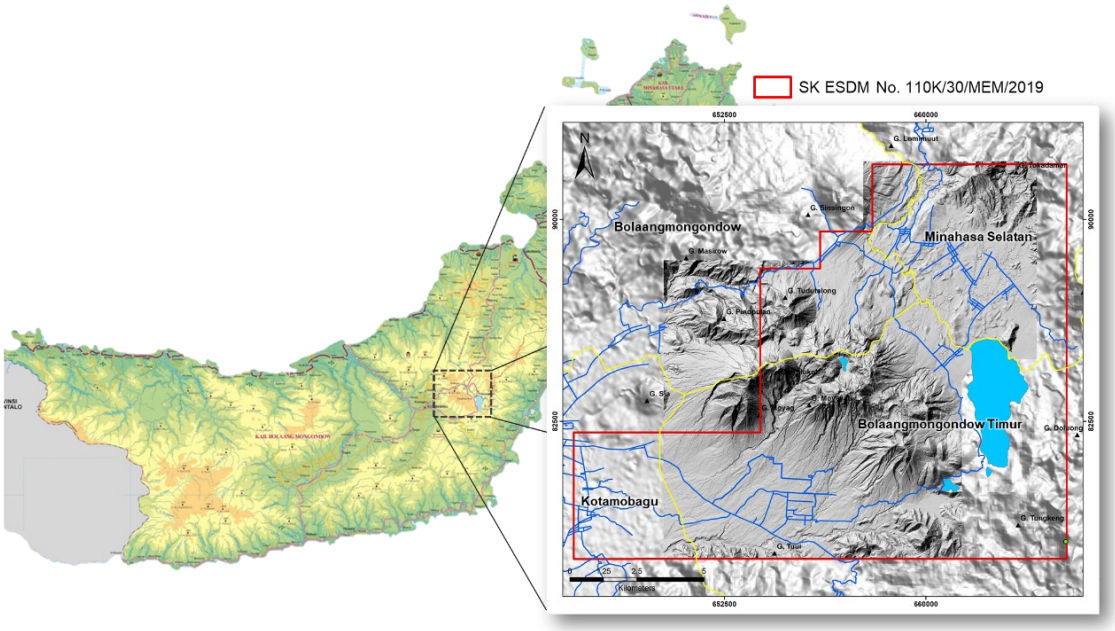

Figure 1: Location map of Kotamobagu Geothermal Field.

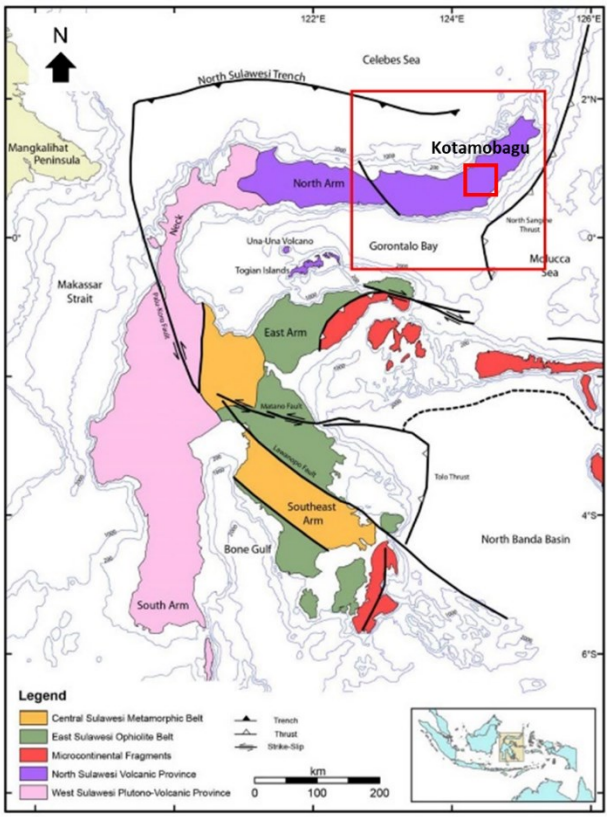

Figure 2: Tectonostratigraphic province of Sulawesi. Modified after Cottam et al. (2011).

2.1.2 Eastern Arm of Sulawesi

The tectonic province of the eastern arm of Sulawesi is located around the Tojo Una-una and Luwu areas. This tectonic province is composed of Ophiolites, which consist of sequences of dunites, lherzolites and harzburgites, ultramafic cumulates, layered gabbros, isotropic gabbros, sheeted dykes and basaltic pillows and lavas

(Simandjuntak 1986; Parkinson 1991,1998 in Cottam et al., 2011). Based on K-Ar dating, the ophiolites that make up this tectonic province are Cretaceous to Eocene in age (Simandjuntak, 1986 in Cottam et al., 2011).

2.1.3 Central Sulawesi

The central tectonic province of Sulawesi is divided into two parts: the northern part around Poso and the southern part around Kendari. This tectonic province is a metamorphic belt that separates the western and eastern arms of Sulawesi (Cottam et al., 2011). Lithologically, this location is composed of the Pomangeo schist complex, predominantly composed of interbanded phyllitic marble, calcareous phyllite, graphitic schist, and quartzite, rocks of terrigenous to shallow marine origin (Parkinson, 1998). This tectonic province was formed at the same time as the subduction process on the western arm of Sulawesi at the end of the Mesozoic (Parkinson, 1998).

2.1.4 Microcontinental Fragments

The microcontinental fragment tectonic province is in the Banggai-Sula complex on the eastern side of Sulawesi. This tectonic province comprises a basement of Palaeozoic or older metamorphic rocks intruded by Permo-Triassic granites associated with felsic volcanic rocks. These rocks are overlain by undated, probably Lower Jurassic, terrestrial sediments and by Jurassic and Cretaceous marine shales and limestones. There are Eocene to Neogene limestones in the western parts of the islands (Garrard et al., 1988; Supandjono & Haryono, 1993; Surono & Sukarna, 1993 in Cottam et al., 2011). Even though this tectonic province is relatively small, the collision processes that occur in this province are often interpreted as the cause of regional deformation in Sulawesi and Borneo. One of them is the Early Miocene collision of the Sula Spur with the North Arm volcanic arc and East Arm Ophiolite, and this continental area was then fragmented during extension caused by subduction rollback into the Banda embayment (Cottam et al., 2011).

2.1.5 Northern Arm of Sulawesi

The tectonic province of the northern arm of Sulawesi extends from Gorontalo to Manado and consists of a dominantly tholeiitic Tertiary volcanic arc built on the Eocene oceanic crust (Cottam et al., 2011). Kotamobagu Geothermal Field is located in this complex tectonic province of North Sulawesi. Its current position is at the meeting point of four plates: the Eurasian, Philippine/Celebes Sea, Molucca Sea, and Indo-Australian. The volcanism in this tectonic province was controlled by the northward subduction of the Indian Ocean lithosphere beneath the north arm of Sulawesi in the Eocene (Figure 3; Cottam et al., 2011; Hall 2002; 2012).

The volcanic products representing this subduction period are bimodal volcanic rocks (felsic and mafic in composition) categorized by Elburg et al. (2003) as Old Series volcanism on Sulawesi Island. The Old Series volcanism (51–17 Mya) in Sulawesi has a Chalk-Alkaline to Tholeiitic affinity spread throughout the West Sulawesi tectonostratigraphic province (Elburg et al., 2003). This indicates that the western and northern arms of Sulawesi were part of a volcanic arc in the Eocene (Elburg et al., 2003).

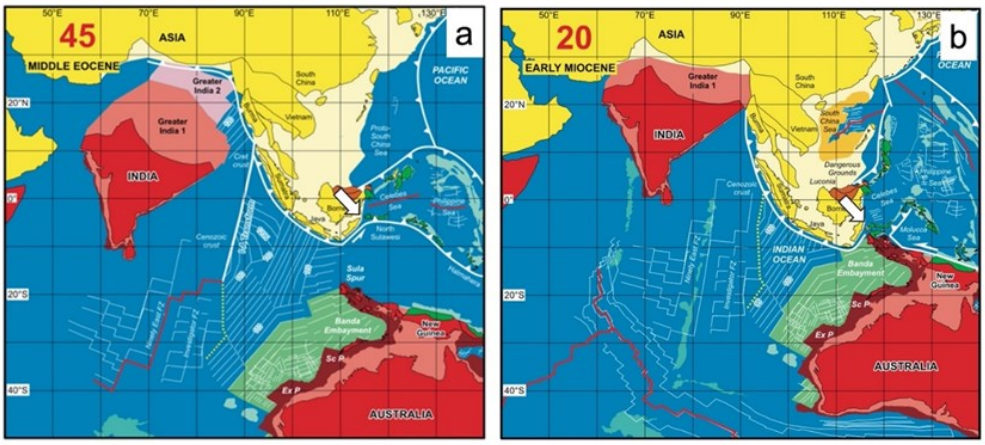

Figure 3: Tectonic reconstruction of the formation of the Northern Arm of Sulawesi volcanic arc through northward subduction of the Indian Ocean lithosphere beneath the north arm of Sulawesi during the Middle Eocene (a) and Early Miocene (b) (Hall 2002; 2012). The white arrow shows where the northern arm of Sulawesi is located.

The easternmost products of volcanism on the northern arm of Sulawesi from this subduction are represented by Ratatotok (12–14 Mya), Lake Tondano (3 Mya), Mount Lokon, and Manado Tua, which have a Calc-Alkaline affinity with potassium values varying from medium-K to shoshonitic (Elburg and Foden, 1998). Elburg and Foden (1998) assume that these volcanic rocks are part of the Sangihe Arc, which resulted from the subduction of the Molucca Sea plate to the west. This is confirmed by the results of seismic analysis of the subducting plate in

North Sulawesi (Cottam et al., 2011). Geochemical isotope trends show that the younger the age of volcanism, the melting of subducting sedimentary material increases (Elburg and Foden, 1998). This is possibly caused by the slowing speed of subduction of the Molucca Sea plate due to the collision process between the Sangihe Arc and the Halmahera Arc (Elburg and Foden, 1998).

The Celebes Sea, which formed in the Middle Eocene, was then subducted under the North Sulawesi arm in the Pliocene (Figure 3.2a; Hall, 2002; 2012). The tectonic process of this subduction also causes the northern arm of Sulawesi to experience a clockwise rotation process with the center of rotation at its western tip (Hall, 2019). The rotation and subduction process also causes the formation of right-hand strike-slip faults that limit segments of the upper crust, for example, Gorontalo, Buol, Malino, Tambarana, and Palu-Koro strike-slip faults (Hall, 2019).

2.2 Regional Stratigraphy

Based on the order of formation from old to young (Figure 4), the formations that make up the Kotamobagu Geothermal Prospect Area and its surroundings (Apandi & Bachri, 1997; Effendi & Bawono, 1997) are as follows:

2.2.1 Bilungala Volcanic Rock Formation (Tmbv)

This formation has a thickness of approximately 1000 meters and was deposited in a radius with the Bilungala Volcanic Limestone Member (Tmbl). Based on the fossil content in the limestone inserts, this unit is Early Miocene - Late Miocene. Bilungala Volcanic rocks are composed of breccia, tuff, and lavas, which are also composed of andesite, dacite, and rhyolite. In the rocks that make up breccia, zeolite, and calcite fragments are often found.

2.2.2 Bilungala Volcanic Rock and Limestone Member (Tmbl)

Members of this formation are composed of gray limestone, and their fossil content indicates that this unit is from the Early Miocene to the Late Miocene.

2.2.3 Tapadaka Formation (Tmts)

The Tapadaka Formation is composed of sandstone, greywacke, eroded sandstone, and shale. Based on the fossil content found, it is of Early Miocene—Late Miocene age.

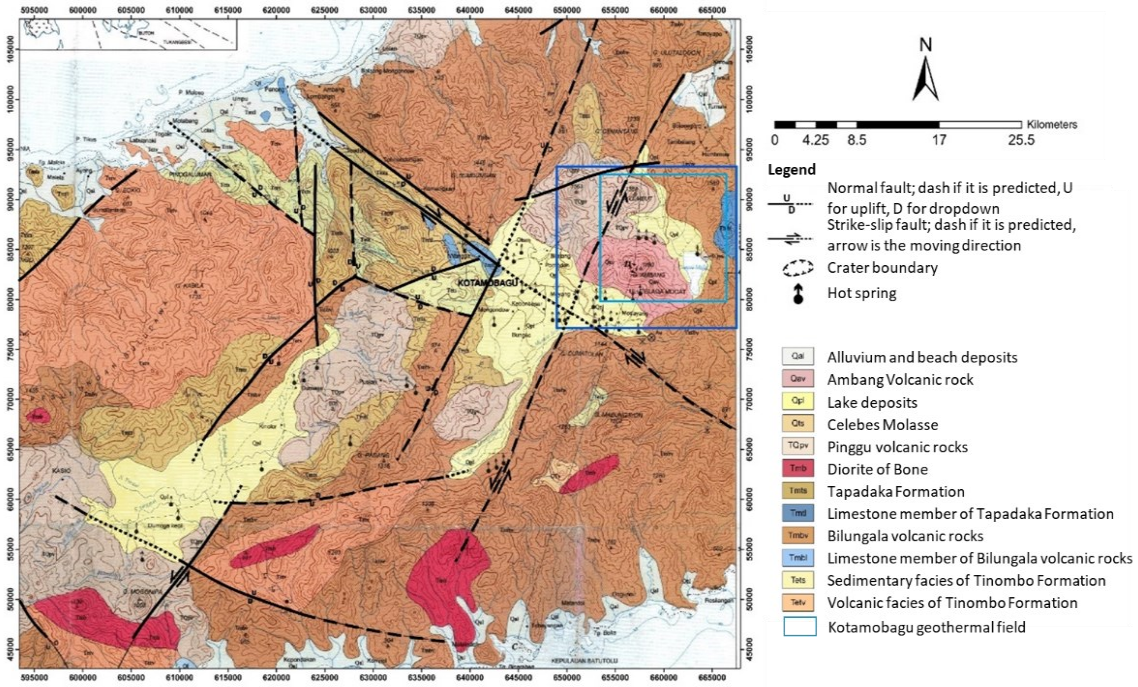

Figure 4: Regional geological map of Kotamobagu (Apandi & Bachri, 1997; Effendi & Bawono, 1997).

2.2.4 Pinogu Volcanic Rocks (TQpv)

This formation comprises tuff, lapilli tuff, volcanic breccia, and lava. Volcanic breccia is generally composed of andesite pyroxene and dacite. The tuff exposed on Mount Lemibut and Mount Lolombulan contains pumice fragments interspersed with lava. This rock unit is estimated to be Pliocene-Pleistocene in age.

2.2.5 Lake Deposits (Qpl)

Lake deposits consist of gray mudstone. In some places, it contains plant remains and lignite. Based on drill data, this unit has a thickness of 94 m.

2.2.6 Ambang Volcanic Rock (QAv)

This formation is composed of tuff, agglomerate, lahar deposits, lava, and sulfur deposits in the crater. Ambang Volcano is an active volcano with a strato cone shape and there are five fumarole fields.

3. DATA AND METHODOLOGY

The geological interpretation in Kotamobagu Geothermal Field is done by doing detailed geological mapping on the 20 x 20 km area. The steps of this research are collecting secondary data and lithology distribution mapping on the 137 observation points, including volcanostratigraphy and volcanic facies, distribution of alteration, and geological structure patterns in the Kotamobagu geothermal field and its surroundings. It also combines the subsurface data from the two existing wells on the southern flank of Mount Amban.

From the detailed mapping, hand specimens were taken and used for petrography and XRD analysis. These two analyses interpret the distribution of volcanostratigraphy and volcanic facies. The volcanostratigraphy and volcanic facies are then displayed on the 2D geological map and 2D cross-section.

4. KOTAMOBAGU GEOLOGICAL SETTING

4.1 Geomorphology

The Kotamobagu geothermal field has unique geomorphological conditions. The main location for this geothermal prospect is in the center, a row of young volcanoes surrounded by hillsides that look like caldera walls. Based on analysis of LiDAR data, topography, and aerial photography, the geomorphological units in the Kotamobagu geothermal field were divided into six units (Figure 5), namely:

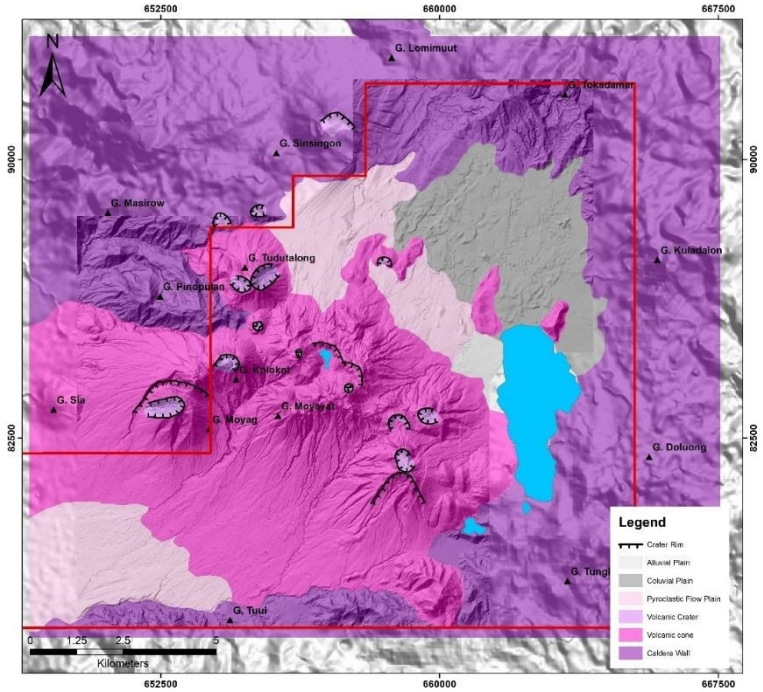

Figure 5: Geomorphological map of Kotamobagu geothermal field.

4.1.1 Alluvial Plain Unit

This unit is located in the middle of the Kotamobagu geothermal field on the northwest side of Lake Moaat. Its highest point is 1075 meters above sea level, and its lowest point is 1070 meters above sea level in the southwest, creating a height difference of 5 meters. The slope in measured units is approximately 1°. This unit is composed of loose deposits of fine material and soil.

4.1.2 Colluvial Plain Unit

This unit is located in the middle of the Kotamobagu geothermal field on the northside of Lake Moaat towards Makaaroyen. Its highest point is 1100 masl in the northeast, and its lowest point is 1079 masl in the southwest,

thus creating a slope that decreases towards the southwest. The slope in the measured unit starts at approximately 1°; however, the northwestern part of this unit has a wavy plain relief.

4.1.3 Pyroclastic Flow Plain Unit

This unit is located within the caldera wall and is a medial-distal slope on the southwest side of Mt. Ambang and north of Mt. Moyayat. This unit on the southwest side of Mt. Ambang has the highest point at 509 meters above sea level and the lowest point at 325 meters above sea level. On the north side of Mount Moyayat, the highest point is 1270 meters above sea level, and the lowest is 938 meters above sea level. The slopes on both parts of the measured unit start at approximately 3°. This unit is composed of lithology in the form of pyroclastic flow deposits and lahar.

4.1.4 Volcano Crater Unit

This unit is spread in the middle of the Kotamobagu geothermal field, especially along a row of mountains. It is the peak of these mountains, including Mt. Lemibut, Mt. Masiron, Mt. Tadutolong, Mt. Guaan 4, Mt. Kolokot, Mt. Kolokot Muda, Mt. Moyag, Mt. Ambang Muda 3, Mt. Ambang Muda 6, Mt. Ambang Muda 7, and Mt. Mooat. The geomorphological appearance of the volcanic crater unit is a volcanic depression at the top of the volcanic cone formed by pyroclastic flows and lava. This unit is included in the central facies, which is the center of the eruption.

4.1.5 Volcano Cone Unit

This unit extends to the center and surrounds the volcanic crater unit. This unit appears to be spread out in an NW-SE direction from Mount Moaat on the southeastern side to Mount Tudutalong and Mount Moyag on the northwest side. This type of unit has the highest point at 1701 meters above sea level and the lowest point at 347 meters above sea level, so it has a height difference of up to 1356 meters. The geomorphological appearance of the volcanic cone unit is a cone formed by pyroclastic flows and lava. This unit is included in the proximal-medial facies close to the eruption center.

4.1.6 Caldera Wall Unit

This unit is spread around the Kotamobagu geothermal field. This unit is interpreted as a horseshoe-shaped moat caldera wall with an opening to the southwest. This unit is the remains of Mount Tuui and Mount Tungkeng on the south and southeast sides, Mount Kuladalon and Mount Doluong on the east side, Mount Tokadamar and Mount Lomimuut on the northside, and Mount Masirow and Mount Pinopulan on the Northwest. This unit has the highest point at 1539 meters above sea level and the lowest point at 302 meters above sea level, so it has a height difference of up to 1237 meters. The geomorphological appearance of the caldera wall unit is a medium slope with wavy to steep relief composed of lava, breccia, and pyroclastic flows.

4.2 Stratigraphy

Based on observations at 137 points and after carrying out petrographic and XRD analysis on selected samples, the rock units in the Kotamobagu geothermal field can be separated into four units (Figure 6). This division is based on rock characteristics and interpretation of their associations. Then, comparisons are made with regional geological data to group these rock units based on the estimated age at which these units were formed because age dating has not been carried out on the existing samples. Based on this, the following rock units in the Kotamobagu geothermal field are sorted from oldest to youngest estimated units, namely:

4.2.1 Tertiary Volcanic Rock Unit

This rock unit is the oldest rock unit in the Kotamobagu geothermal field. This unit is spread around the Kotamobagu geothermal field. This unit is the remnant of an old Moaat volcanic cone. The lithology that makes up this unit includes andesite lava, which is the dominant constituent. Lithology is also found locally in the form of tuff breccia. Among the constituent lithologies, andesite lava is still exposed throughout the entire caldera wall, but the tuff breccia has experienced quite intense weathering, so no fresh samples were found (Figure 7).

Based on field analysis, andesite lava shows a yellowish gray to dark gray color, has a phenocryst size of 1-4 mm and a groundmass of <0.1 mm, is hypocrystalline, porphyro-aphanitic, with a phenocryst composition of plagioclase, pyroxene, hornblende, and fine-size groundmass. Photos of outcrops in the field can be seen in Figure 7a. Based on petrographic analysis (Figure 8), andesite lava has a porphyro-aphanitic texture and hypocrystalline crystallinity with phenocrysts in the form of plagioclase, biotite, and clinopyroxene as primary minerals. Phenocrysts measure 0.1-1.6 mm. Volcanic glass and plagioclase microliths are present as groundmass. Meanwhile, secondary minerals identified were sericite, opaque minerals, and fe-oxide. The name based on petrographic observations is pyroxene andesite (Streickesen, 1978 in Le Maitre, 2002).

Observation of the tuff breccia shows a grayish brown to brownish red color, some of the rock has experienced weathering and alteration, the material is fine ash - chunks. The rock fragments are brownish gray to reddish gray

andesite, have a porphyro-aphanitic texture, have a hypocrystalline rock structure with phenocrysts measuring 1-3 mm, and the groundmass is fine. The phenocryst composition consists of plagioclase, pyroxene, hornblende, biotite fine-sized groundmass, and secondary minerals. The matrix of the tuff breccia is grayish brown to yellowish brown, and the material is fine gray – coarse gray. The appearance of the outcrop in the field can be seen in Figure 7b.

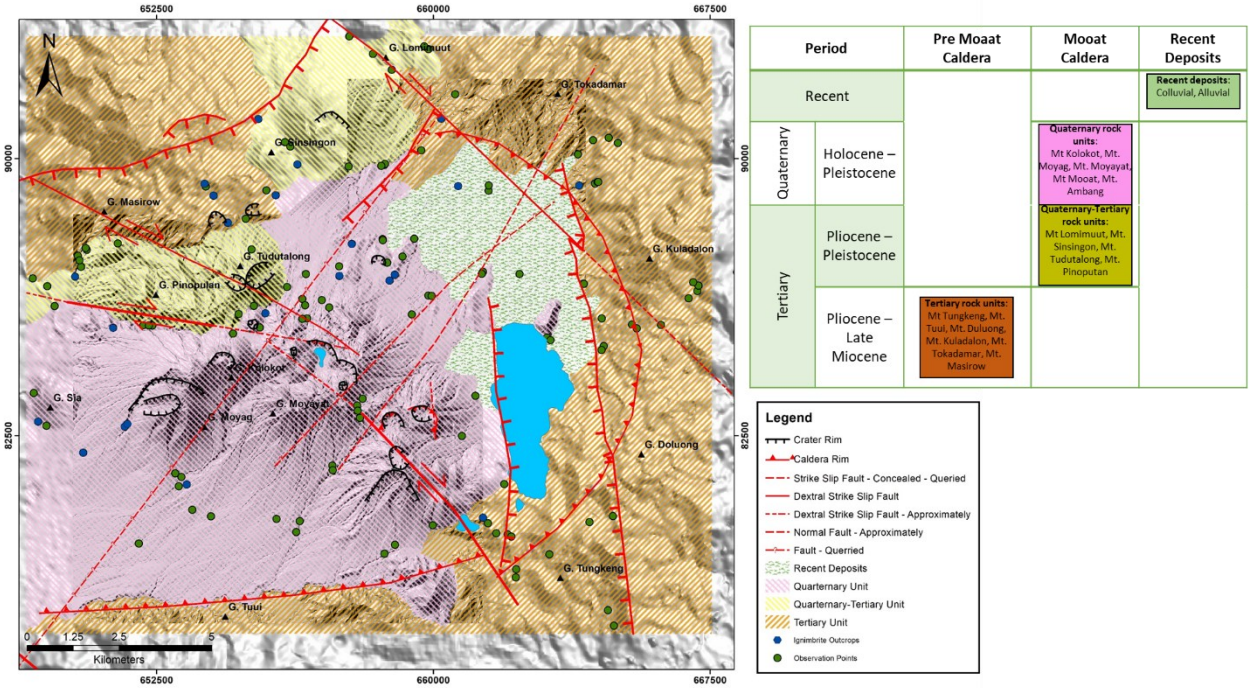

Figure 6: Geological map of Kotamobagu geothermal field. The lithological unit can be divided into four units based on the correlation with regional geology.

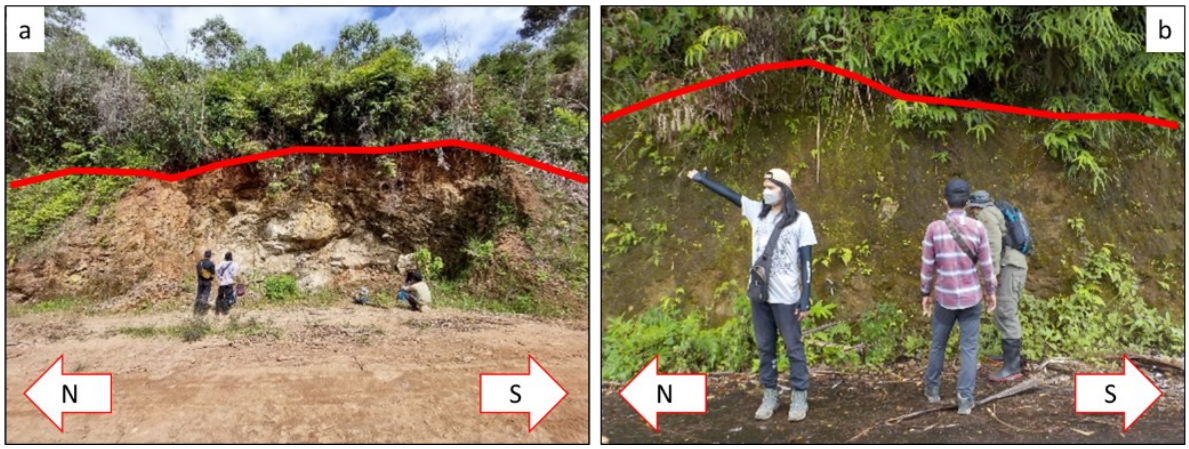

Figure 7: Outcrop of tertiary rock unit, a) Andesite lava outcrop near MT. Duluong, b) Tuff breccia outcrop near Mt. Kuladolon.

parallel and cross nicols respectively.

4.2.2 Quaternary-Tertiary Rock Unit

Quaternary-tertiary rock units are limited to the north and northwest sides of the Kotamobagu geothermal field. This unit appears in the northwesternmost part of the sill volcanic series and is deposited on top of tertiary rock units. Lithologically, the composition of this unit is not much different from that of tertiary rock units, namely composed of andesite lava and tuff breccia. However, what is different is that the tuff breccia lithology in this unit is only limited to around MT. Tudutalong and MT. Pinopulan and has fresher characteristics than the tuff breccia in the tertiary unit, although sampling cannot still be carried out.

The andesite lava that makes up the quaternary-tertiary rock unit shows a light to dark gray color, has a phenocryst size of 1-5 mm, and a fine groundmass, hypocrystalline, porphyro-aphanitic texture. The phenocryst composition

is plagioclase, pyroxene, hornblende, and fine groundmass. Photos of outcrops in the field can be seen in Figure 9a. Based on petrographic analysis (Figure 9c and Figure 9d), andesite lava has a porphyro-aphanitic texture and hypocrystalline crystallinity with phenocrysts in the form of plagioclase, clinopyroxene, biotite, and hornblende as primary minerals. Phenocrysts measure 0.1-1 mm. Volcanic glass and plagioclase microliths are present as groundmass. The rock experienced intensive alteration (IA = 0.6), which presented secondary minerals in the form of sericite, iron oxide, opaque minerals, quartz, and clay minerals. The name based on petrographic observations is biotite andesite (Streickesen, 1978 in Le Maitre, 2002).

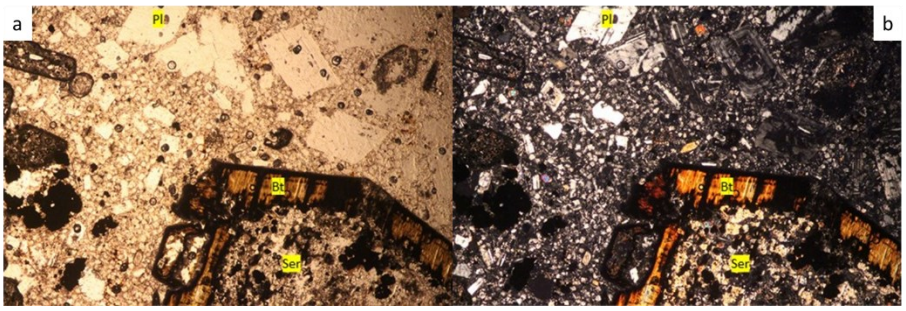

Figure 8: Andesite lava of tertiary rock unit under petrographic analysis. a) parallel nicols, b) cross nicols.

Figure 9: Outcrop of quarternary-tertiary rock unit, a) Andesite lava outcrop, b) Tuff breccia outcrop. Both of the outcrop located near Mt.Pinopulan, (c) and (d) are thin section of andesite lava in

The tuff breccia in Mount Pinopulan shows a characteristic brown color; some of it has experienced weathering (Figure 9b). The rock fragments are dark gray andesite, porphyro-aphanitic texture, hypocrystalline, and 1-3 mm phenocrysts. The groundmass is fine. The phenocryst composition consists of plagioclase, pyroxene, and fine groundmass minerals. The matrix of the brown tuff breccia is composed of fine ash - coarse ash-sized material.

4.2.3 Quaternary Rock Unit

This rock unit is in the central part of the Kotamobagu geothermal field and is the deposit of a row of young volcanoes that emerged in Kotamobagu. This rock unit is spread from Mt. Kolokot on the northwest side to Mt. Moaat on the southeastern side. The distribution of this rock unit is closely related to the geological structure in the form of the Ambang-Poopo dextral strike-slip fault with an NE-SW direction (Figure 13). The lithology exposed in this rock unit is closely related to the formation and eruption period of the existing volcano.

The dominant lithology that makes up this rock unit is andesite lava. These rocks are scattered throughout the volcanoes along the NE-SW Ambang-Poopo fault, including on Mt. Moyayat, Mt. Kolokot, Mt. Moyag, Mt. Moaat, Guaan, and Mt. Ambang, which are the youngest volcanoes in the Kotamobagu area. Andesitic lava has field characteristics showing a brownish gray, reddish color, has a phenocryst size of 1-3 mm, and a fine, hypocrystalline, and porphyro-aphanitic groundmass. The phenocryst composition consists of plagioclase minerals, hornblende, and fine groundmass (Figure 10a). Based on petrographic observations, a porphyritic

texture and hypocrystalline crystallinity were found, with the main phenocryst composition being plagioclase, biotite, hornblend, clinopyroxene, and opaque minerals (Figure 11a and Figure 11b). The phenocrysts in this rock measure between 0.1 to 4 mm and are euhedral-subhedral. The groundmass is composed of plagioclase microliths, biotite microliths, pyroxene microliths, and glass material. The secondary minerals that appear are alunite, chlorite, iron oxide, clay minerals, opaque minerals, and sericite.

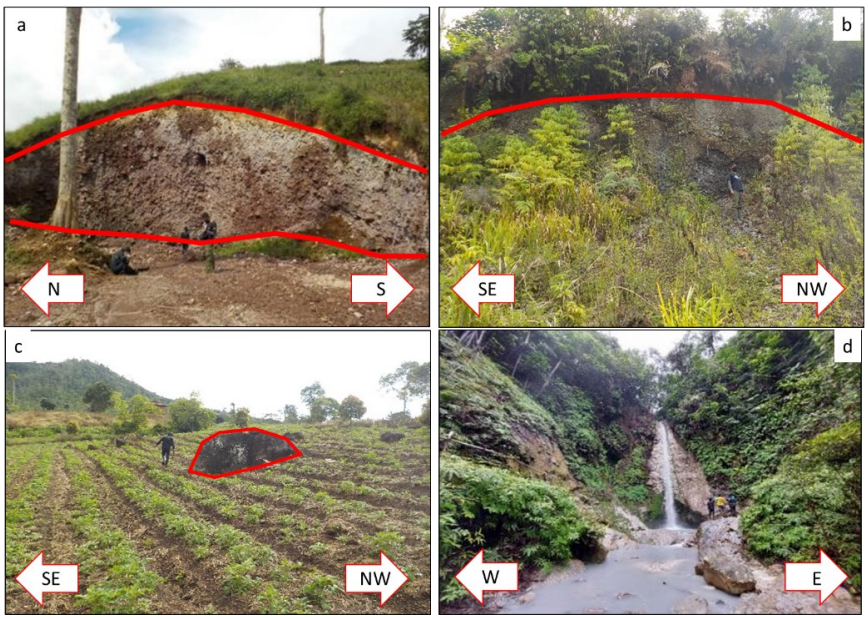

Figure 10: Outcrop of quarternary rock unit, a) Andesite lava near Guaan, b) Tuff breccia near Mt. Moyayat, c) Laharic breccia near Mt. Moyayat, d) Dacitic breccia near Mt. Ambang.

The other lithology that makes up Quaternary rock units is tuff breccia, which appears locally in Mt.Moaat, Mt.Moyag, Mt.Kolokot, and Mt.Moyayat (Figure 10b). Tuff breccia shows a yellowish-brown color that has undergone alteration and is composed of fine ash-lump-sized material. The rock fragments are gray andesite, porphyro-aphanitic, and hypocrystalline texture with phenocrysts measuring 1-4 mm; the groundmass is fine. The phenocryst composition consists of plagioclase, pyroxene, hornblende minerals, and a groundmass of fine-sized intermediate minerals. The matrix of the yellowish-brown tuff breccia is composed of fine ash - coarse ash-sized material.

Laharic breccia deposits were also found at several points in this Quaternary rock unit, especially in the Mt. Kolokot and Mt. Moyayat areas. This deposit was identified from chunk-sized andesite fragments in the middle of rice fields. These fragments were identified as a matrix of laharic breccia that had experienced intense weathering (Figure 10c).

The final lithology that makes up the Quaternary rock unit is dacite lava, which appears in the youngest volcanoes in the Kotamobagu area, including Mt. Moaat and Mt. Ambang (Figure 10d). This dacite lava often appears around the Mt. Ambang crater, especially on the southwest slopes. Observations of dacite in the field show a bright gray color, a phenocryst size of 1-5 mm, a fine hypocrystalline, and porphyro-aphanitic groundmass. The phenocryst composition consists of plagioclase, quartz, hornblende, pyroxene, biotite, and a groundmass of fine-sized intermediate minerals. Based on petrographic observations, a porphyritic texture and hypocrystalline crystallinity were found, with the main phenocryst composition being plagioclase, biotite, quartz, clinopyroxene, and hornblend (Figure 11c and Figure 11d). The phenocrysts in this rock measure between 0.1 to 4 mm and are euhedral-subhedral. The groundmass is composed of plagioclase microliths and glass material. The secondary minerals that appear are opaque minerals and sericite. The name of the rock is based on the petrographic description, namely biotite dacite (Streickesen, 1978 in Le Maitre, 2002).

4.2.4 Recent Depositional Units

Recent deposit units are spread on the north side of Lake Moaat towards Makaaroyen and reach the walls of the Moaat caldera. In terms of field appearance, there are two groups of rocks from recent sedimentary units. These, namely colluvial deposits, are the result of erosion of the caldera walls on the north and east sides (Figure 12a and Figure 12b). Colluvial deposits are composed of sand-gravel depositional lithology. Observations in the field showed a whitish-brown color and fine sand grain size, but they were not consolidated. The composition consists of sand-sized volcanic material and pebble-sized tuff - gravel. Based on petrographic analysis of this depositional fragment, a porphyritic texture, and hypocrystalline crystallinity were found, with the main phenocryst

composition being plagioclase, biotite, clinopyroxene, and hornblende. The phenocrysts in this rock measure between 0.1 to 3 mm and are euhedral-subhedral (Figure 12c and Figure 12d). The basic mass is composed of plagioclase microliths and glass material. The secondary minerals that appear are opaque minerals and sericite. There is also mineral filling in the form of alunite. The naming of the rock is based on the petrographic description, namely biotite andesite (Streickesen, 1978 in Le Maitre, 2002).

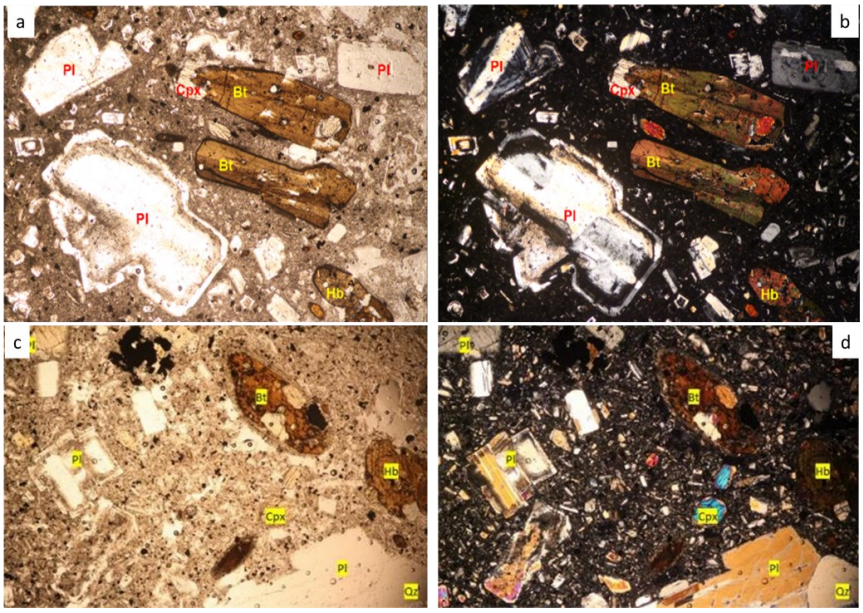

Figure 11: Thin section of quaternary rock units. (a) and (b) parallel and cross nicols of Andesite lava, (c) and (d) are parallel and cross nicols of Dacitic lava.

Figure 12: Outcrop of recent depositional units (a) and (b). Thin section of colluvial deposit in parallel and cross nicols (c) and (d).

In contrast to colluvial deposits, other recent depositional units are composed of alluvial deposits. This deposit is the result of the deposition of a moat lake, which has the characteristics of being composed of sand-gravel depositional lithology. Observations in the field showed a whitish-brown color, fine sand grain size, and gravel that was not consolidated. The composition consists of sand-sized volcanic material and pebble-sized tuff.

4.3 Geological Structure

Interpretation of geological structures in the Kotamobagu geothermal field is quite difficult. This is because most outcrops have experienced weathering, and alluvial and colluvial deposits cover the middle part of the location. Based on an analysis of satellite and LiDAR images, there is an NE-SW trend lineament (Ambang-Makaaroyen

Fault) that extends from Ambang Mountain to Makaaroyen. This lineaments interpreted to connect the manifestations in the Mt. Ambang crater and the Makaaroyen manifestations. The structure characterized by this lineament is not exposed on the surface because it is buried by colluvial sediment units deposited in the last sedimentation period.

The main geological structure that controls the evolution of volcanoes in the Kotamobagu geothermal field is the Ambang-Poopo fault, which is at the center of this field. This geological structure is exposed on the southeast side of the Kotamobagu geothermal field on the caldera wall (Figure 13). The outcrop is a cliff with dimensions of 2 x 4 x 4 meters (Figure 13a). Indications of the geological structure found at this location are stepping on the fault plane with an average orientation of N312°E/78° from 15 measurements. The stepping pattern on the fault plane at this location shows right-hand (dextral) shear dynamics.

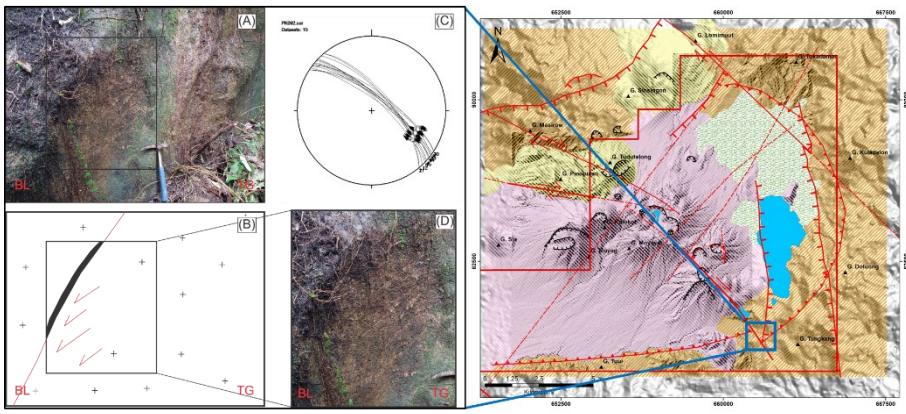

Figure 13: Field features and a sketch of the main geological structure trending NW-SE, a dextral strike-slip fault.

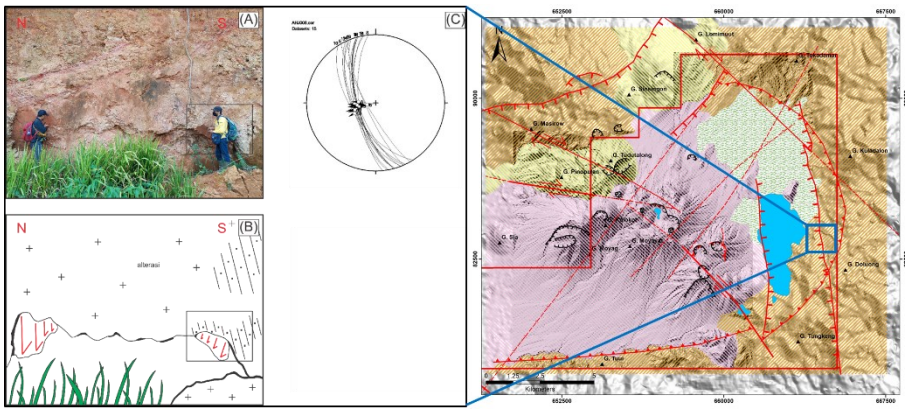

Figure 14: Field features and a sketch of the N-S normal fault near Mt. Duluong.

Another geological structure in the Kotamobagu geothermal field is found on the east wall of the Mooat caldera (Figure 14). This structure was found in the andesite lava lithological unit and is an outcrop in a field measuring 15 x 20 meters. Indications of the geological structure found at this location are structural mirror striations with a fault plane orientation with an average of N164°E/69° from 15 measurements (Figure 14). Observation and measurement of striations at this location indicate downward movement of the deformed block to the west.

4. DISCUSSION

The evolution of the formation of the Kotamobagu geothermal field is interpreted using existing data, including lithology, geological structure, and geomorphology data. Based on the interpretation of the existing topography and geomorphological units, the Kotamobagu geothermal field began to form during the Tertiary with the presence of the old Mooat Volcano, which then erupted and produced the Moaat Caldera. Evidence of this eruption is marked by the appearance of ignimbrite deposits around the Kotamobagu location and reaching the Tutuyan area (Figure 6). The ignimbrite was spread out when the big eruption of the old Mooat Volcano happened. It is characteristic of pumice that is vesicular and filled with quartz in the cavity (Figure 15).

In the Late Miocene to Pliocene, based on regional tectonics, the subduction process of two tectonic plates, namely the Celebes Sea and the Sula-Button, resulted in the formation of NW-SE trending dextral strike-slip faults along the northern arm of Sulawesi (Figure 16) (Hall & Wilson, 2000; Hall, 2012), one of the faults that appears is the

Ambang fault. The appearance of this Ambang fault started the process of volcanism in the Kotamobagu field, where this Ambang fault was interpreted as a way for magma to escape, forming a row of volcanoes in the Kotamobagu field (Figure 17).

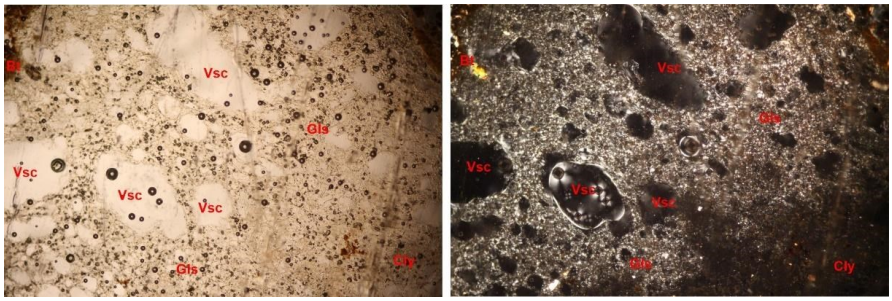

Figure 15: Thin section of the pumice with the vesicular is filled by quartz.

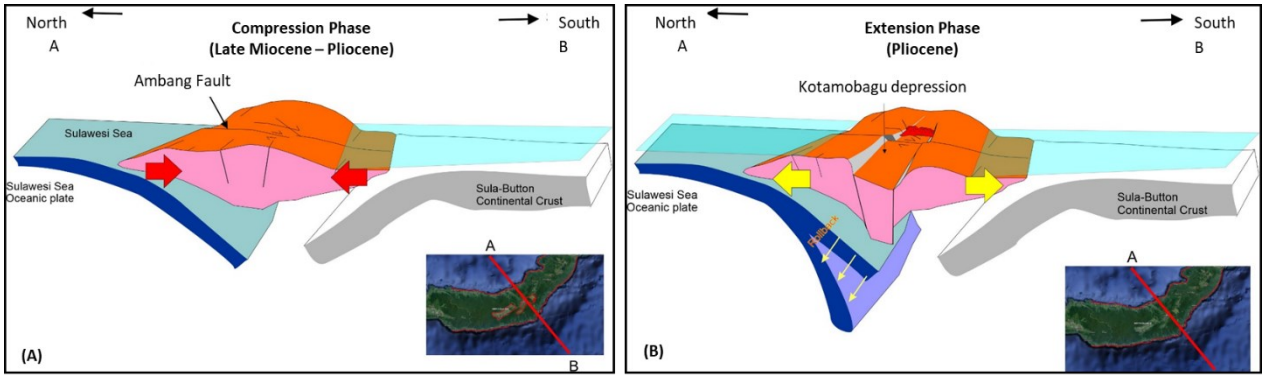

Figure 16: Tectonic process in North arm of Sulawesi at Late Miocene – Pliocene (A) compression phase, (B) extension phase (modified from Hall & Wilson, 2000; Hall, 2012).

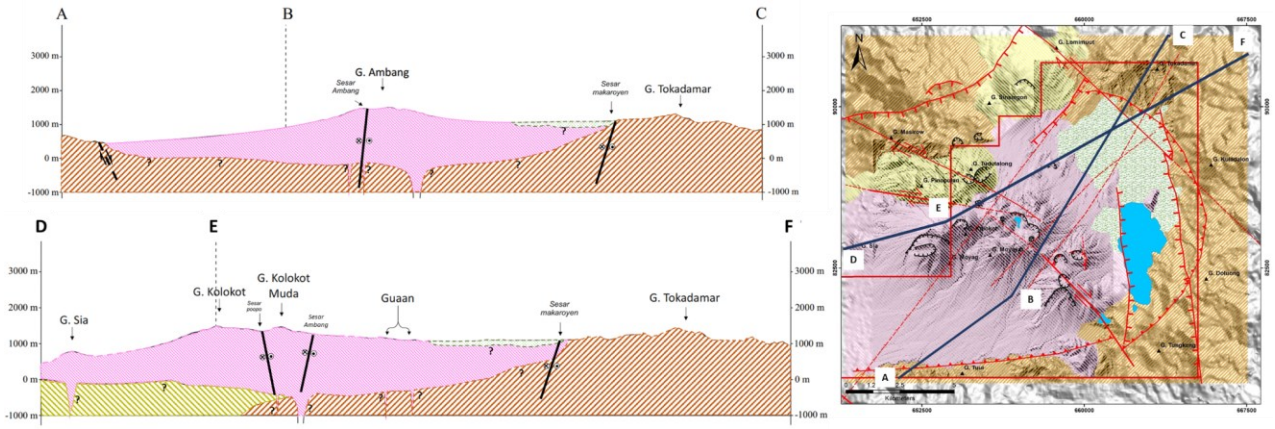

Figure 17: Cross section of the geological map. Showing the Quaternary rock units intruded the Tertiary rock units near the Ambang Fault.

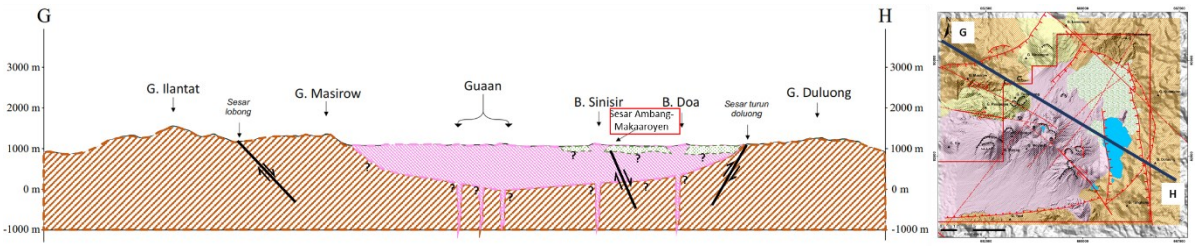

Figure 18: Geological cross section showing Ambang-Makaaroyen Fault (red square).

The process of magmatic evolution in the series of volcanoes in Kotamobagu starts from the northwest side, which is identified with the emergence of Mt. Tudutalong, Mt. Pinoputan, Mt. Kolokot, and Mt. Moyayat. Then, the magma evolution moved southeast towards Mt. Moaat and Mt. Ambang, which are the youngest volcanoes in the

Kotamobagu field. This magma evolution is categorized by a difference in the magmatic content of the lava in the northwest volcanoes, which are dominated by andesite-type lava. Meanwhile, on the mountains on the southeast area, there is dacitic-type lava, which has more acidic characteristics caused by the magma differentiation process.

During the process of volcanism during the Pliocene, it is interpreted that an extension phase occurred in the northern arm of Sulawesi (Hall & Wilson, 2000; Hall, 2012). This extension phase causes a rollback in the Celebes Sea tectonic plate, which provides an extension force and causes NE-SW trending structures to appear, one of which is the Ambang-Makaaroyen Structure, which is interpreted from drilling data on the southwest side of Mount Ambang and the alignment in satellite image data (Figure 18). Furthermore, due to the weathering process on the rocks on the moat caldera walls and rocks along the volcano, materials were deposited that filled the NE-SW structure (Ambang-Makaaroyen Fault), which was formed at a lower location.

5. CONCLUSION

The geological interpretation of the Kotamobagu Geothermal Field, conducted through detailed geological mapping, reveals a complex and dynamic geological history. The study covers a 20 x 20 km area, incorporating 137 observation points and integrating subsurface data from two wells on the southern flank of Mount Amban. The research methodology involves collecting secondary data, lithology distribution mapping, and analyzing volcanostratigraphy, volcanic facies, alteration distribution, and geological structure patterns. Hand specimens collected during the mapping were analyzed using petrography and X-ray diffraction (XRD) to interpret the distribution of volcanostratigraphy and volcanic facies, subsequently displayed on 2D geological maps and cross-sections.

The geomorphology of the Kotamobagu Geothermal Field is characterized by diverse units, including alluvial plains, colluvial plains, pyroclastic flow plains, volcano craters, volcano cones, and caldera walls. Each unit displays unique topographical features and geological compositions. For instance, the alluvial plain unit is composed of loose deposits of fine material and soil. In contrast, central to the geothermal field, the volcano crater unit consists of volcanic depressions formed by pyroclastic flows and lava. The stratigraphic analysis identifies four primary rock units, ranging from the oldest Tertiary rock units, predominantly andesite lava and tuff breccia, to the youngest Quaternary rock units, which include andesite and dacite lavas.

Despite the challenges posed by weathered outcrops and sediment cover, geological structure analysis highlights the significance of the NE-SW trending Ambang-Poopo fault. This fault plays a crucial role in the magmatic and volcanic evolution of the Kotamobagu field, facilitating magma escape and the formation of volcanoes. The magmatic evolution appears to progress from northwest to southeast, transitioning from andesite-dominated lavas to more acidic dacitic lavas due to magma differentiation.

The study concludes that the formation of the Kotamobagu Geothermal Field is deeply intertwined with regional tectonic activities, particularly the subduction and extension phases in the northern arm of Sulawesi. These tectonic processes influenced volcanic activity, resulting in the diverse geological features observed in the field today. The extension phase, in particular, facilitated the formation of NE-SW trending structures, such as the Ambang-Makaaroyen structure, crucial for understanding the region's geothermal potential.

ABSTRACT

During the exploration phase, identification of geological structures, especially faults, has a very important role in determining geothermal potential based on rock permeability characteristics. However, in its implementation, there are a number of technical obstacles that hinder the accuracy of identifying these structures, including the complexity of field conditions which is often caused by the presence of cloud cover, dense vegetation, and subjectivity in the lineament delineation process. This study tackles the challenge of identifying geological structures, like faults, crucial for geothermal exploration in Kotamobagu, North Sulawesi.

This study introduces the application of the mSTA (modified Segment Tracing Algorithm) method as a solution for automatically detecting alignment from Synthetic Aperture Radar (SAR) images produced by the SENTINEL-1 satellite in the Kotamobagu geothermal area, North Sulawesi. Analysis of the results shows that the mSTA method is able to produce identification of 1657 lineaments in the ascending orbit and 2089 in the descending orbit. The identified lineament patterns depict strong associations with existing tectonic and volcanic structures.

By categorizing lineaments based on orientation and length, we discern a dominant radial pattern in the central study area. Furthermore, the high frequency density (Lf) anomaly observed on this lineament is significantly correlated with the local geological structure and the presence of hot springs. These findings underscore the promising utility of mSTA in overcoming environmental constraints for geothermal exploration.

1. INTRODUCTION

The use of remote sensing methods is remarkably effective in identifying geological structures to estimate subsurface geological features from the Earth's surface. In geothermal exploration, pinpointing geological structures, particularly faults, helps locate potential geothermal areas by assessing rock permeability. Visual analysis correlating lineaments with geological structures is commonly employed to gauge surface rock permeability. However, challenges such as cloud cover, vegetation, and the subjective nature of lineament delineation often hinder the accuracy of these assessments.

Remote sensing methods have been extensively and effectively utilized in geological tasks such as mapping alterations, distinguishing lithologies, and exploring minerals (Van der Meer et al., 2012). The advancement of satellite remote sensing systems has thus provided geologists with a potentially cost-effective substitute for conventional methods, which are known to be expensive, time-consuming, and labor-intensive. In utilizing these advantages, the lineament detection method is automated using the mSTA (modified Segment Tracing Algorithm) to estimate the presence of faults and fracture permeability in the Kotamobagu geothermal field, North Sulawesi (Figure 1).

The mSTA method is an automated lineament detection technique applied to Synthetic Aperture Radar (SAR) imagery, based on digital value contrast to detect lineament segments (Saepuloh et al., 2018). SAR imagery obtained from radar satellite sensors at microwave wavelengths can overcome cloud cover and vegetation canopy, thus enabling detected lineaments to closely approximate actual geological structure features (Saepuloh, 2021). The accuracy of lineament detection determines the precision of identifying geological structures (faults) and surface fracture permeability.The study utilizes automated detection of geological structure lineaments through the mSTA method, followed by statistical analysis to identify faults. Fracture permeability calculations are then derived from the identified mSTA lineaments. Verification of both structure and fracture permeability accuracy is conducted using full polarimetric SAR imagery.

2. GEOLOGICAL SETTING

Sulawesi Island, shaped by complex tectonic since the Late Mesozoic and Cenozoic periods (Figure 2), exhibits a diverse geological landscape comprising magmatic arcs, metamorphic rocks, ophiolites, and microcontinental fragments. These features are organized into distinct tectonic provinces separated by major faults (Hall, 2002; Cottam et al., 2011).

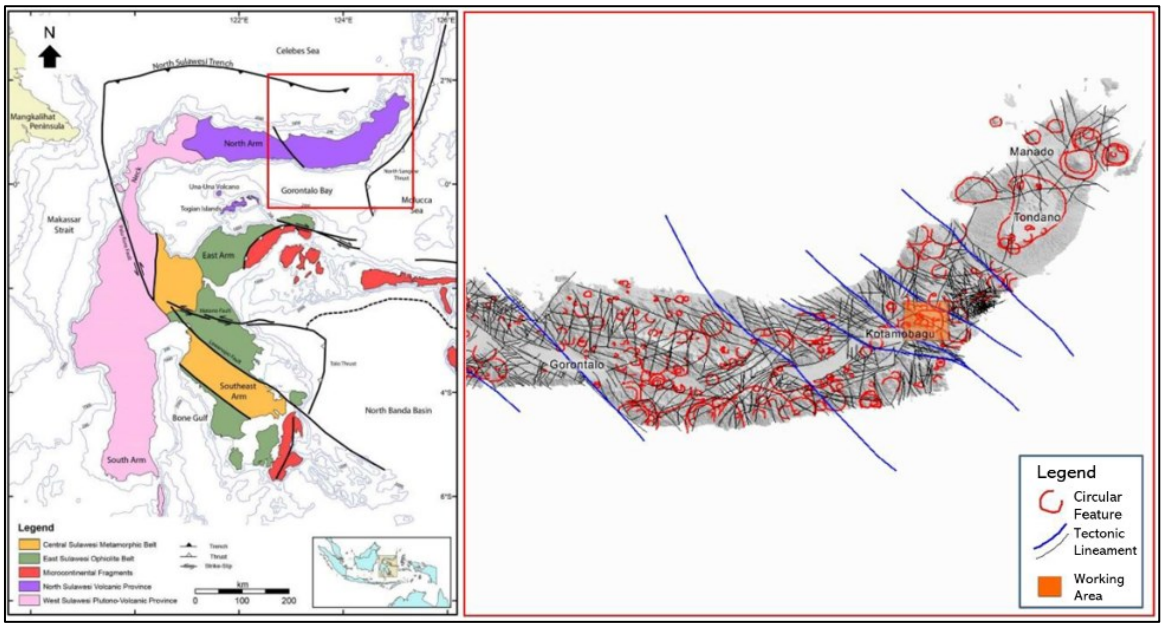

Figure 2: Tectonic Complex of Sulawesi (left) and North Sulawesi (right).

The western arm of Sulawesi spans from Gorontalo Bay to Makassar and developed as a continental margin in the Late Mesozoic on Sundaland's southeastern edge. Its basement includes metamorphic complexes like the Bantimala Complex, formed during Late Cretaceous subduction beneath Sundaland. Rift processes in the Early Tertiary thinned the lithosphere in the Makassar Strait, accompanied by intermittent volcanic activity until the Early Miocene, which deposited carbonate and siliciclastic deposits.

The eastern arm, encompassing areas such as Tojo Una-una and Luwu, is characterized by ophiolites dating from the Cretaceous to Eocene periods. Central Sulawesi, divided into northern Poso and southern Kendari regions, acts as a metamorphic belt separating the western and eastern arms. The Banggai-Sula complex hosts

microcontinental fragments with Palaeozoic metamorphic rocks intruded by Permo-Triassic granites and associated volcanic rocks, including Eocene to Neogene limestones.

The northern arm of Sulawesi, from Gorontalo to Manado, features a Tertiary volcanic arc on Eocene oceanic crust, influenced by northward subduction of the Indian Ocean lithosphere. This area, which includes the Kotamobagu Geothermal Field, illustrates complex interactions among tectonic plates such as the Eurasian, Philippine/Celebes Sea, Molucca Sea, and Indo-Australian plates. Volcanic formations range from Eocene bimodal rocks to recent Calc-Alkaline formations, shaped by ongoing tectonic processes and subduction activities (Elburg and Foden, 1998; Hall, 2012). These geological insights highlight Sulawesi's dynamic tectonic history, providing a framework for understanding its diverse geological formations and their implications for resource exploration and hazard assessment in the region.

The Kotamobagu Geothermal Field (Figure 3) is situated within four districts in North Sulawesi Province, positioned on the northern arm of Sulawesi, approximately 200 km south of Manado City. At its core lies within the Mount Ambang complex, indicative of the volcanic activity prevalent in this area.

3. DATA AND METHOD

3.1. Data

3.1.1 Sentinel-1A/B

Sentinel-1 is the first satellite constellation of the Copernicus Program operated by the European Space Agency (ESA). The Sentinel-1 mission consists of two satellites, Sentinel-1A and Sentinel-1B, sharing the same orbit. They carry C-band Synthetic Aperture Radar (SAR) instruments capable of providing all-weather, day-and-night data with spatial resolution up to 5 meters and swath width up to 400 kilometers. The satellite constellation operates in a near-polar, sun-synchronous orbit (98.18°), completing 175 orbits per 12-day cycle. Two scenes of Sentinel-1 images, in ascending and descending orbits with dual polarization, are utilized for lineament detection, geological structure identification, and fracture permeability assessment.

3.1.2 ALOS PALSAR

The Phased Array type L-band Synthetic Aperture Radar (PALSAR) is an active microwave sensor utilizing L-band frequency for cloud-free land observation both day and night. Installed on the ALOS satellite, this sensor offers enhanced performance compared to previous generation SAR sensors like JERS-1. The development of PALSAR was a collaborative project between JAXA and the Japan Resources Observation System Organization (JAROS). Two scenes of ALOS PALSAR images in ascending orbit with full polarization are employed for visual verification of geological structures and fracture permeability.

3.2 Pre-Processing

The Sentinel-1 image footprint in both ascending and descending orbits has covered the study area adequately, requiring only one scene each (Figure 4). In contrast, the ALOS PALSAR image footprint in ascending orbit with full polarization requires two scenes due to the study area being located at the boundary edge of the scene.

NO	SENSOR	ID	TANGGAL	ORBIT	POLARISASI
1	SENTINEL-1B	S1B_IW_SLC__1SDV_ 20210716T100236	2021/07/16	ASCENDING	VV VH
2	SENTINEL-1A	S1A_IW_SLC__1SDV_ 20221115T212619	2022/11/15	DESCENDING	VV VH
3	ALOS PALSAR	ALPSRP064990000	2007/05/30	ASCENDING	HH HV VH VV
4	ALOS PALSAR	ALPSRP064990010	2007/05/30	ASCENDING	HH HV VH VV

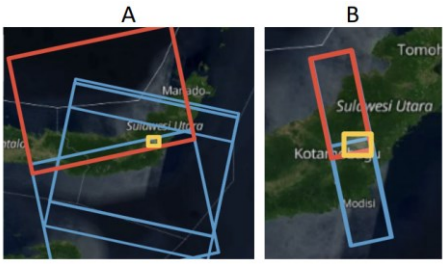

Figure 4: Dataset of Alos Palsar (left) and Sentinel-1A/B (right).

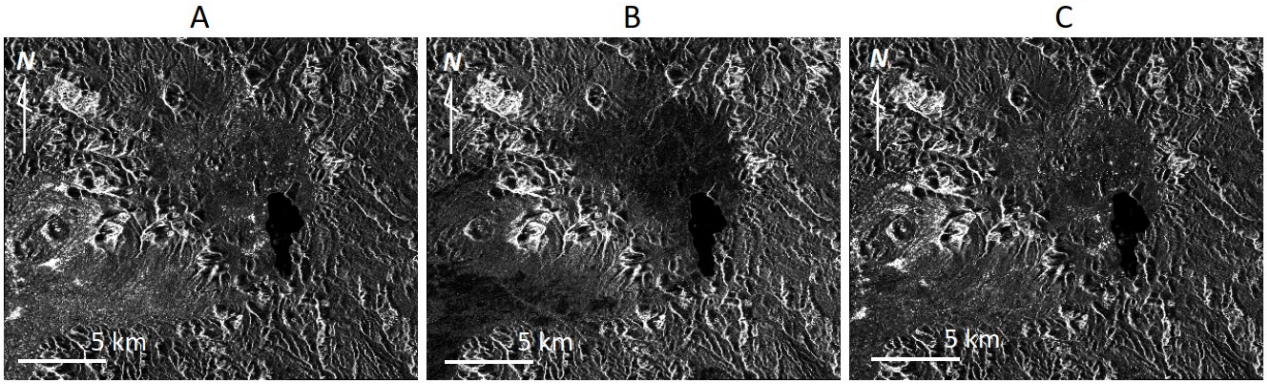

Figure 5: ALOS PALSAR HH, HV, and VV polarizations.

The study commences by obtaining data from ALOS PALSAR, followed by extracting images and performing polarimetric decomposition using the Yamaguchi method. Processing ALOS PALSAR data involves seven distinct steps, starting with: (1) data preprocessing, (2) multilooking, (3) ALOS deskewing, (4) geometric correction, (5) polarimetric matrix generation, (6) polarimetric speckle filtering, and (7) polarimetric decomposition. The geometrically corrected polarimetric image displays different tones and textures for HH, HV, and VV polarizations (Figure 5). The H and V polarizations represent the horizontal and vertical orientations of the wave propagation transmitted by the sensor and returned by objects on the surface.

Meanwhile, the processing of Sentinel-1 data involves seven distinct steps, starting with: (1) data preprocessing, (2) Multilooking, (3) Speckle filtering, (4) geometric correction, (5) automated lineament detection using mSTA. These processing stages are conducted using the SNAP software platform and subsequently continued with MATLAB scripts. Geometrically corrected Sentinel-1 images from both ascending and descending orbits exhibit clear morphological features from two different viewing perspectives (Figure 6).

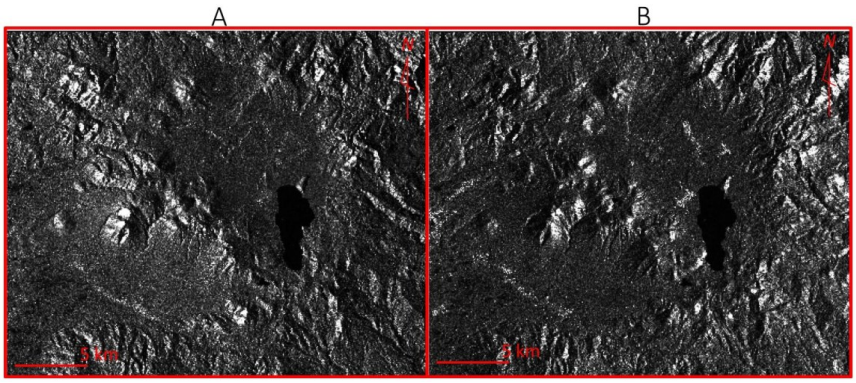

Figure 6: SENTINEL-1/B Pre-Processed Data.

4. PROCESSING

4.1 Lineament Detection

In detecting the geological structure lineaments, Synthetic Aperture Radar (SAR) images from dual-orbit observations of the same surface object are used. These observations include ascending orbits, which move from south to north, and descending orbits, which move from north to south. Illustration of ascending and descending orbits of SAR satellites.

The detection of geological lineaments utilizes SAR (Synthetic Aperture Radar) images from dual-orbit observations, crucial for reducing geometric distortions from off-nadir SAR image acquisitions and providing information from both viewing directions. Automated extraction of geological lineaments employs the modified Segment Tracing Algorithm (mSTA) on processed SAR images (Saepuloh et al., 2018). Initially, a window size of 11×11 pixels is set to assess whether the center of the window represents a line element.

16 directions at intervals of 11.25 degrees passing through the window center are defined to examine local variations in grayscale intensity. The orientation is determined by calculating deviations from the center pixel along the defined scan lines. The direction with the minimum value is assumed as the line direction and denoted as kmin. In the second step, along the perpendicular direction to kmin, denoted as kmax, analysis is conducted based on the equation:

$$\Lambda = \sum_{i=-(a-1)}^{a-1} \lambda_i = \sum_{i=-(a-1)}^{a-1} \left[\frac{(Z_{i+1} - 2Z_i + Z_{i-1})^2}{Z_i} \right]$$

where Zi is the grayscale intensity at pixel i. Λ is used to create a dynamic threshold (T), so line elements closer to the azimuth angle have lower threshold levels. The average (m) and standard deviation (σ) of Λ define the threshold (T) as $T = m + \mu\sigma$, with μ calculated using equation (3).

In the third step, evaluation determines whether the center pixel represents a ridge or a valley. Along the scan line from kmax, the sum of grayscale levels at i = -a to -1 and l to a are calculated and denoted as $\tau 1$ and $\tau 2$. If $\tau 1 \geq \tau 2$, the center pixel is assumed to be located in a valley (potential pixel). The fourth step involves connecting the line elements obtained from the previous steps. For a specific center pixel (p) in the direction kmin, it is linked to another center pixel within the direction range of kmin - 11.25 degrees to kmin + 11.25 degrees. The distance between p and the farthest potential pixel within the distance range (D) is calculated using equation (4).

Lastly, if multiple pixels align along the same valley, they may form multiple intersecting line elements with the same direction. Step five transforms complex line elements and curved valleys into straight lines using Principal Component Analysis.

4.2 Fracture Permeability Identification

After extracting lineaments successfully from dual-orbit SAR images, a grouping process is conducted to eliminate lineaments originating from backscatter or noise. Density calculations are then performed for each grid of a specified size to obtain three density parameters: length density (l), intersection density (i), and frequency density (f). Length density represents the total length of lineaments within each grid. Intersection density indicates the number of intersections of lineaments within each grid.

Frequency density denotes the total number of detected lineaments within each grid. A grid size of 1×1 km is considered optimal for extracting geological features, given the image size of approximately 800×800 pixels (Figure 7; Saepuloh et al., 2018).

4.3 Visual Analysis of Polarimetric SAR Images

The use of full-polarization SAR data channels is highly effective for identifying surface geological features in tropical regions. Polarimetric images can map the boundaries of volcanic products, which serve as the basis for determining volcanic stratigraphic units such as khuluk and gumuk, as well as visualizing geological structures for 1:30,000 scale mapping. Analysis of the distribution boundaries of volcanic products and geological structures is based on patterns of tone, texture, and brightness of SAR backscatter intensity pixels. The morphology and structure of volcanoes play a crucial role in geothermal exploration. Detected morphological and structural features include lava flow patterns filling valleys on volcanic slopes, structural fractures, and circular and radial patterns formed by eruption centers such as craters, domes, and lava flows (Figure 8). Bright tones indicate high backscatter from complex-geometry volcanic products and/or high rock reflectivity. Dark tones indicate volcanic products with simpler geometries like plains and water surfaces, or low reflectivity rocks like dry alluvial sands. Dark and bright contrasts can be analyzed to potentially identify geological structures such as faults visually.

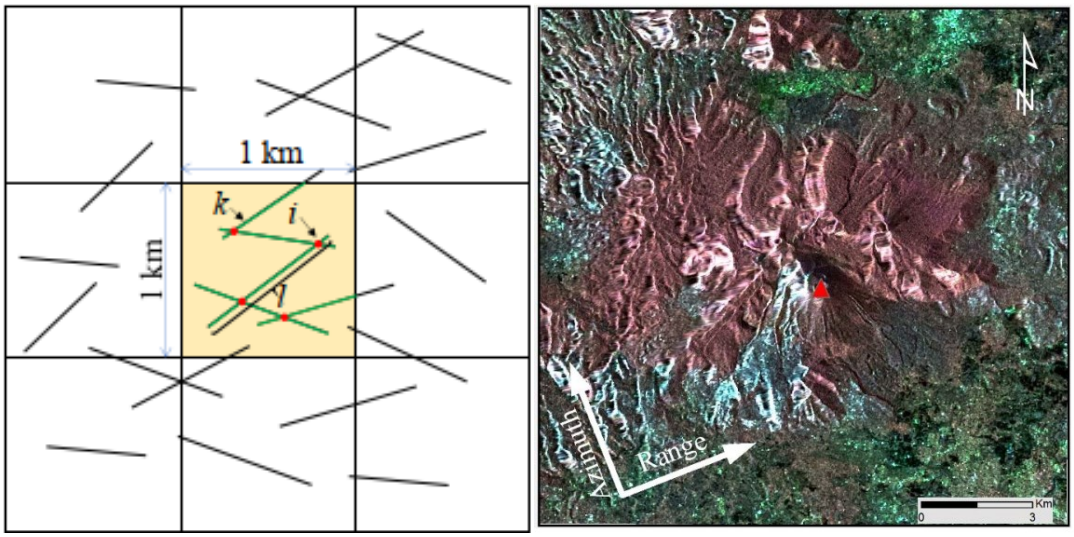

Figure 7: (Left): Illustration of lineament density for each 1×1 km grid; Figure 8 (Right): The composite polarimetric SAR backscatter intensity image from ALOS PALSAR with R,G,B = σHH, σHV, σVH highlights the morphology and structural features of volcanic products originating from eruption centers, marked by the red triangle (Bakker and Saepuloh, 2017).

4.4 Lineament Detection using modified Segment Tracing Algorithm (mSTA)

The modified Segment Tracing Algorithm (mSTA) detects linear features automatically. Essentially, mSTA utilizes differences in backscattering intensity (contrast and relief) from the image to identify linear patterns (Saepuloh et al., 2018). The mSTA method implemented here utilizes a MATLAB script developed by Saepuloh et al. (2018). There are several steps involved in the mSTA method for detecting linear features or lineaments in SAR images: (1) setting the observation area in pixels to detect linear elements, (2) determining secondary quadratic differentiation for grayscale levels, (3) evaluating each line representing ridge or valley features, (4) defining linear elements, and (5) performing principal component analysis to identify features with the same direction intersecting each other.

5. IMAGE PROCESSING

5.1 SAR Images Extraction

The satellite ALOS PALSAR level 1.1 images were classified using polarimetric methods, including matrix generation, speckle filtering with a refined Lee filter, and Yamaguchi decomposition. The refined Lee filter was applied to smooth out speckles in the intensity data, preserving image sharpness while reducing noise. The Yamaguchi decomposition yielded four scattering models: surface scattering, volume scattering, helix scattering, and double bounce (Figure 8). This decomposition aimed to separate scattering contributions for each type of information and generate distinct scattering types. Subsequently, the processed results were color-composited to facilitate easier classification and interpretation of the images.

Image compositing is a process where three channels are merged into a single image, showcasing the strengths of each individual channel. This composite image is utilized due to the limitations of human vision, which struggles to differentiate color gradients and finds it easier to comprehend with added color. Human vision can only

distinguish prominent objects in a single channel, making it difficult to identify other objects. Therefore, image compositing is conducted to facilitate the identification of objects in the image.

In this study, a color composite was created using the following parameters: the red channel represents the double bounce scattering parameter, the green channel represents the volume scattering parameter, and the blue channel represents the surface scattering parameter. This resulted in Figure 10, which aids in the classification of objects at the research site.

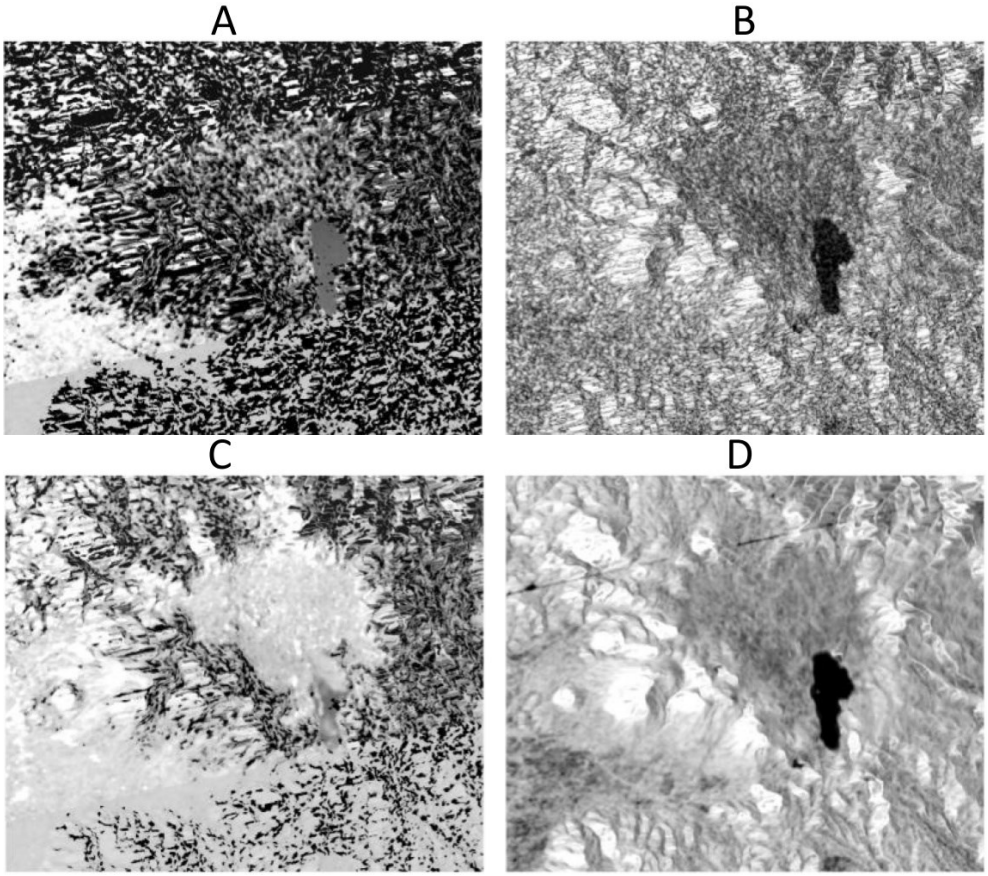

Figure 8: Yamaguchi decomposition of full polarization resulted in four scattering models from the ALOS PALSAR image at the observation site: double bounce (A), helix scattering (B), surface scattering (C), and volume scattering (D).

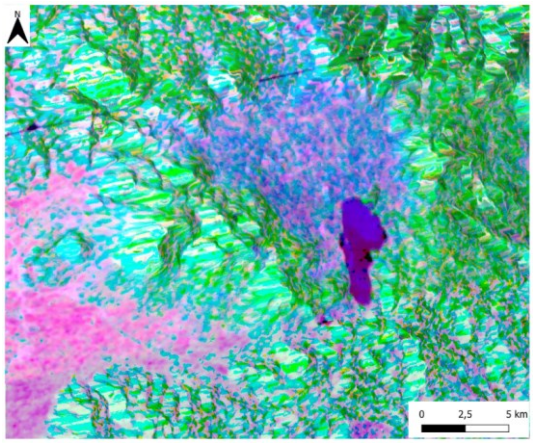

Figure 9: The RGB composite result from various Yamaguchi decomposition parameters for surface scattering, double bounce, and volume scattering types.

5.2. Lineament Extraction

The mSTA method produces linear features and interpretive structural analysis similar to the Yamaguchi method. This study applies the mSTA method to SAR data with a 25-meter resolution. Due to radar viewing geometry,

linear features with strike angles of 0 – 10° from the radar look direction (range) cannot be detected. Therefore, the dual-orbit mode of SENTINEL-1, with two different viewing directions, is used to detect linear features and interpret structures. The mSTA method automates linear feature detection using MATLAB scripts, resulting in significantly more detections compared to manual methods. Features are extracted based on surface roughness changes and slope steepness variations.

The mSTA method eliminates short linear features originating from noise with low backscatter intensity, primarily detecting features on both front and back slopes. It detects more linear features compared to the previous STA method. In the research location, mSTA identifies linear features interpreted as faults or fractures using SENTINEL-1 data in ascending and descending modes. A total of 1419 linear features are detected in the ascending direction and 1267 in the descending direction. More linear features are extracted from the ascending images, indicating directional influence on feature visibility.

In addition to extracting linear features, the study generates rose diagrams combining features from ascending and descending images. Based on linear features extracted from SENTINEL-1 images using the mSTA method, dominant strike directions are identified as northwest-southeast for both ascending and descending images (Figure 10).

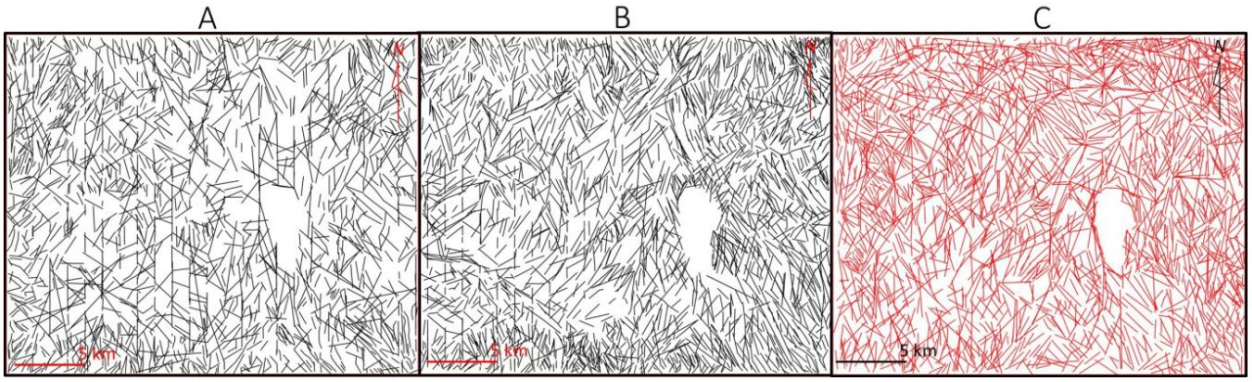

Figure 10: The map of detected lineaments using the mSTA method for Sentinel-1 images in ascending orbit (A), descending orbit (B), and their combination using grouping process (C).

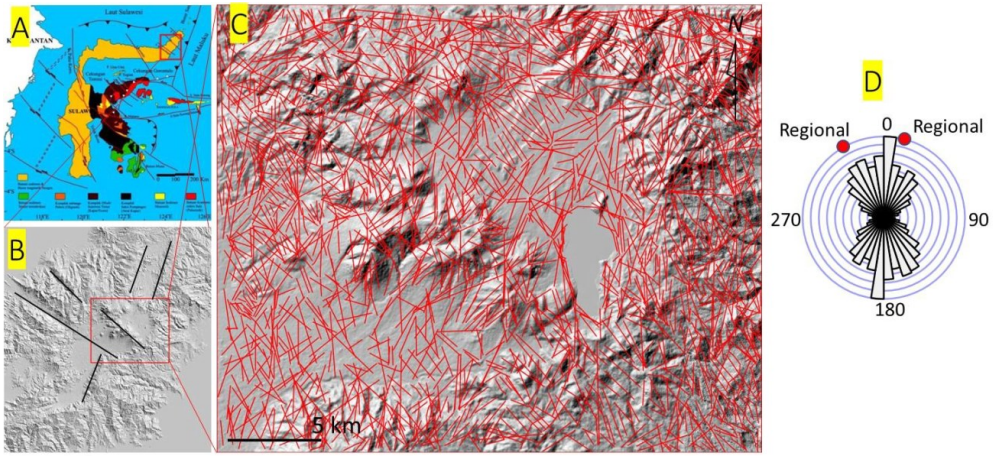

Figure 11: Regional Structure of Sulawesi Island (A), major alignments based on SRTM 30 m imagery (B), alignments derived from grouping Sentinel-1 images with ascending and descending orbits, and directional statistics presented in a rose diagram (D).

5.3 Lineament Structure Grouping and Verification

After extracting lineaments from both ascending and descending Sentinel-1 images, the next step involved grouping these lineaments. Enhanced mSTA data was obtained by merging lineaments from both orbits and subsequently grouping and eliminating short lineaments, resulting in the identification of the main directions of mSTA lineaments after merging. The processed lineaments totaled 160, predominantly oriented northwest-southeast, corresponding to the main structural trend at the study site (Figure 11).

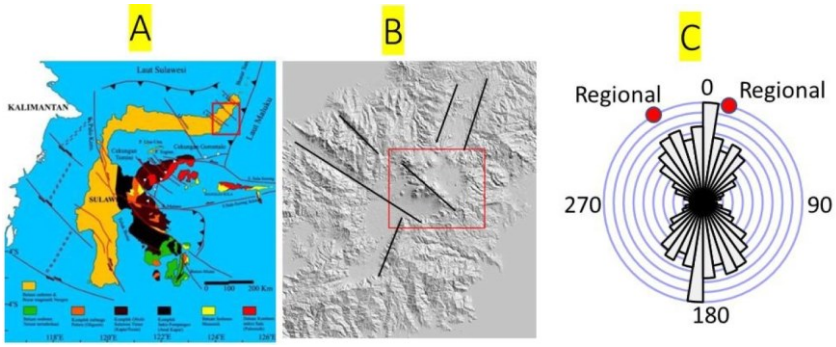

Figure 12: Regional geological structure map at the research site (A and B), and the frequency of alignments obtained from the mSTA method indicates similar directions (C).

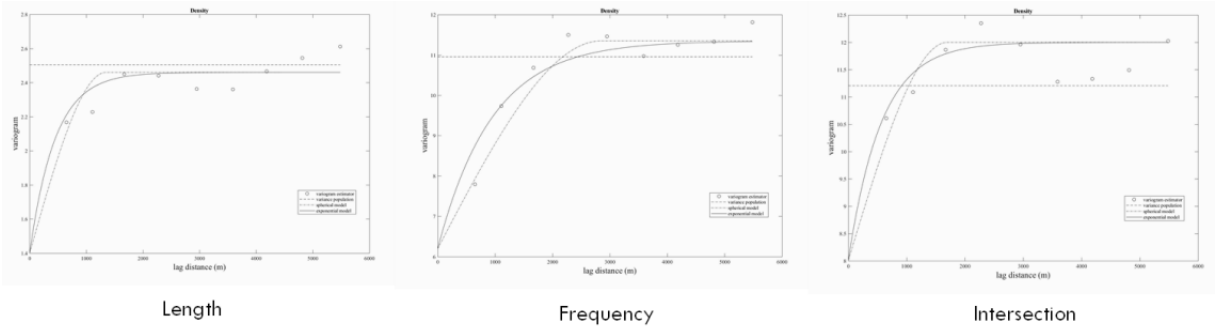

Figure 13: Experimental omnidirectional semivariogram of lineament density indices Li (left), Lf (middle), and Ll (right) for lineament distribution within 1×1 km² grid cells.

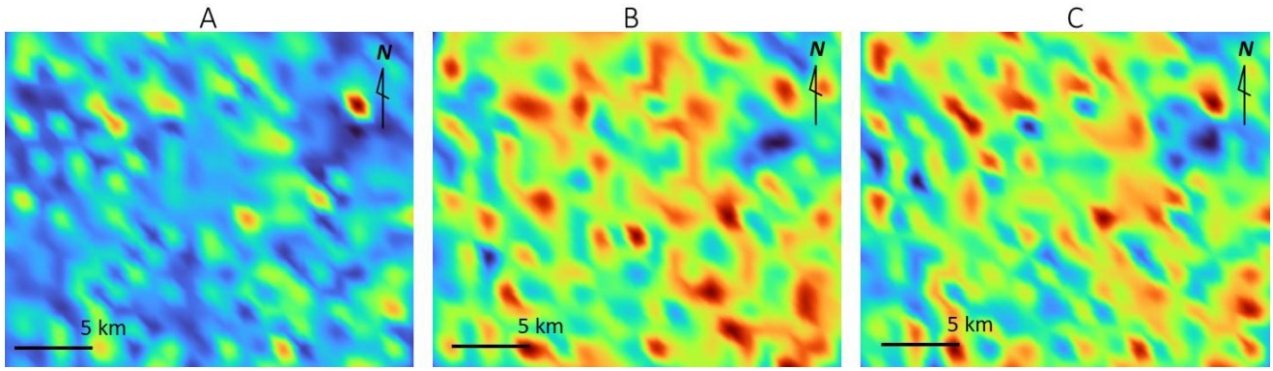

Figure 14: Ordinary kriging maps of three lineament indices: length Ll (A), intersection Li (B), and frequency Lf (C), depicting the spatial concentration of lineaments in Kotamobagu.

The mSTA method is employed to detect lineaments in the research area and identified a total of 1419 lineaments with a dominant northwest-southeast trend. This dominant trend aligns with the regional structure at the study site. This consistency demonstrates that the use of mSTA yields a representative detection of lineaments aligned with regional structures in the research area (Figure 12). This similarity validates that the mSTA method effectively identifies lineaments associated with geological structures in SAR images, defined as continuous and linear morphological features.

5.4 Calculation of Lineament Structure Density

From the grouping of these alignments, three lineament density indices are obtained: Li (Lineament intersection), Lf (Lineament frequency), and Ll (Lineament length), where their semivariograms are computed omnidirectionally and all data fit well to an exponential model (Figure 13).

These variograms are used to generate lineament maps using ordinary kriging in three index maps, where high and low index values are depicted in red and blue, respectively (Figure 14). The strong correlation observed between faults and lineament density across all three index maps validates the mSTA method's capability in detecting geological structure lineaments.

6. RESULTS AND DISCUSSIONS

To facilitate the analysis of lineaments in relation to tectonic and volcanic controls, lineament grouping was conducted based on two criteria: Lineament Direction Grouping and Length Grouping. (a) Lineament Direction Grouping: Lineaments were classified according to their directional alignments. The methodology involved utilizing the mSTA method to derive directional statistics, which are indicative of regional geological structures. Lineaments aligned with these regional structures were interpreted as products of tectonic activity, whereas lineaments exhibiting diverse directional orientations were associated with volcanic activity. A direction frequency threshold of 100 was determined based on histogram analysis, where predominant lineament directions aligned with regional geological structures (N 320° E and N 20° E) were observed at a frequency of 100 (Figure 14A). Lineaments exceeding this frequency threshold were classified as tectonically influenced, while those below were categorized as volcanically influenced. (b) Lineament Length Grouping: Lineaments were also categorized based on their lengths. Longer and continuous lineaments were considered characteristic of regional geological structures, while shorter lineaments converging to a point were deemed indicative of volcanic activity. A lineament length threshold of 1000 m was established from histogram data, showing a concentration of lineaments at approximately 1000 m in length (Figure 14B). Lineaments longer than 1000 m were identified as likely products of tectonic activity, whereas those shorter than 1000 m were associated with volcanic processes. Histograms of lineament direction and length were analyzed to establish threshold values for distinguishing between tectonically and volcanically influenced lineaments (Figure 15). These criteria and thresholds provide a systematic approach for delineating and interpreting lineaments in terms of their geological origins within the study area.

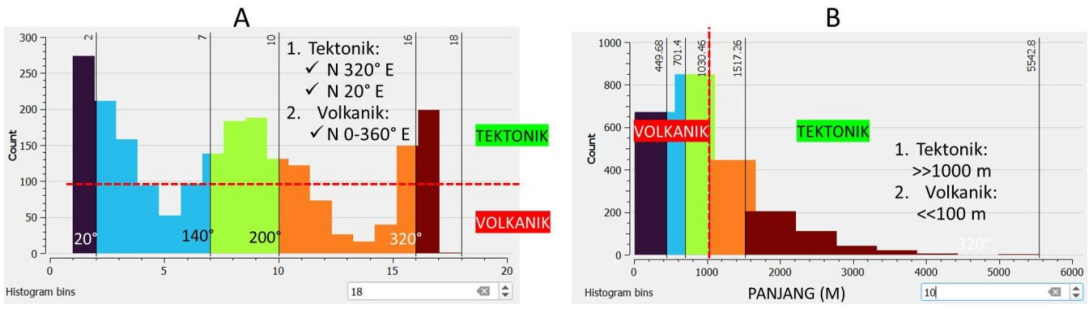

Figure 15: Histogram of lineament directions derived from mSTA analysis every 20° from the north (A), and histogram of lineament lengths resulting from mSTA analysis with 10 different length classes (B).

6.1 Lineament Direction Grouping

Lineament direction classification associated with tectonic and volcanic processes was performed using 20° class intervals (Figure 15A). The merging process of azimuth and back azimuth directions facilitated analysis, resulting in nine lineament classes (Figure 16). Tectonic lineament classification was based on directions aligned with regional geological structures, specifically N 320° E and N 20° E. Lineaments outside this range were assumed to be volcanic in origin, categorized into four tectonic-associated classes and five volcanic-associated classes.

Tectonically associated lineaments clustered in specific locations with nearly identical directions, while volcanic-associated lineaments exhibited a dispersed pattern ranging from N 0° E to N 180° E. When combined, volcanic lineaments displayed a radial pattern indicative of volcanic features such as flow structures, volcanic unit contacts, erosion surfaces, faults, fractures, and surface depressions. Typically, radial patterns converge towards a focal point where volcanic material is erupted, known as a volcanic vent. Locating older Tertiary or older volcanic vents in the field is challenging in Indonesia due to intense erosion and weathering processes. However, with lineaments detected using the mSTA method, identifying volcanic vents can be expedited. Field verification is essential to confirm that these lineaments are indeed associated with the intended target.

6.2 Lineament Length Grouping

Length classification of lineaments associated with tectonic and volcanic processes was conducted using a threshold value of 1000 m based on the histogram frequency of lineament lengths (Figure 15B). Lineaments longer than 1000 m, falling within quartiles 3 and 4, were assumed to be tectonically associated, whereas those shorter than 1000 m, falling within quartiles 1 and 2, were considered volcanic in origin. Tectonically associated lineaments exhibited a pattern predominantly oriented NW-SE and NE-SW (Figure 17A), with little significant presence around the lake area. Volcanically associated lineaments displayed a radial pattern emanating from several centers (Figure 17B). Radial patterns clustered in the central part of the study area, while circular patterns formed from continuous lineaments in the NE and terminal lineaments in the SW.

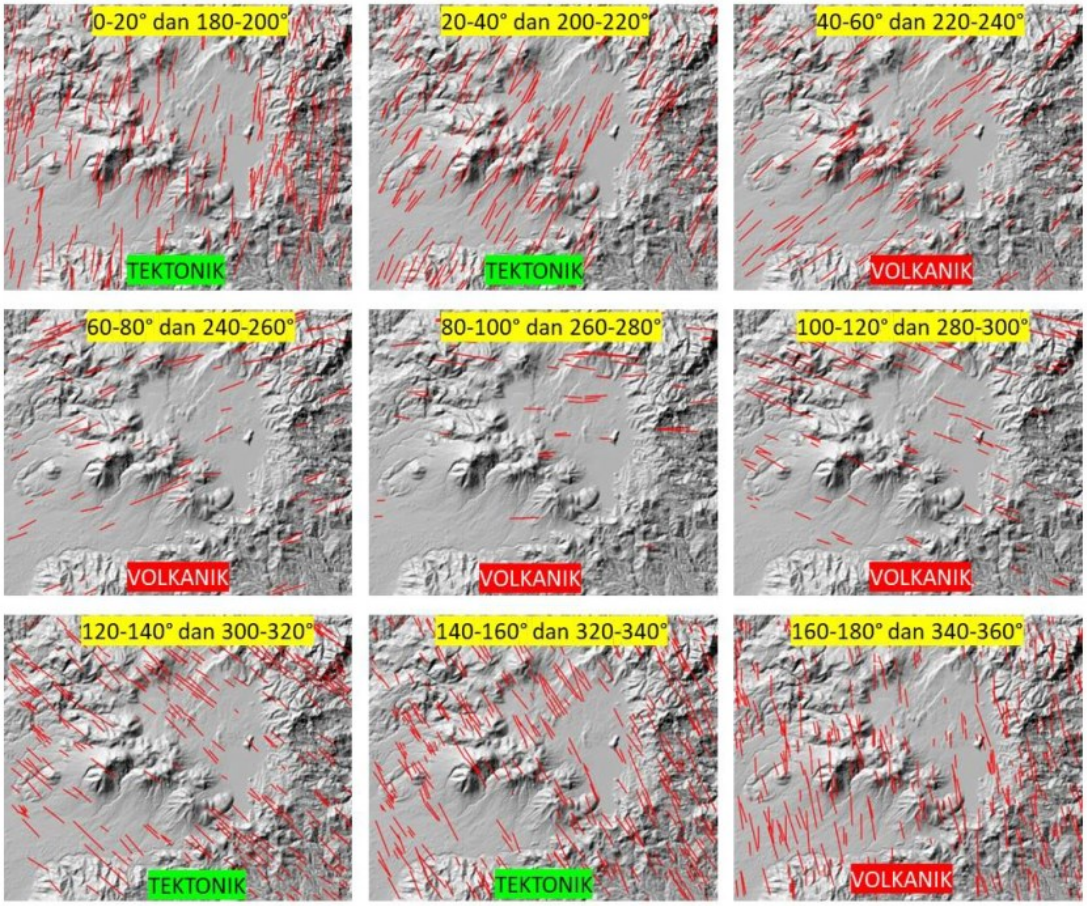

Figure 16: Classification of lineaments from mSTA analysis, grouped every 20° by combining azimuth and back-azimuth, to estimate lineaments associated with tectonic and volcanic processes.

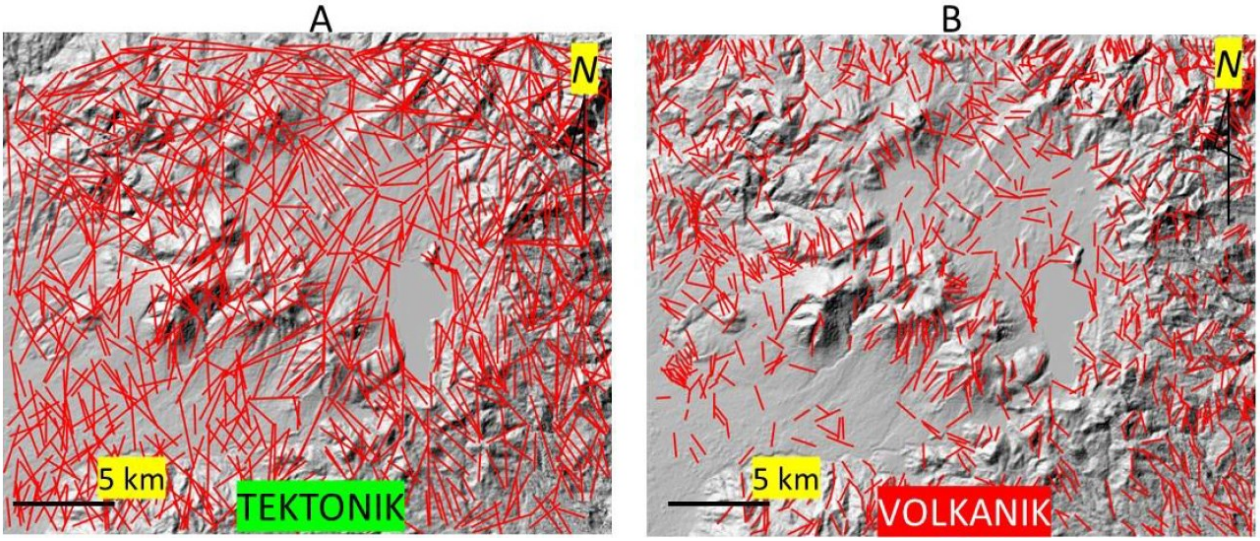

Figure 17: Classification of lineament lengths longer than 1000 m associated with tectonics (A) and less than 1000 m associated with volcanic activity (B).

6.3 Fault Identification

Based on two classification scenarios of detected lineaments using the mSTA method, the presence of faults is defined as lineaments that share similar orientation with regional structures and exhibit continuity or elongation. Fault presence is indicated by the continuity of several detected lineament segments.

In the direction classification scenario, the continuity of lineament segments largely corresponds to local geological structures (Figure 18). Some faults can be identified from continuous segments aligned with regional geological structures.

In the length classification scenario, the continuity of lineament segments follows the direction of local geological structures (Figure 19). Some faults can be identified from continuous segments aligned with regional geological structures (Figure 19A). Circular structures are detected from segments less than 1000 m in length, represented by short continuous segments (Figure 19B).

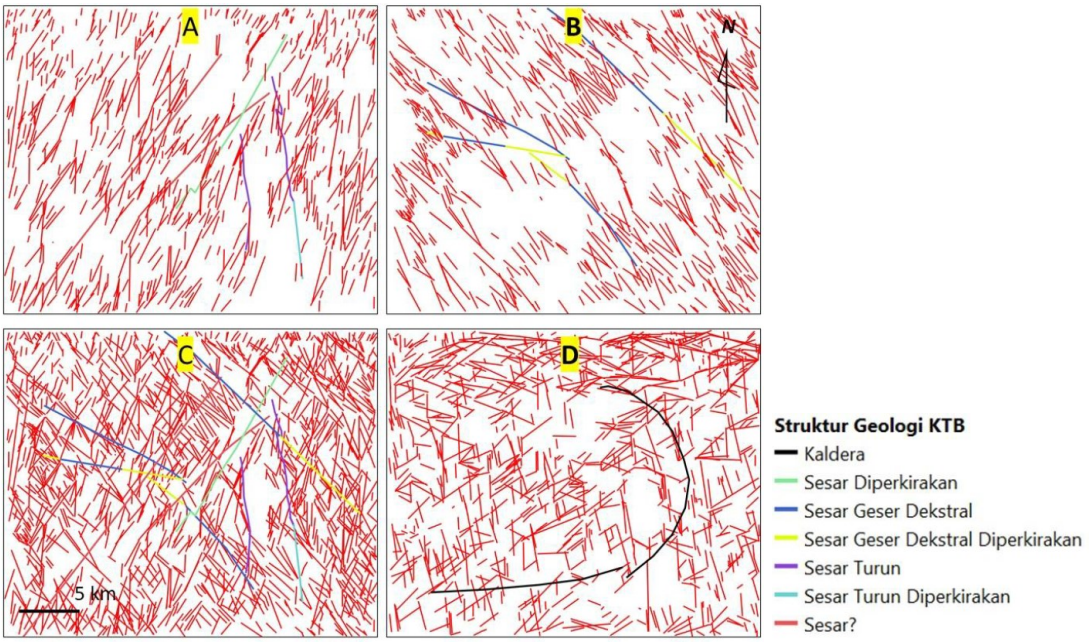

Figure 18: Classification of lineaments from mSTA results with tectonic orientations 0-40° (A), 120-160° (B), total (C), and volcanic lineament orientations (D), overlaid with local geological structures.

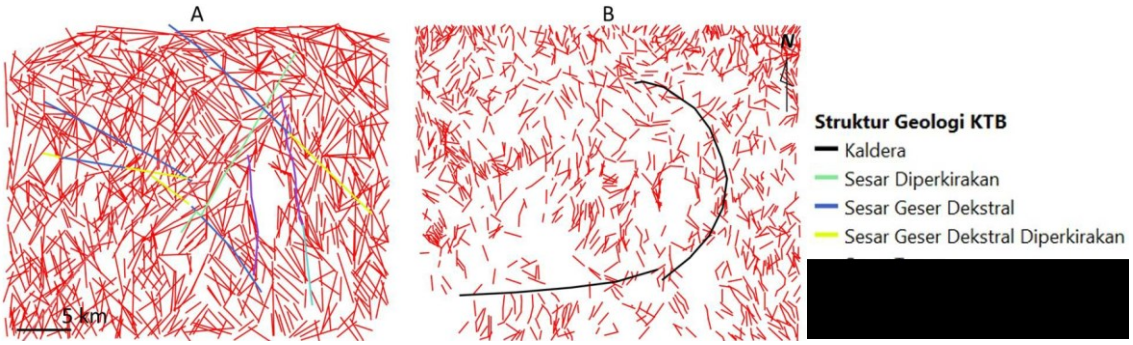

Figure 19: Classification of lineament lengths less than 1000 m (A) and greater than 1000 m (B) in relation to the presence of local geological structures.

6.4 Surface Permeability Identification

Surface permeability identification through fracture density calculation, as detailed in the previous section, was conducted. The concept revolves around the idea that a higher density of detected lineaments indicates potentially higher permeability compared to lower densities. Lineament density was computed using three parameters: length (Ll), intersection (Li), and frequency (Lf). High anomalies in these three density parameters were identified using the fourth quartile threshold of their respective histograms (Figure 20).

Among these density parameters, high anomalies in frequency density (Lf) showed the highest correlation with local geological structures, particularly at fault intersections. Another correlation was observed with the presence of hot springs, all of which coincided with high density values of lineament frequency (Lf) (Figure 21). Dark red shades in the central study area indicated high Lf anomalies on relatively flat terrain. Despite low topographic contrast, Sentinel-1 radar sensors detected lineaments suspected to originate from near-surface geological features. Surface roughness contrast and rock dielectric values are key factors recorded by radar sensors, aside from topographic factors. The high anomalies in the central area were within circular features indicating concentrations

of high permeability associated with volcanic processes. Verification with subsurface geophysical data is necessary to understand the manifestation of high permeability on the surface relative to subsurface geological features.

Figure 20: High anomalies of mSTA lineament density for Length Ll (A), intersection Li (B), and frequency Lf (C) overlaid with local geological structures.

Figure 21: High-frequency density anomalies overlaid on ALOS PALSAR polarimetric composite imagery and local geological structures such as faults. Backscattering mechanisms for the study area are illustrated by the three images on the left.

7. CONCLUSION

The processing of SENTINEL-1 images using mSTA for lineament extraction detected 1657 lineaments in ascending orbits, 2089 in descending orbits, and grouped 1971 with dominant trends at N 320° E and N 20° E. The sensitivity analysis of the mSTA method demonstrated representative results with dominant trends aligned parallel to regional structures at the study location.

Classification of lineament directions associated with tectonics and volcanics separated based on the regional geological trends of N 320° E and N 20° E. Tectonically associated lineaments clustered in specific locations with nearly identical directions, whereas volcanic lineaments exhibited a dispersed pattern ranging from N 0° E to N 180° E. Length classification of lineaments associated with tectonics and volcanics utilized a threshold of 1000 m based on histogram frequency. Tectonic lineaments displayed NW-SE and NE-SW directional trends, while

volcanic lineaments showed radial patterns and clustered in the central study area. Circular patterns formed from continuous lineaments in the NE and terminal segments in the SW.

Processing of ALOS PALSAR level 1.1 imagery involved several stages including data preparation, multilooking, terrain correction, matrix generation, and polarization decomposition. High-frequency density anomalies (Lf) corresponded well with local geological structures, as indicated by anomalies at fault intersections and the presence of hot springs associated with high Lf frequency lineament densities. Dark red shades in the central study area indicated high Lf anomalies despite low topographic contrast, demonstrating the Sentinel-1 radar sensor's ability to detect lineaments possibly originating from near-surface geological features.

These findings underscore the effectiveness of radar imaging and mSTA analysis in delineating geological structures and highlighting potential areas of high permeability associated with volcanic processes. Further validation through subsurface geophysical data is recommended to enhance understanding of these surface manifestations relative to subsurface geological features.

Keywords: magnetotelluric, polar diagram, phase tensor, induction arrow, forward modeling

ABSTRACT

Magnetotelluric (MT) is a common geophysical method used in exploring a geothermal system, as it is one of the powerful tools for delineating subsurface conditions. A common challenge in this method is the complexity of the subsurface condition that influences the dimensionality of its inversion. Which produces a model that may not accurately represent the actual condition and lead to misinterpretation. This study aims to construct several synthetic models to understand its impact on MT parameters, such as polar diagram, phase tensor, and induction arrow/tipper.

The result shows that polar diagrams form a circular shape when the MT station is located at a model with the same resistivity value laterally and on conductive zones that are relatively far from resistive boundaries while forming elliptical or peanut shapes on transitioning to resistive boundaries. The phase tensor phi value ranges between 0 to 45 degrees for resistivity increasing with depth, for models with lateral resistivity differences ranging between 40 to 50 degrees. The induction arrow/tipper will always have the highest value when the station is located far from the conductive anomaly.

1. INTRODUCTION

The Magnetotelluric (MT) method is a passive geophysical technique that measures changes in electric and magnetic fields over time to determine the distribution of rock resistivity under the Earth's surface. The Magnetotelluric (MT) technique can penetrate to enormous depths. As a result, it can examine a wide range of deep and geological features on Earth. The form of geological features, such as two-dimensional arrangements in sedimentary rocks or three-dimensional configurations in more complicated geological settings, influences subsurface resistivity. The mapping of subsurface resistivity is based on MT data processing, which typically includes 1-D and 2-D analysis. 3D processing needs more powerful computing resources. The main objective of MT data processing is to get a transfer function represented by the impedance tensor (Z), which consists of four impedance components (Simpson & Bahr, 2005). The MT technique is frequently used as the default instrument for investigating particular natural resources, such as groundwater and geothermal (Abdelzaher et al. 2012; Kebede and Saibi 2016; Kerbadj et al. 2017; Saibi et al. 2018). Its cost-effectiveness improves geothermal resource exploitation by aging reduced resistivity anomalies in geothermal systems (Cumming and Mackie 2010). A geothermal system is identified by considerably lower resistivity anomalies than the surrounding rocks and the degree of mineralization, water quantity, and temperature, which correspond to resistivity fluctuation (Spichak et al., 2007).

It is essential to remember that increasing the complexity of data processing does not necessarily result in a more accurate depiction of the real subsurface conditions. Ledo's (2006) research shows that when a 3-D conductive anomaly exists under the surface, 2-D modeling fails to reflect the anomaly adequately. This study aims to examine Transverse Electric (TE) and Transverse Magnetic (TM) mode curves, assess the dimensionality of resistivity zones, calculate geoelectrical strike, and map the distribution of conductive anomalies using MT modeling.

2. MT DATA

This study's data is synthetic and consists of 25 MT measurement points. The collected data was in MT data in EDI file format, which included tensor impedance and phase tensor values relative to time. Five north-south lines and five west-east lines exist. Four synthetic models with varied resistivity values were created using the 25 MT station location.

2.1 Model 01

The resistivity values in model 01 vary with depth. The thickness of each layer is one kilometer. Surface layers have resistivity values of 10 Ω m, 100 Ω m, 500 Ω m, and 1000 Ω m, respectively.

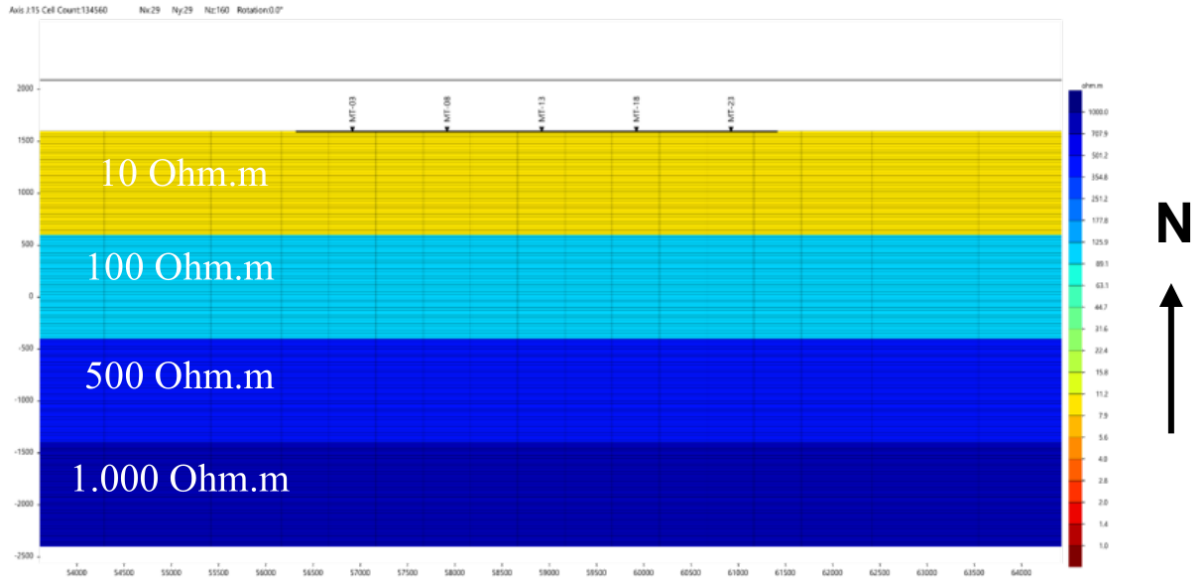

Figure 1: Model 01.

2.2 Model 02

Model 02 is a two-block model with contrasting resistivity values. The resistivity values for the right and left blocks are 1 Ωm and 1000 Ωm, respectively. The depth of each block is 4 kilometers.

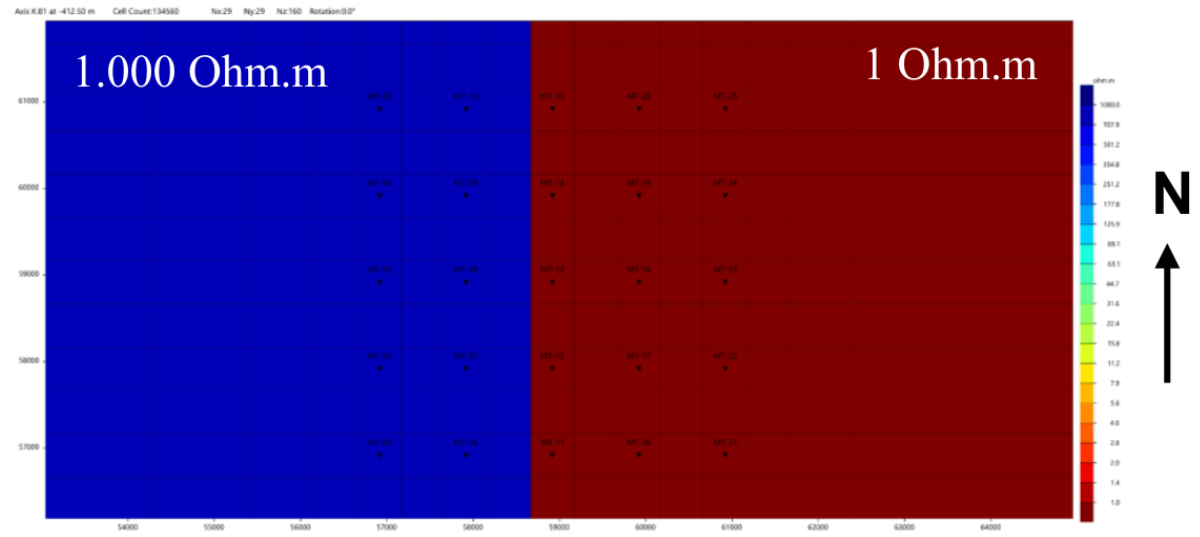

Figure 2: Model 02.

2.3 Model 03

Model 03 consisted of a diagonal conductivity anomaly model with a thickness of 2 km. Conductive anomalies have a resistivity value of 1 Ωm compared to an ambient value of 100 Ωm.

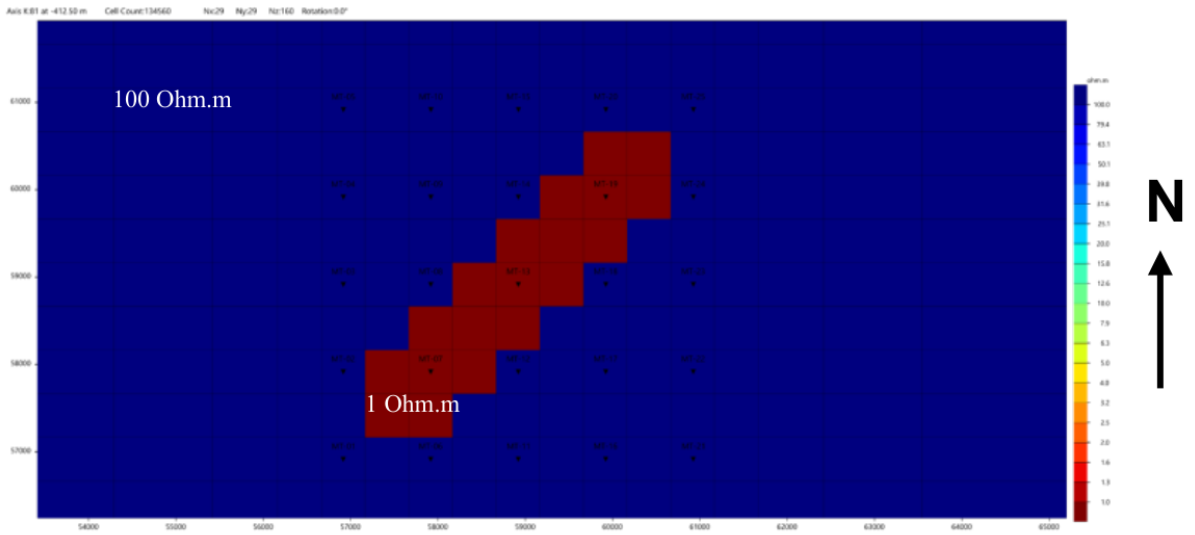

Figure 3: Model 03.

2.4 Model 04

Model 04 includes an anticline with a conductive anomaly value of 1 Ωm and a surrounding layer of 100 Ωm. The conductive anomaly is located 500 meters below the surface.

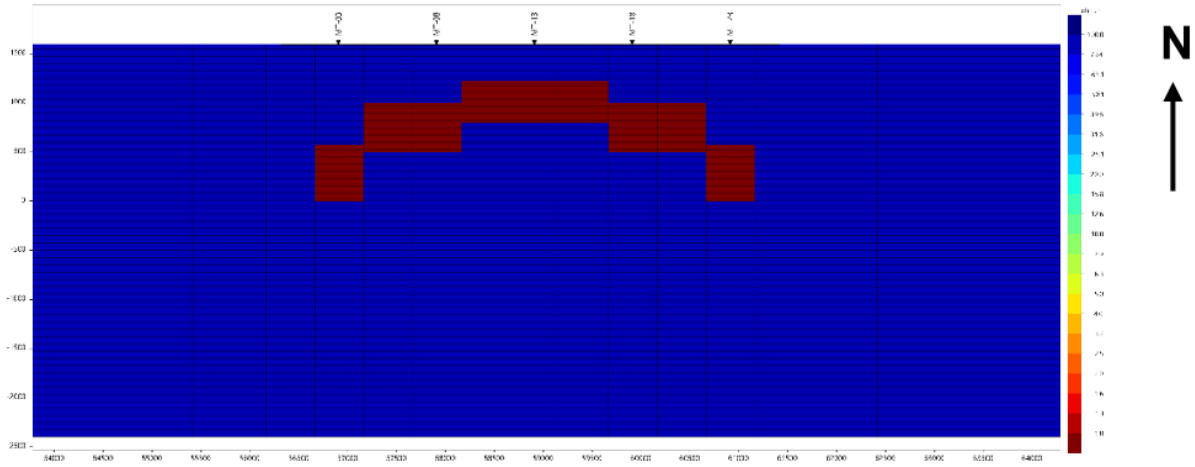

Figure 4: Model 04.

3. MAGNETOTELLURIC METHOD

The Magnetotelluric (MT) method is a geophysical method that utilizes natural electromagnetic waves from the source interaction of the solar wind and/or meteorological activity to take the distribution of resistivity values below the surface. The MT method measures the earth's magnetic field and the earth's electric field simultaneously with a function of time. Electromagnetic waves have a frequency range (0.00001 Hz - 10000 Hz). The lower the frequency value, the deeper the penetration, and vice versa; the higher the frequency value, the shallower the depth penetration will be (Vozzof, 1991). Electromagnetic signals are generated by the interaction of solar wind and lightning, which creates a magnetic field that penetrates Earth. The time-varying magnetic field penetrating the Earth interacts with rock strata, causing eddy currents and generating a primary electric field. The temporal fluctuation of the primary electric field produces a secondary magnetic field. The temporal change of the secondary magnetic field produces a secondary electric field. Magnetotelluric surveys in the field measure secondary electric and magnetic fields.

3.1 Forward Modeling

Forward modeling, a computational process, is employed to derive observational measurement outcomes based on specified physical parameters. This technique is pivotal in hypothesizing subsurface conditions (Turkoglu, 2009). Initially, the geometry is constructed using a synthetic model, which is then aligned with the target model to mitigate potential impacts on subsequent analysis. The horizontal cell value is defined in meters, and padding

is incorporated to ensure complete polarization of resistivity data at the MT station points. Additionally, the "enable outer core area" option should be selected to include the observation's external core area while configuring the cell size and extension.

In forward modeling, padding plays a critical role; insufficient padding can introduce edge effects at MT points during modeling, leading to data loss. It is advisable that the padding be ten times the size of the MT measurement layout to facilitate proper interpolation of resistivity data and prevent data loss. Subsequently, the appropriate depth limit is specified, followed by the width of the vertical axis cell, which is then expanded as necessary.

The next step involves generating a model by inputting the resistivity value and the population property of the total resistivity value. The desired synthetic data's resistivity values are then distributed along the i (length), j (width), and k (vertical/map view) axes within each segment relative to the distance. To refine the modeling, frequency range parameters and points per decade are introduced, indicating the interpolation of several points within a decade. Following the forward modeling of the generated 3-D synthetic data, the EDI data is exported with a complete tensor and subsequently utilized for MT curve parameter analysis.D synthetic data, the EDI data is exported with complete tensor and then loaded in for MT curve parameter analysis.

3.2 Impedance Tensor

MT measures orthogonal variations in electric fields (E) and magnets (H) on the earth's surface. Simpson and Bahr (2005) compare electric and magnetic field components coupled with an impedance tensor (Z). Z is a complex number made up of real and imaginary numbers. As a result, each impedance component (Zij) has its own magnitude and phase. The number Z must be transformed to pseudo-resistance and phase as a function of time. It is important to convert since Z is a complex number made up of real (Pseudo-Resistivity) and imaginary (Phase) values.

3.3 Phase Tensor

The Phase Tensor compares the real and imaginary parts of the complex impedance tensor. According to Caldwell et al. (2004), the phase tensor is defined by an angle α, which is not an invariant rotation. There are three invariant rotation parameters: the maximum axis (Φxy), the minimum axis (Φyx), and the skew angle (β). Phase Tensors help identify the distribution of conductive anomalies and determine the direction of the geoelectrical strike at the measurement site. In a 1-D medium, the phase tensor is diagonal with identical values for Φxy and Φyx, forming a perfect circle. In a 2-D medium, the phase tensor is also diagonal but with different values for Φxy and Φyx, resulting in an elliptical shape. The skew angle (β) in 2-D media is zero ($\beta = 0$). In a 3- medium, the phase tensor has distinct values for Φxy and Φyx, meaning the skew angle (β) is not zero ($\beta \neq 0$) and is often greater than 3.0. The phase tensor in 3-D is represented as an ellipse. Ellipses are created by mapping phase angle values in polar coordinates over a frequency range from 0° to 360° (Caldwell et al., 2004).

3.4 Induction Arrow (Tipper)

The Induction Arrow is a vector that represents the ratio of complex numbers, which include both real and imaginary parts. Induction arrows help us see if there are changes in conductivity across different areas. If the Earth is uniform, the induction arrow value is zero. However, if there is a conductive object underground, the induction arrow will point towards that object (Simpson and Bahr, 2005). There are two types of induction arrow representations: reversed and non-reversed. The reversed convention, introduced by Parkinson in 1959, shows the vector pointing towards the concentration of internal electric current anomalies. The non-reversed convention, introduced by Wiese in 1962, shows the vector pointing away from the concentration of internal electric current anomalies.

3.5 Polar Diagram

A Polar Diagram provides information about the characteristics of the subsurface medium based on changes in the impedance tensor (Z). The direction of the polar diagram's axis indicates the dimensional changes relative to the strike. In a 1-D medium, the polar diagram forms a perfect circle because $Zxx = Zyy = 0$. A 2-D medium is represented by an elliptical shape in the polar diagram, as variations in resistivity occur in one lateral direction and depth, indicated by the impedance amplitude where ($Zxy \neq Zyx$) with components $Zxx = Zyy = 0$. In contrast, a 3-D medium has measurement coordinate axes that are not aligned (Berdichevsky, 2008).

3.6 Inverse Modeling

Inverse Modelling is a mathematical process used to directly obtain a subsurface geophysical model based on geophysical measurement data. This differs from forward modeling, which relies on a trial-and-error approach to match measured data with calculated data. The type of inversion used in this study is Non-Linear Conjugate Gradients (NLCG). The inversion process using the NLCG algorithm aims to find a model solution that minimizes the objective function (ψ) based on data residuals and the second derivative of resistivity values (Rodi and Mackie, 2010). This study employs both 1-D and 2-D inversion modeling steps.

3.6.1 1-D Inversion

One-dimensional (1-D) inversion can be effectively conducted after performing 1-D modeling at each MT (Magnetotelluric) measurement point along the survey line. This process involves fitting the observed and calculated curves to determine the thickness of each subsurface layer accurately. Following the 1-D modeling at each measurement station, interpolation is applied between stations to derive the spatial distribution of resistivity values across the survey profile.

3.6.2 2-D Inversion

In 2-dimensional (2-D) inversion modeling, it is essential to first construct a grid that aligns with the initial geometry. The parameters to be defined include the width of the horizontal cells, the presence of top elevation, padding to avoid edge effects, and the boundaries of the left and right cells. Next, the vertical cells are arranged by setting the boundaries of each layer and the thickness of the cells, with an option for vertical cell enlargement if needed.

Once the grid dimensions are established, an initial model with a background value tailored to the specific model is created, as this initial model will influence the inversion results. The following step involves inputting the inversion parameters based on the analysis of the MT (Magnetotelluric) data. These parameters include the selection of the MT transfer mode that is parallel to the geoelectrical strike, frequency modeling boundaries, the number of interpolation points per decade, and smoothing.

Performing inversion requires a trial and error approach for each parameter to ensure that the resulting model accurately represents the subsurface conditions. This iterative process helps prevent errors in data interpretation due to incorrect modeling.

4. RESULT AND DISCUSSION

4.1 Variations in TE and TM Curves

The responses of the TE and TM curves from each model exhibit unique characteristics, which are influenced by the geometry and resistivity values of the conductive anomalies. The shapes of the TE and TM curves in each synthetic model can be utilized to identify the distinctive features of each modeling curve. When the resistivity values vary solely with depth, the TE and TM curves demonstrate consistent trends across all MT station points.

4.1.1 Model 1

The TE and TM curves will overlap when there are no lateral changes in resistivity. Consequently, the resistivity values indicated by both TE and TM are identical across the period from 0.01 to 1000 seconds. Therefore, a single curve is selected, as shown in Figure 4.1, where the apparent resistivity value increases with the period, consistent with the synthetic model. From the period of 0.08 to 0.9 seconds, the response from the first layer is obtained, the second layer response is acquired from 0.9 to 10 seconds, and the third layer response is observed from 1 to 10 to 100 seconds. The subsequent layer responses appear in the period of 100 to 1000 seconds. At the 100-second mark, the TE and TM curves begin to flatten, indicating proximity to the last layer, with an apparent resistivity value of 1000 Ωm and a total layer thickness of 4 km. The phase of the TE and TM curves shows a 45-degree angle from 0.08 to 0.1 seconds, then decreases to 10 degrees at 0.6 seconds. It returns to 45 degrees at 1000 seconds. The phase decreases with increasing depth due to higher resistivity in deeper layers, reducing the angle between the electric and magnetic fields. The phase increases again as the electric field propagation tends to shift towards the more conductive upper layers.

4.1.2 Model 2

Regarding the geometry of Model 02, which features a resistivity contrast between two blocks, the discussion will focus on a single transect perpendicular to the vertical contact, comprising five points, as illustrated in Figure 6. This transect spans 4 km. In the figure, the two graphs on the left are within the resistive medium, while the three graphs on the right are in the conductive medium. The x-axis represents the period, and the y-axis indicates apparent resistivity and phase.

First, the TE curve response is discussed. The TE curve, which is the Ex/Hy component, shows a decrease in apparent resistivity with increasing depth, influenced by the Ex component's direction towards the conductive zone. At stations located above the resistive block, a resistive response (1000 Ωm) is observed at low periods, which then transitions to a conductive response as the period increases. The phase flattens at 45 degrees around a period of 20 seconds.

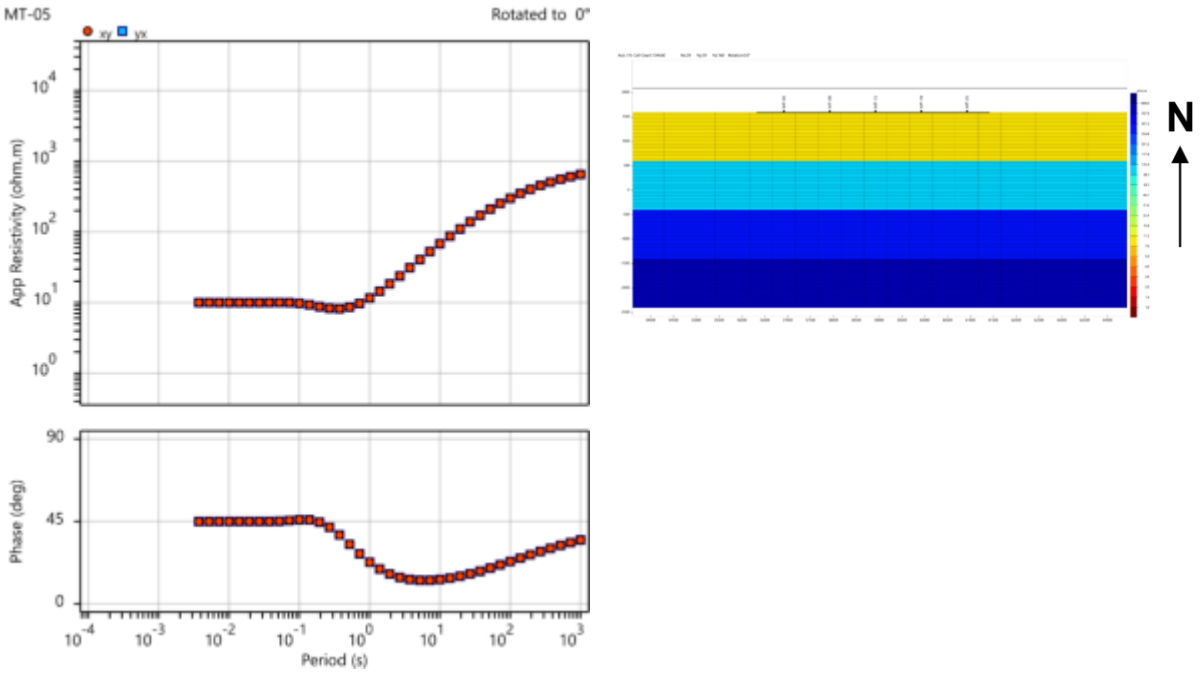

Figure 5: TE and TM Curves for Model 01.

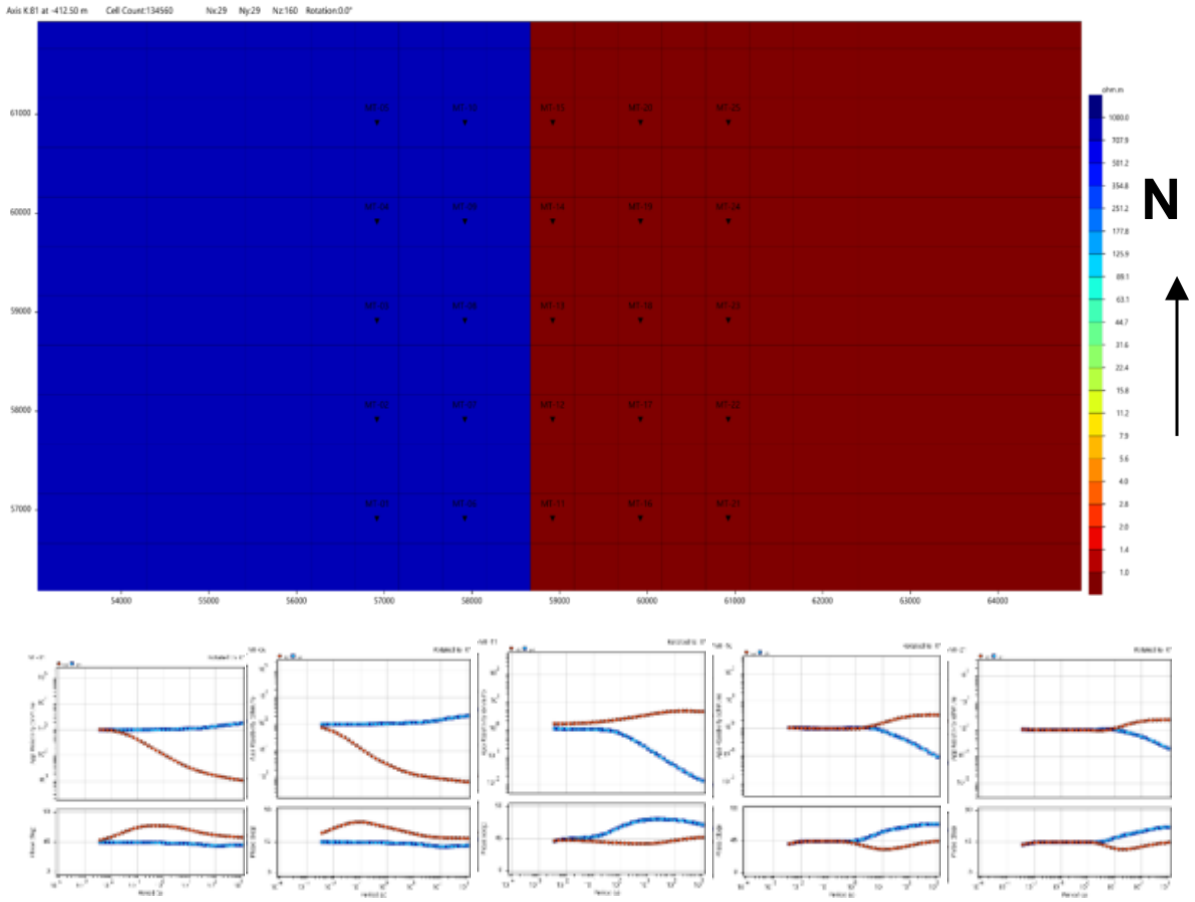

Figure 6: Characteristics of TE (red) and TM (blue) curves across resistivity contrast of two blocks.

Secondly, the TM response provides an intriguing observation. In the resistive block, from low to high periods, the TM response remains relatively constant at 1000 Ωm, then increases to approximately 1100 Ωm at higher periods. The phase remains flat at 45 degrees across all periods.

At MT stations situated above the conductive block and near the resistivity contrast, an inversion of the TE and TM curves is observed. At low periods, the TE curve's apparent resistivity exceeds 1 Ωm and rises to 8 Ωm at high periods. The TM curve, however, decreases from 1 Ωm at low periods to 0.01 Ωm at high periods. The TE phase starts at 45 degrees at low periods and drops to around 40 degrees, while the TM phase follows a similar trend as the TE phase until 0.6 seconds, then diverges at 0.4 seconds, with the TM phase increasing to about 70 degrees at 1 second. The maximum separation between the TE and TM phases is approximately 30 degrees.

The inversion of the TE and TM curves in terms of both apparent resistivity and phase at observation points near the resistivity contrast is attributed to boundary charges. The accumulation of electric charges at the vertical contact plane on the conductive side enhances the electric field reading during MT data acquisition. At points within the conductor and further from the resistivity contrast, the TE and TM curve separation occurs at higher periods. This is also influenced by the direction of the surrounding electric and magnetic fields. The TE and TM apparent resistivity values are identical from 0.08 seconds and begin to diverge at around 2 seconds. The TE phase flattens at 0.08 seconds, then slightly decreases to 35 degrees at 2 seconds. The TM phase remains flat at 45 degrees at 0.08 seconds, rises to 65 degrees at 10 seconds, and then decreases to 45 degrees at 100 seconds.

4.1.3 Model 3

Model 03 has a more complex resistivity structure compared to Models 01 and 02, featuring different resistivity values and geometries. Therefore, the discussion is divided into three sections: points above the anomaly, points near the anomaly, and points at the edge of the conductive anomaly.

a. Points at the Center of the Conductive Anomaly

As shown in Figure 7, the TE and TM curves overlap from low to high periods with a response of 1 Ohm.m, decreasing to 0.7 Ωm from 2 to 1000 seconds. The phase starts at 45 degrees, rises to 55 degrees, and then drops back to 45 degrees as the period approaches 1000 seconds. In this model, there are three station points exhibiting similar characteristics because the anomaly is on the surface and does not extend deeply, affecting the response at higher periods.

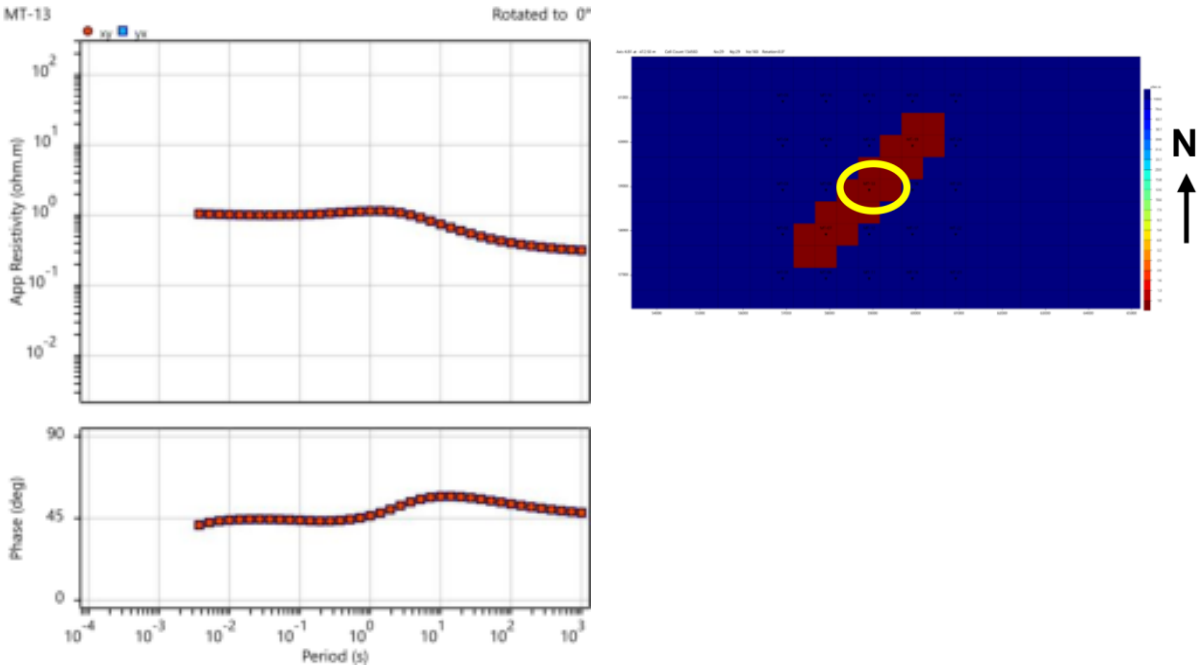

Figure 7: TE and TM curves of the diagonal conductive anomaly model at the center of the conductive anomaly.

At the stations located at the center of the conductive anomaly, the TE and TM curves overlap, with apparent resistivity values ranging from 0.01 to 0.1 seconds 100 Ωm. From 0.1 to 1000 seconds, there is a slight decrease in apparent resistivity to 90 Ωm. The phase values for TE and TM also overlap, forming a 45-degree angle. The overlapping of the TE and TM curves occurs because the measurements are taken precisely at the center of the conductive anomaly.

b. Points Near the Conductive Anomaly

The separation of the TE and TM curves as a function of the period can be observed at MT points near the anomaly, as shown in Figure 8, at a distance of 500 meters from the conductive anomaly. This study identified six stations with similar characteristics, detailed as follows. The apparent resistivity value from the TE response is 20 Ωm at a period of 0.08 seconds. This value decreases to 10 Ωm as the period increases and flattens at 10 Ωm from a period of 100 seconds. The phase angle is approximately 47 degrees at a period of 0.08 seconds, then drops to 45 degrees at a period of 0.1 seconds, rises to 50 degrees at a period of 20 seconds, and flattens at 45 degrees.

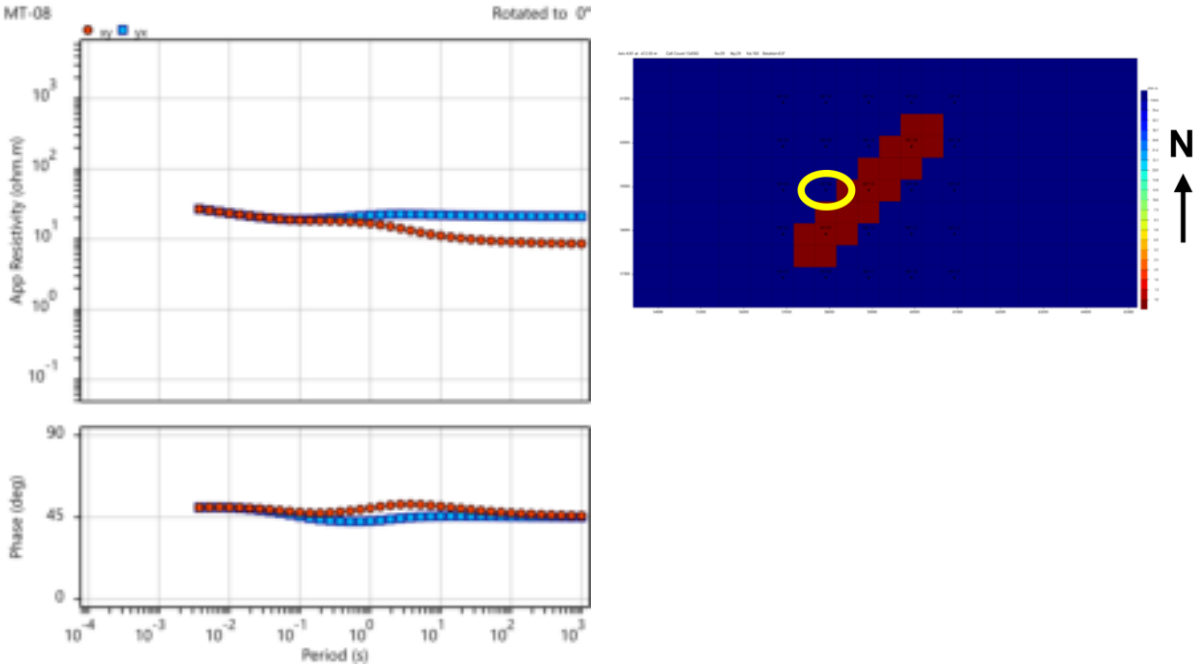

Figure 8: TE and TM curves of the diagonal conductive anomaly model at stations near the conductive anomaly.

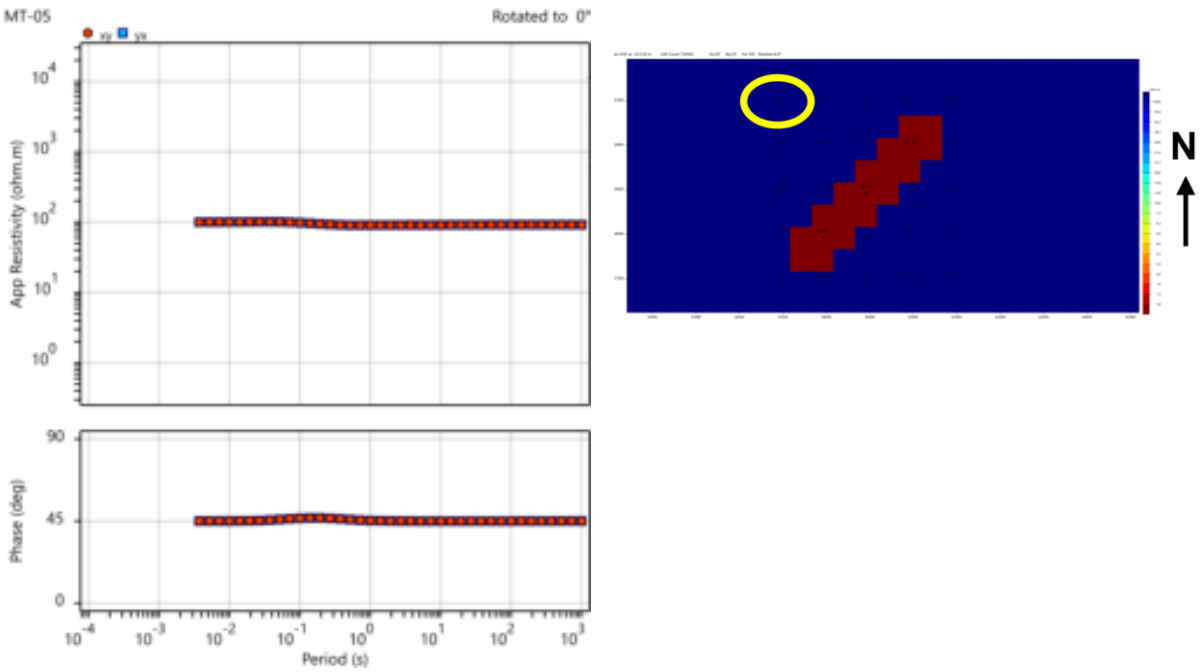

Figure 9: TE and TM curves of the diagonal conductive anomaly model at stations furthest from the conductive anomaly.

The TM response has an apparent resistivity of 30 Ωm at a period of 0.08 seconds, which then decreases to 20 Ωm at a period of 0.5 seconds and flattens towards 30 Ωm. The TM phase is around 47 degrees at a period of 0.08 seconds, then flattens at 45 degrees as the period increases. The characteristics of the TE and TM curves near the conductive anomaly exhibit separation. This separation is crucial for identifying the presence of an anomaly near the observation point. The separation occurs due to anisotropy, in this case, a diagonal-shaped conductive anomaly, where both the size and depth of the anisotropy influence the separation of the TE and TM curves. At higher periods, surface anisotropy does not affect lower periods. The degree of separation between the TE and TM phase curves is around 10 degrees.

c. Stations Furthest from the Conductive Anomaly

Measurements of the TE and TM points at the furthest measurement station from the 3-D anomaly are shown in Figure 9. At this distance, the conductive anomaly does not affect the shape of the TE and TM curves, and both have the same apparent resistivity value of 100 Ωm across all periods. Similarly, the phases of the TE and TM curves overlap at 45 degrees throughout the period. It is important to note that this condition may not hold if the size of the anomaly is increased while maintaining the same distance.

4.1.4 Model 4

Model 04 features a resistivity structure in the form of an anticline. The discussion is divided into three sections: points above the anomaly, points near the anomaly, and points at the edge of the conductive anomaly. The responses of the TE and TM curves from the anticline model are categorized as follows:

a. Points Above the Conductive Anomaly

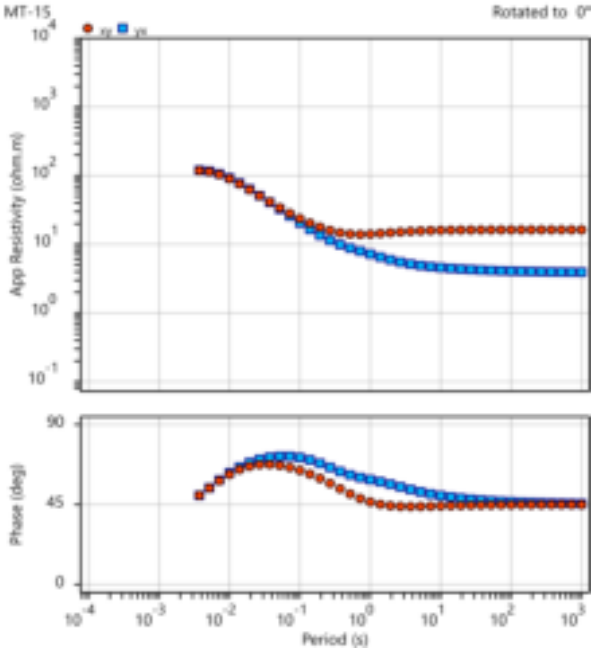

Figure 10: TE and TM curves of the anticline model at measurement points above the anticline.

The separation of the TE and TM curves at observation points above the anticline is shown in Figure 10. The characteristics of the TE and TM curves can be described as follows: The apparent resistivity value from the TE response is 100 Ωm at a period of 0.08 seconds and flattens at 20 Ωm from a period of 0.01 seconds. The phase angle starts at 45 degrees at a period of 0.08 seconds, rises to 60 degrees at a period of 0.8 seconds, then drops and flattens at 45 degrees. The TM response follows the TE response until a period of 0.9 seconds, then drops to 2 Ωm at a period of one second and flattens towards 2 Ωm up to a period of 1000 seconds. The initial TM phase matches the TE phase, but the TM curve begins to separate at a period of 0.01 seconds, with a slightly larger angle than the TE curve at a period of 0.1 seconds, then the phase decreases and flattens from a period of 20 seconds at an angle of 45 degrees.

In general, it can be concluded that the TE and TM curves above the conductive anomaly will overlap up to a certain period, then begin to separate. The apparent resistivity of the TE curve follows the resistivity of the anomaly, while the apparent resistivity of the TM curve follows the resistivity of the surrounding area. The phase curves initially and finally overlap, with slight separation in between. The phase separation between the TE and TM curves is approximately 20 degrees. The separation of the TE and TM curves is caused by the presence of the conductive anomaly at a period of 0.1 seconds.

b. Stations Adjacent to the Conductive Anomaly

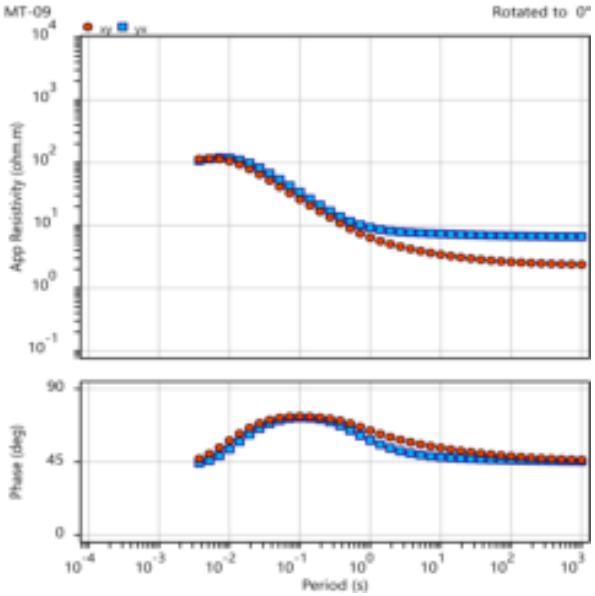

Figure 11: TE and TM curves of model 04 at stations adjacent to the conductive anomaly.

The characteristics of the TE and TM curves at stations adjacent to the conductive anomaly can be described as follows: The apparent resistivity value from the TE response is 100 Ωm at a period of 0.08 seconds, then it decreases from 0.01 to one second and flattens at an apparent resistivity value of 2 Ωm. The phase angle starts at 45 degrees at a period of 0.08 seconds, rises until a period of 0.1 seconds, then drops and flattens at 45 degrees. The TM response is similar to the TE response until a period of 0.01 seconds, then it decreases to 10 Ωm at a period of 0.9 seconds and flattens at 10 Ωm up to a period of 1000 seconds. The initial TM phase matches the TE phase, but the TM curve's angle decreases earlier at a period of 0.9 seconds, with a slightly smaller angle than the TE curve, and flattens from a period of 9 seconds at an angle of 45 degrees.

The characteristics of the TE and TM curves near the conductive anomaly begin to show separation at a period of 0.01 seconds, though the separation is not very pronounced. The separation becomes more distinct from a period of 0.9 seconds, where the conductive anomaly is located. In general, the TE and TM curves above the conductive anomaly will overlap up to a certain period and then begin to separate. The apparent resistivity of the TE curve follows the resistivity of the anomaly, while the apparent resistivity of the TM curve follows the resistivity of the surrounding area. The phase curves initially and finally overlap, with slight separation in between. The phase separation between the TE and TM curves is approximately 8 degrees. The separation of the TE and TM curves is caused by the presence of the conductive anomaly at a period of 1 second.

c. Stations Furthest from the Conductive Anomaly

The characteristics of the TE and TM curves at stations located at the edge of the anticline wing, as shown in Figure 12, can be described as follows: The apparent resistivity value from the TE response is 100 Ωm at a period of 0.08 seconds, then it decreases from 0.5 seconds and flattens at an apparent resistivity value of 10 Ωm. The phase angle starts at 45 degrees at a period of 0.08 seconds, rises until a period of 0.1 seconds, then drops and flattens at 45 degrees. The TM response is similar to the TE response until a period of 0.9 seconds, then it decreases to 70 Ωm at a period of 0.3 seconds, rises again, and flattens at 100 Ωm up to a period of 1000 seconds. The initial TM phase matches the TE phase, but the TM curve forms a smaller angle compared to the TE curve, despite experiencing a phase increase, and flattens from a period of one second at an angle of 45 degrees.

The characteristics of the TE and TM curves near the conductive anomaly start to show separation at a period of 0.1 seconds, where the conductive anomaly is located. In general, the TE and TM curves above the conductive anomaly will overlap up to a certain period, then begin to separate. The apparent resistivity of the TE curve follows the resistivity of the anomaly, while the apparent resistivity of the TM curve follows the resistivity of the surrounding area. The phase curves initially and finally overlap, with slight separation in between. The phase separation between the TE and TM curves is approximately 20 degrees. The separation of the TE and TM curves at the edge of the anticline wing occurs at a period of 0.1 seconds, due to the presence of the conductive anomaly at that period.

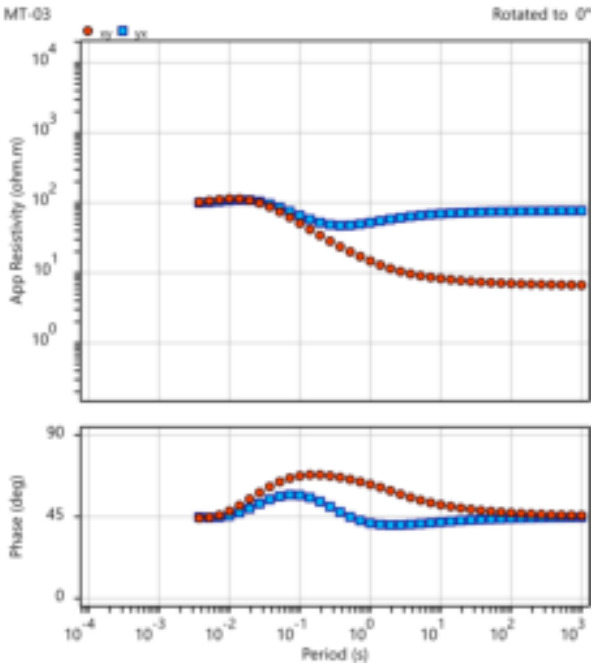

Figure 12: TE and TM curves of model 04 at stations located at the edge of the anticline wing.

4.2 Dimensionality of MT Data

4.2.1 Model 1

The changes in the polar diagram shape and the angles formed on the beta phase tensor can provide dimensionality information of MT data as a function of the period. The dimensionality derived from the polar diagram and the beta phase tensor can validate each other. The information obtained from these two parameters will serve as the basis for selecting the modeling method and determining the data constraints to be modeled.

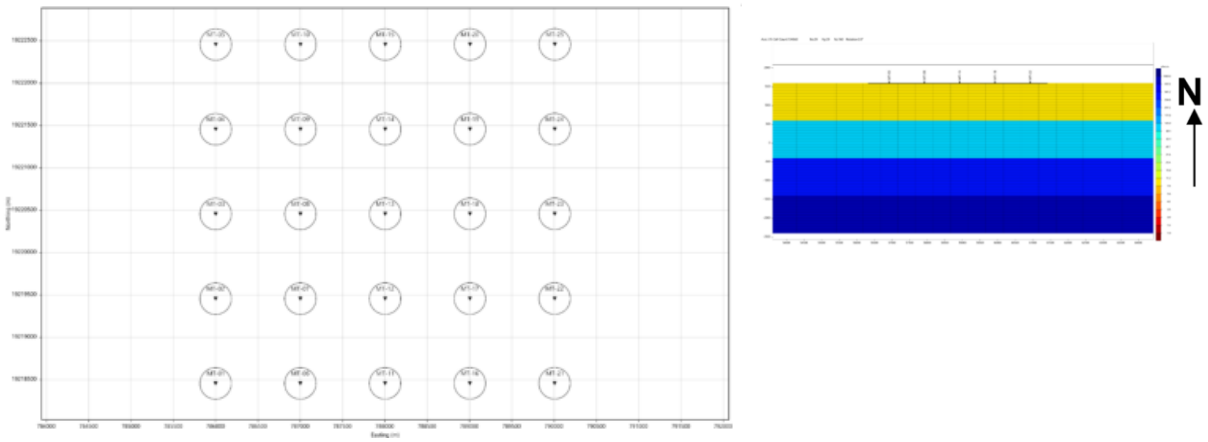

Figure 13: Polar diagram of model 01.

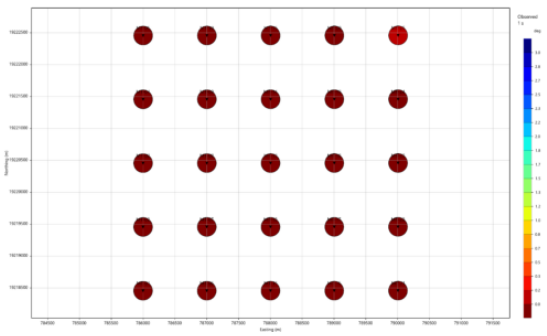

Figure 14: Beta phase tensor of model 01 at a period of 0.01 Seconds

In Model 01, the shape of the polar diagram at each period is a perfect circle, which means Zxy = -Zyx and Zxx = Zyy = 0. The dimensionality at each period is 1-D. An example of a polar diagram at a period of 0.01 seconds is shown in Figure 13. The circular polar diagram physically means that the resistivity measurement will give the same value in all directions.

Figure 14 provides information on the beta phase tensor where the angle formed is close to 0 degrees (indicated by the brown color). This beta angle remains the same at each period. The observation of the beta phase tensor has a consistent relationship with the polar diagram discussion above.

4.2.2 Model 2

The shape of the polar diagram for Model 02 varies as a function of the period, including circles, ellipses, and a peanut shape. At low periods, such as 0.01 seconds, the circular shape is observed at nearly all observation points, indicating that the vertical contact has not yet been detected. Points close to the vertical contact can capture the effect of resistivity contrast, shown by a weak north-south elongation. At this period, points near the resistivity contrast between two blocks exhibit a slightly elliptical polar diagram with a north-south orientation.

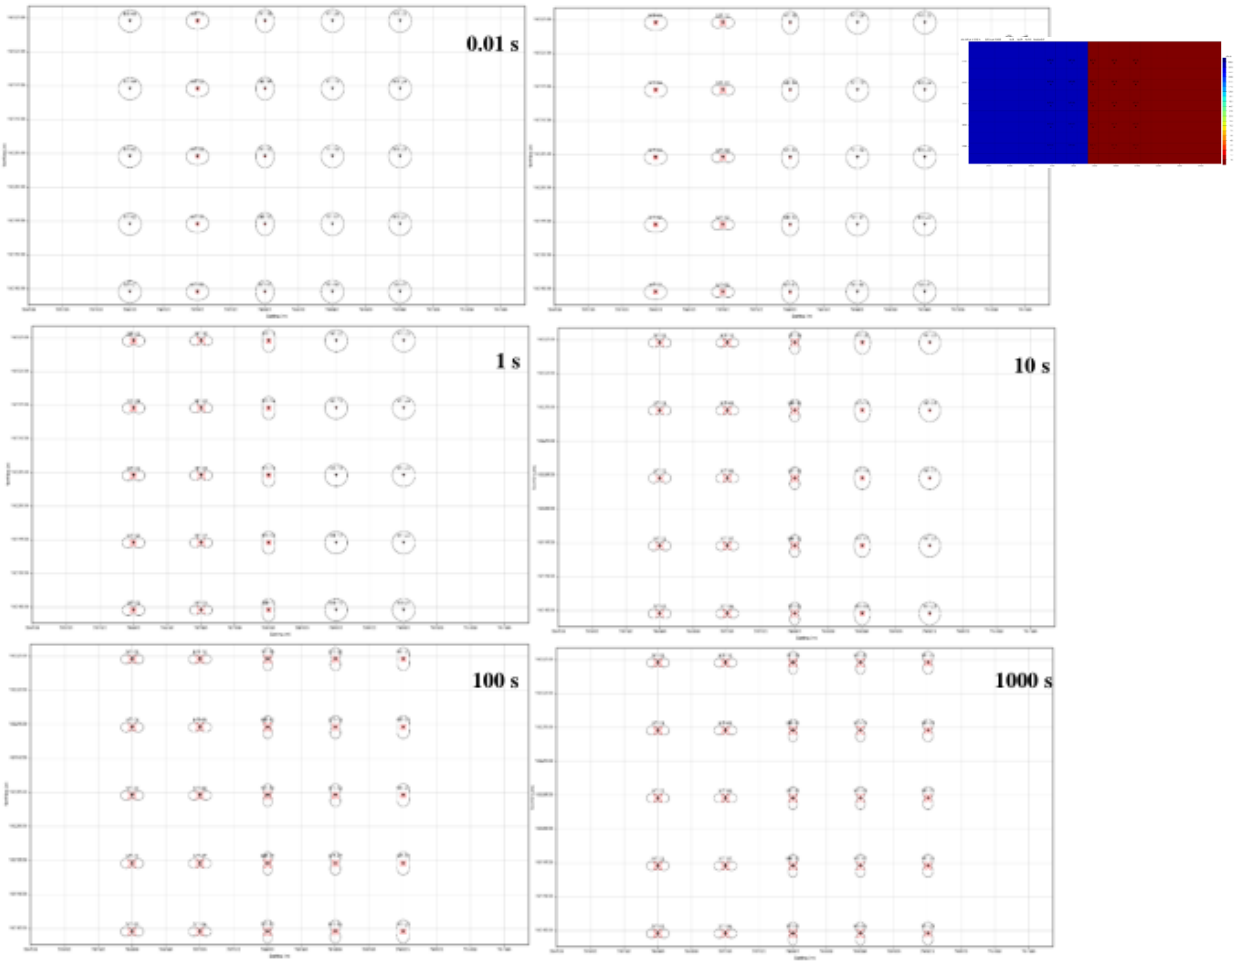

Figure 15: Polar Diagram of Model 02.

At a period of 0.1 seconds, the transition begins to detect the presence of resistivity contrast at all points, shown by the polar diagram in the resistive block. Points above the resistive block exhibit a west-east orientation, while the conductive block shows a north-south orientation. At a period of 1 second, the response from the resistivity contrast between the two blocks is recorded by all points. However, points above the resistive block already show a peanut-shaped polar diagram with a west-east orientation, while points above the conductive block still exhibit an elliptical shape. Notably, MT points near the resistivity contrast between the two blocks have a peanut-shaped polar diagram.

The characteristics of the polar diagram at a period of 10 seconds are similar to those at 1 second, with the following observations: the presence of a peanut shape in the conductive block at points near the resistivity contrast, and as the distance from the contrast increases, the shape in the conductive block becomes elliptical. At higher periods, represented by 100 seconds and 1000 seconds, the polar diagram response shows that as the period

increases, the peanut shape appears at all measurement points, both above the resistor and the conductor. The peanut shape becomes more pronounced above the conductor, where it becomes clearer. Measurement points above the conductor, whether near or far from the vertical contact, have a similar polar diagram shape.

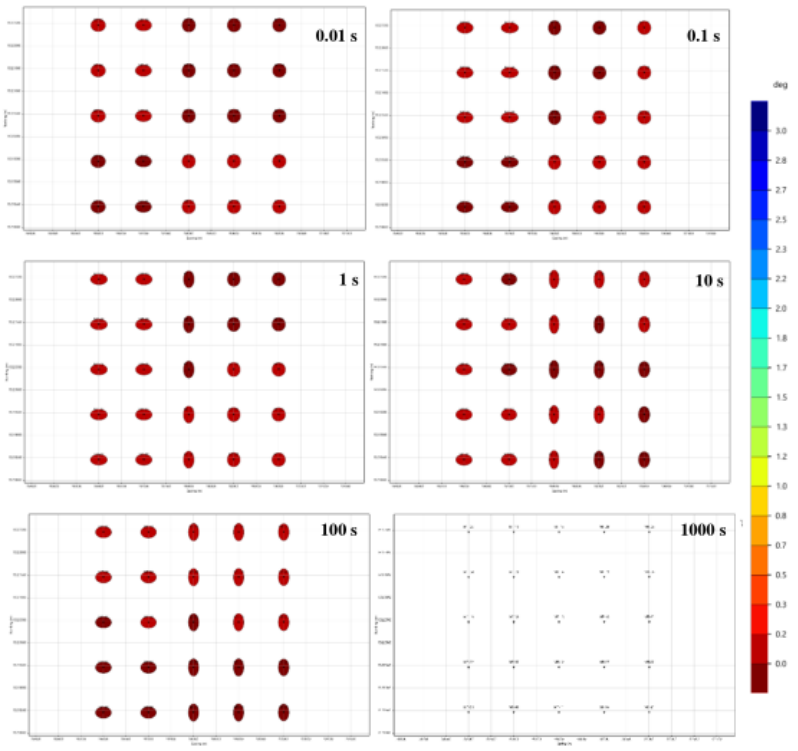

Figure 16: Beta phase tensor of model 02.

The dimensionality analysis of the beta phase tensor for Model 02 is shown in Figure 16, covering periods from low to high. At a glance, the beta phase tensor analysis indicates a 1-D dimensionality, where the angle formed is 0 degrees. This is understandable because the synthetic model is a simple 2-D model. However, upon closer examination, starting from a period of 0.01 seconds, the value of the beta phase tensor slightly increases to 0.2 degrees, indicating the presence of minor 2-D data.

4.2.3 Model 3

The shape of the polar diagram for Model 03 varies as a function of the period, including circles, ellipses, and a peanut shape. At low periods, such as 0.01 to 0.1 seconds, a circular shape is observed over the resistive part far from the conductive anomaly and at observation points above the conductive anomaly. However, measurement points near the conductive anomaly exhibit weak elliptical elongation perpendicular to the conductive anomaly.

At a period of 1 second, the presence of the conductive anomaly begins to be detected, with the polar diagram pattern changing to a radial shape relative to the anomaly's geometry. For example, at five points on the north side of the measurement area, the direction of elliptical elongation changes from southeast (MT-05) to south (MT-20), and then to southwest (MT-25). A similar pattern is observed at five points in the center of the measurement area, with the peanut shape elongation changing from southeast at MT-03 and MT-08 to northeast at MT-13 above the anomaly. However, at MT-18 and MT-23, the elongation is northeast. The radial pattern is also observed at periods of 10 to 100 seconds, with strong peanut shape elongation at measurement points above and near the conductive anomaly. Observation points far from the conductive anomaly still show weak elliptical elongation. Overall, anisotropy effects are detected at MT points as a function of the period and distance from the anomaly. These anisotropy effects will be further analyzed with the beta phase tensor.

The dimensionality analysis of the beta phase tensor for Model 03 is shown in Figure 18. Generally, at periods of 0.01 and 0.1 seconds, the beta phase tensor is 0 degrees, indicating that the response from the conductive anomaly is not clearly visible at these periods. Specifically, at MT measurement points near the conductive anomaly, the angle ranges from 0 to 1 degree. For points far from the conductive anomaly, the beta phase tensor remains at 0 degrees. This clarifies the previous analysis that the position of the conductive anomaly does not affect distant measurement points.

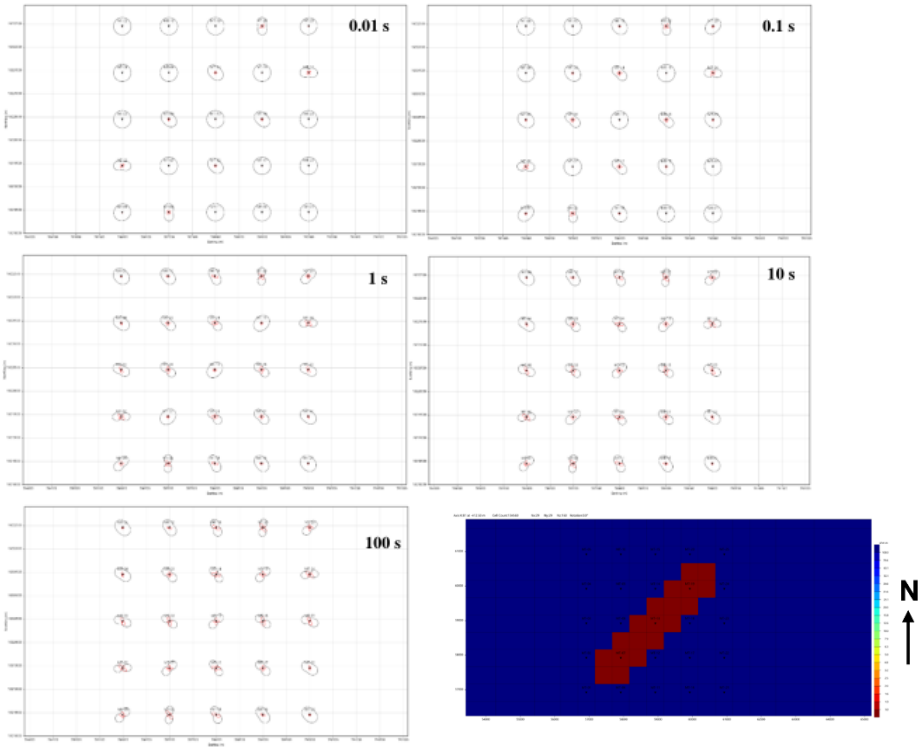

Figure 17: Polar diagram of model 03.

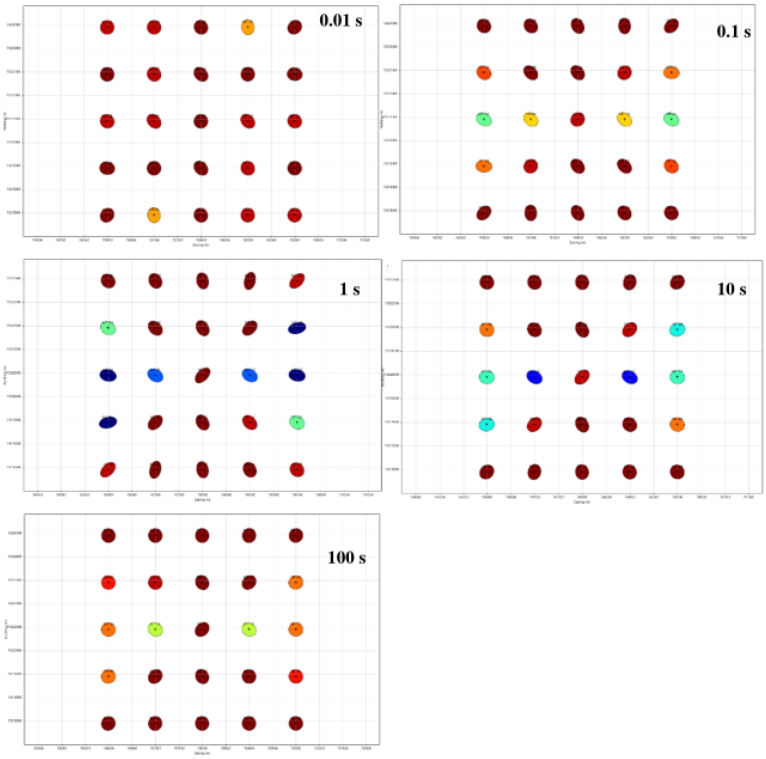

Figure 18: Beta phase tensor of model 03.

At a glance, the beta phase tensor analysis from 0.01 to 0.1 seconds indicates a 2-D dimensionality, with angles less than 3 degrees. The conductive anomaly's response starts to be recorded at all measurement points at a period of 1 second. Near the anomaly, the beta phase tensor shows a 3-degree angle. At this point, the angle between Φ\PhiΦ and the conductive anomaly is 3 degrees. For points near the center of the conductive anomaly, the beta phase tensor angle is 2.7 degrees, while other nearby points have a 0-degree angle. Above the conductive anomaly, the beta phase tensor angle is 0 degrees, and points far from the anomaly also have a 0-degree angle, indicating 3-D dimensionality.

At higher periods, such as 10 to 100 seconds, the beta phase tensor angle at MT stations decreases from 3 degrees to 1.7 degrees. However, near the conductive anomaly, particularly in the center, the angle remains at 2.7 degrees. Measurement points above the conductive anomaly show a slight increase to 0.2 degrees, while distant points remain at 0 degrees. In conclusion, the analysis of the polar diagram and beta phase tensor for Model 03 confirms that this model exhibits 3-D dimensionality.

4.2.4 Model 4

The shape of the polar diagram for Model 04, as shown in Figure 19, varies as a function of the period, including circles, ellipses, and a peanut shape. At low periods, such as 0.01 seconds, the polar diagram at all MT measurement points is circular, as it is not yet influenced by the deeper conductive anomaly. A similar pattern is observed at 0.1 seconds, where the response from the conductive anomaly is still not clearly visible.

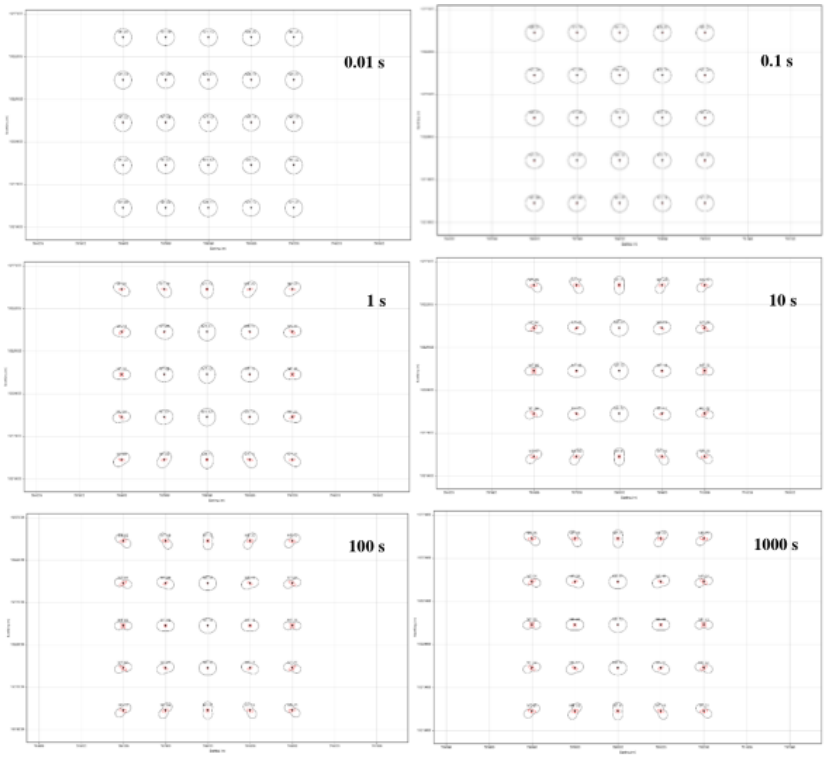

Figure 19: Polar diagram of model 04.

At a period of 1 second, the presence of the transition starts to be detected at measurement points above the edge of the anticline wing, marked by a change in the polar diagram shape at MT points near the conductive anomaly, shown by medium elliptical elongation. The direction of the polar diagram from the MT measurement points is perpendicular to the location of the conductive anomaly, which is in an east-west direction. MT measurement points above the conductive anomaly exhibit a circular polar diagram, while points above the anticline wing show very low elliptical elongation. This indicates that the conductive anomaly significantly influences the polar diagram shape at the edge of the anticline wing.

At higher periods, such as 10 to 1000 seconds, the polar diagram shows a similar pattern. MT measurement points at the edge of the anticline wing exhibit strong peanut shape elongation, points above the anticline wing show strong elliptical elongation, and points above the anticline show weak elliptical elongation. Based on this observation, the discussion will continue with the beta phase tensor analysis.

The dimensionality analysis of the beta phase tensor for Model 04 is shown in Figure 20. At low periods, particularly 0.01 seconds, the angle formed by the beta phase tensor is 0–0.3 degrees at each measurement point. This is influenced by the deeper location of the conductive anomaly, which does not significantly affect the measurement points at this period. The beta phase tensor angle begins to increase at MT points near the edge of the anticline wing, particularly in the northeast and southwest directions at a period of 0.1 seconds. The increase in the beta phase tensor angle at these points is due to the conductive anomaly starting to be recorded at this period. The beta phase tensor angle formed ranges from 0.2 to 1 degree.

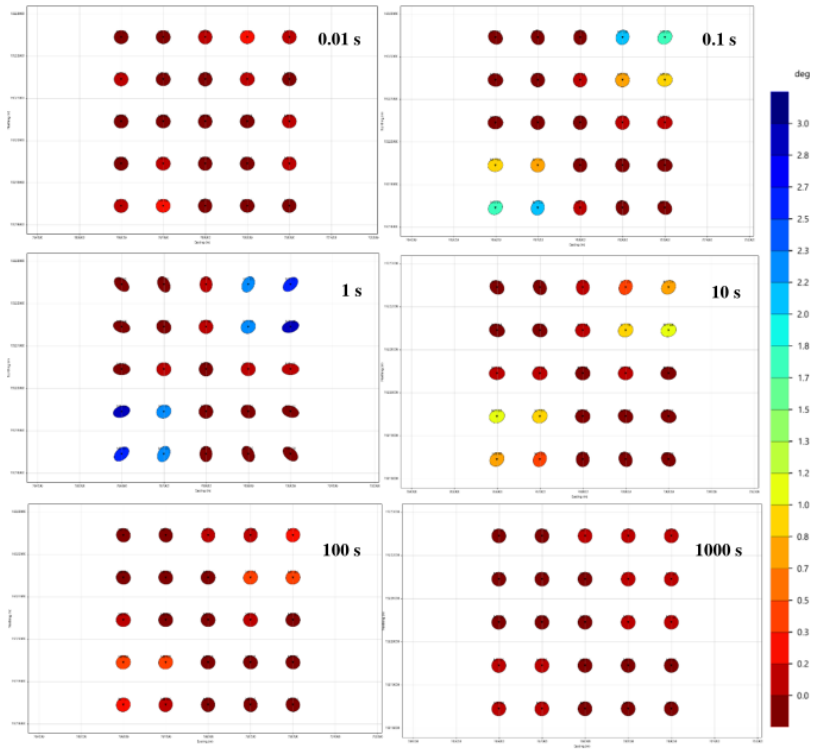

Figure 20: Beta phase tensor of model 04.

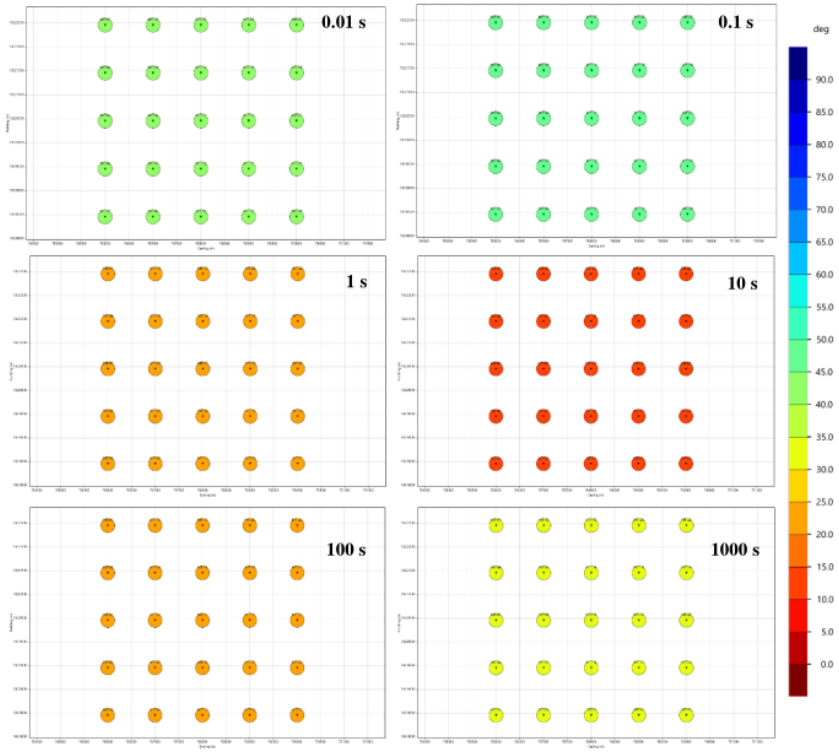

Figure 21: Phase Tensor Φ of Model 01.

The response of the conductive anomaly is recorded at all measurement points at a period of 1 second. At MT measurement points at the edge of the anticline wing, particularly in the northeast and southwest directions, the beta phase tensor response shows a beta angle of 3 degrees. At these points, the angle between Φ and the conductive anomaly is 3 degrees, indicating the presence of 3-D dimensionality at this period. At higher periods (10 to 1000 seconds), the beta phase tensor angle returns to 0 degrees, as the conductive anomaly is no longer detected at these periods.

4.3 Direction of Linearity

4.3.1 Model 1

The phase tensor Φ of Model 01 is shown in Figure 21. At a period of 0.01 seconds, the angle formed is 45 degrees, indicating that the electric and magnetic fields are perpendicular to each other. As the period increases, the Φ angle decreases to 10 degrees at a period of 10 seconds due to increasing resistivity with depth. However, the Φ angle at periods of 100 and 1000 seconds increases again because the electric field tends to move toward the surface where a conductive layer is present. Model 01 exhibits resistivity variation with depth, so there is no linear zone, as evidenced by the constant phase tensor Φ across all periods.

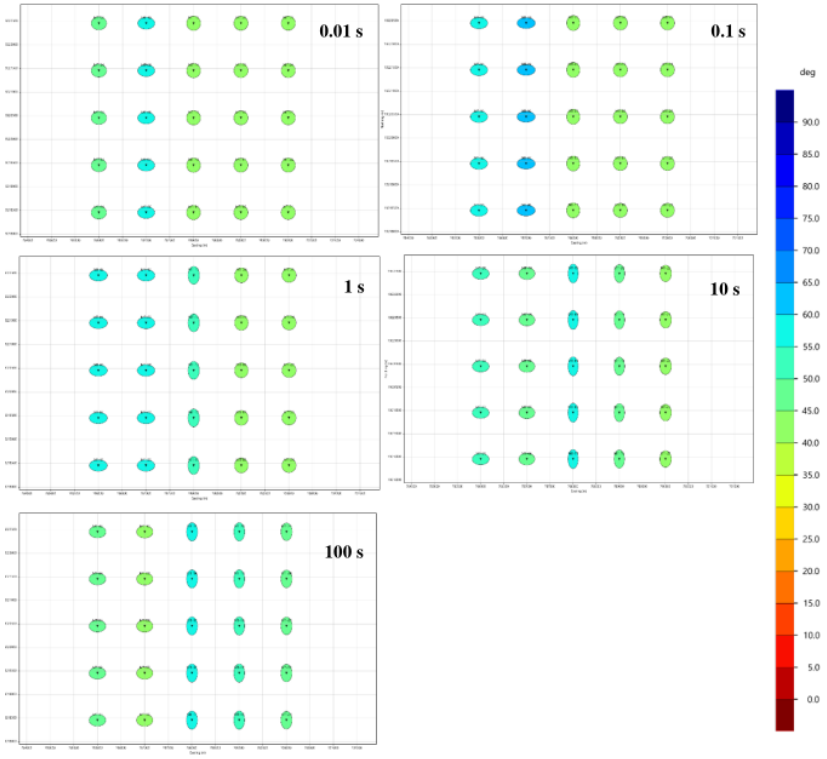

Figure 22: Phase tensor Φ of model 02.

4.3.2 Model 2

The Φ phase tensor of Model 02 is shown in Figure 22. In Model 02, the Φ phase tensor values range from 45 to 60 degrees. At a period of 0.01 seconds, a resistive layer is observed, with MT measurement points near the geoelectrical strike showing an angle of 60 degrees. The resistivity contrast between the two blocks at this period has little effect on the resistive block measurement points, while other points are not yet influenced. As the period increases, the impact of the resistivity contrast becomes more apparent, indicated by the increasing Φ angle from the resistive block to the conductive block. At a period of 1 second, the strong influence of the resistivity contrast is evident, with the resistive block having a Φ phase tensor direction perpendicular to the conductive block. The conductive block shows linearity in the Φ phase tensor direction, and as the period increases, the conductive block has a larger Φ phase tensor value compared to the resistive block. At this period, the resistive block has an electric and magnetic field angle of 45 degrees, indicating perpendicularity.

4.3.3 Model 3

The Phi phase tensor values for Model 03, ranging from 45 to 60 degrees, are shown in Figure 23. From 0.01 to 0.1 seconds, the influence of the conductive anomaly is not clearly recorded. As the period increases, the direction of the polar diagram containing the Phi phase tensor values for the resistive block becomes perpendicular to the conductive anomaly. MT points above the conductive anomaly show a diagonal linearity in the Phi phase tensor direction with a northeast-southwest orientation. At higher periods, such as 10 to 100 seconds, the Phi angle formed by the Phi phase tensor of the conductive block is larger than that of the resistive block. At these periods, the Phi phase tensor has electric and magnetic field angles of 45 degrees, indicating perpendicularity.

4.3.4 Model 4

In Model 04, the Phi phase tensor values range from 45 to 60 degrees. From 0.01 to 0.1 seconds, MT points above the conductive anomaly have larger angles compared to other MT points, with angles of 80 degrees at 0.01 seconds and 85 degrees at 0.1 seconds. This indicates that the influence of the conductive anomaly starts to be recorded at

these periods. The response from the conductive anomaly can still be recorded up to a period of 1 second, indicating proximity to the anomaly. The linear zone shown by Model 04 is in the middle of the MT measurement points with an east-west orientation. As the period increases, the Phi phase tensor angle approaches 45 degrees, indicating perpendicularity between the electric and magnetic fields, and no longer showing linearity.

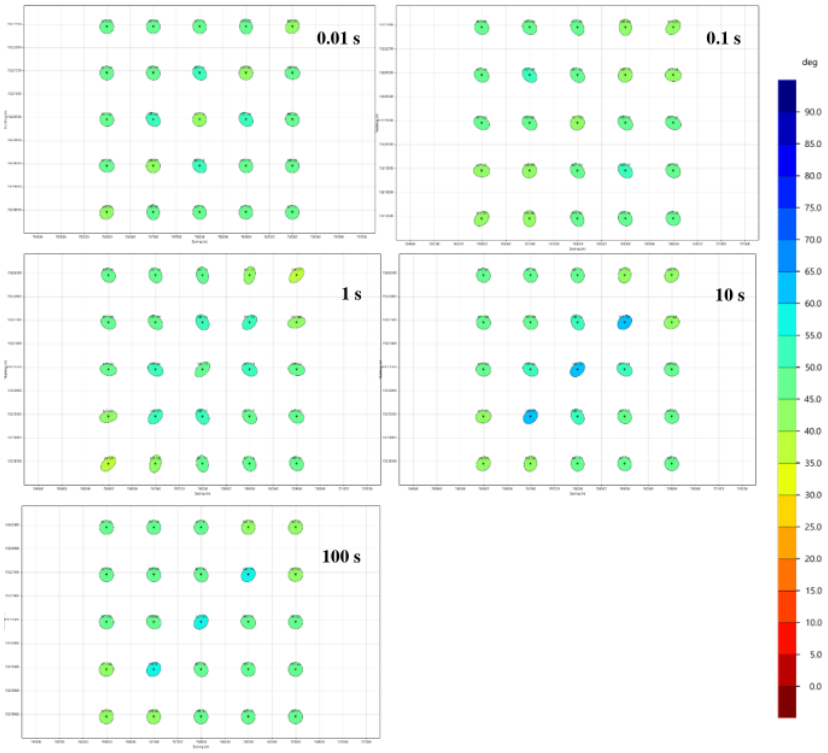

Figure 23: Phase tensor Φ of model 03.

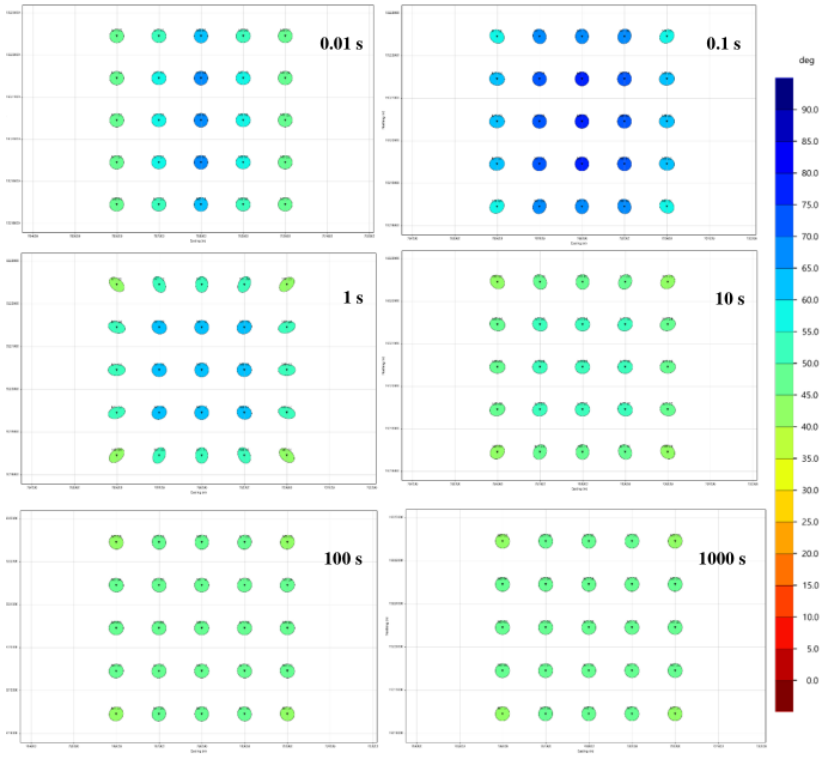

Figure 24: Phase Tensor Φ of Model 04.

4.4 Distribution of Conductive Anomalies

The distribution of conductive anomalies can be identified using phase tensors and induction arrows. Changes in the phase tensor values are displayed over several periods to observe angle variations with depth. Phase tensor maps with high and constant angles as depth increases can represent the presence of conductive anomalies. Induction arrow analysis is used to observe changes in subsurface resistivity structures. Using Parkinson's conversion, vectors approach conductive materials from the surrounding environment. The induction arrow discussion is focused on points above the resistor.

4.4.1 Model 1

Model 01 represents a layer with varying resistivity values with depth. The induction arrow for Model 01 points toward the surface at all MT point periods, indicating that the conductive layer is at the surface. The distribution of conductive anomalies in Model 01 can also be observed with the Phi phase tensor shown in Figure 21. At low periods, the angle formed is 45 degrees, decreasing with increasing period. At high periods, the Phi phase tensor increases because the electric field tends to flow to the more conductive surface layer.

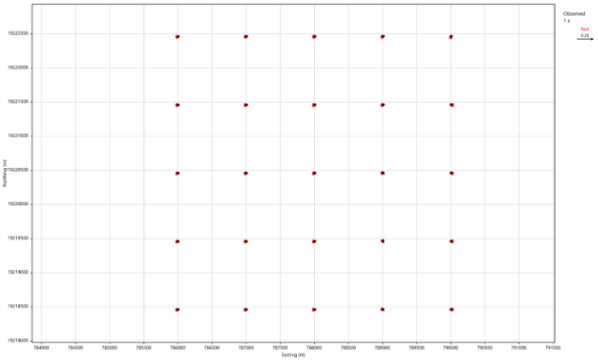

Figure 25: Induction Arrow of Model 01.

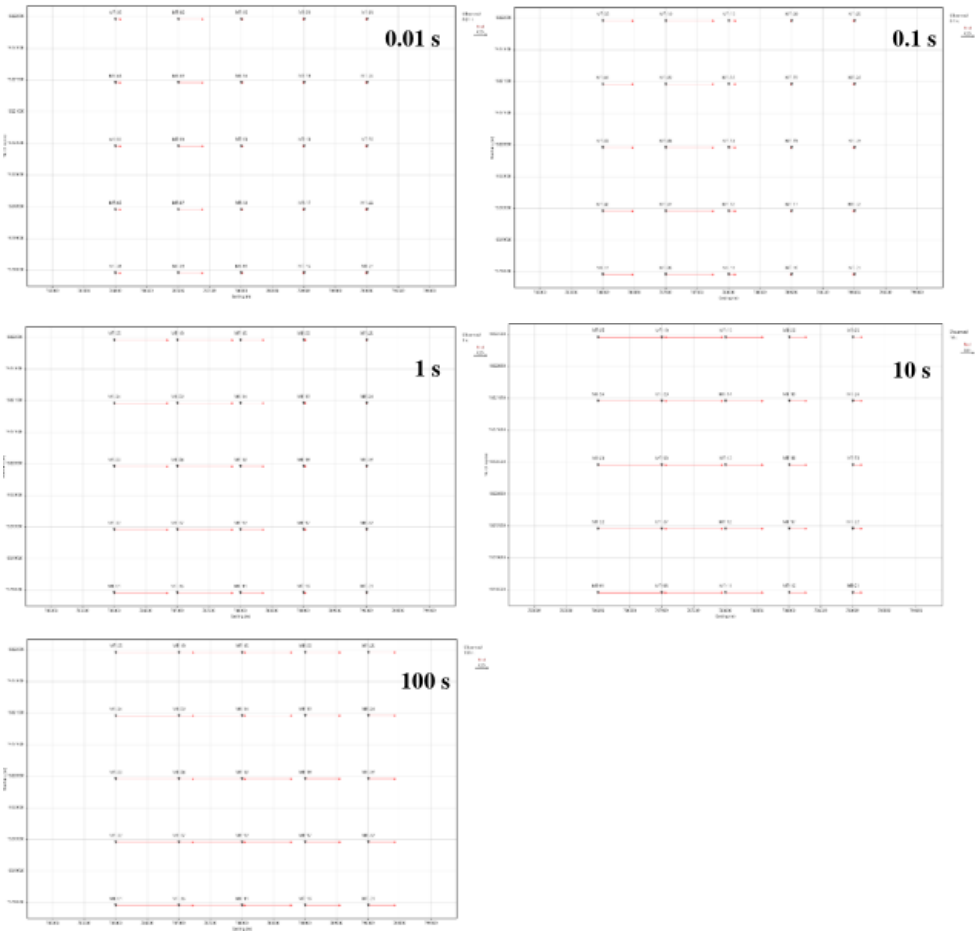

Figure 26: Induction arrow of model 02.

4.4.2 Model 2

The distribution of conductive anomalies in Model 02 is shown in Figure 26. At low periods (0.01 seconds), weak induction arrows are observed pointing east, indicating the location of the conductive medium. Across all periods, the magnitude of the induction arrow increases with the period. The conductive block shows arrows pointing east, influenced by the rectangular padding used. The distribution of conductive anomalies in Model 02 can also be analyzed using the Phi phase tensor shown in Figure 22. At high periods, the conductive block has a higher Phi phase tensor angle compared to measurement points above the resistor.

4.4.3 Model 3

The direction of the induction arrow for Model 03 is shown in Figure 27. From a period of 0.01 seconds, the response from the conductive anomaly is recorded, indicated by the induction arrow pointing toward the center. The magnitude of the induction arrow increases at 0.1 seconds, indicating the presence of the conductive anomaly. The magnitude decreases with depth, meaning the anomaly's influence lessens. Induction arrows at the center of the conductive anomaly point to the surface. MT points beside the conductive anomaly point toward the center with greater magnitude than points at the edge of the anomaly. The distribution of conductive anomalies in Model 03 can also be observed with the Phi phase tensor shown in Figure 23. The conductive anomaly has a larger Phi angle compared to the resistive block as depth increases.

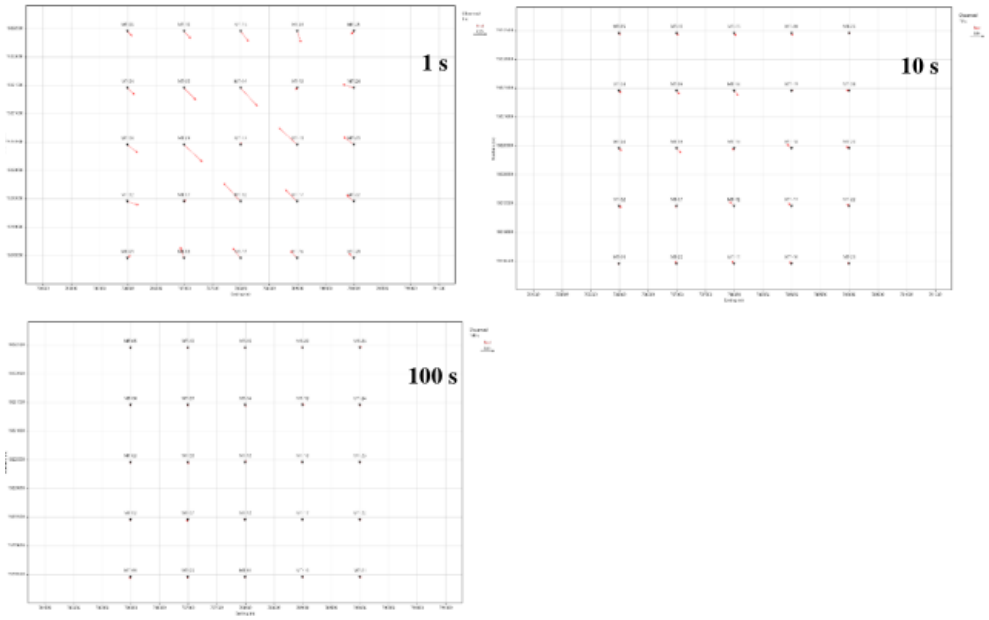

Figure 27: Induction arrow of model 03.

4.4.4 Model 4

The distribution of conductive anomalies in Model 04 using induction arrows is shown in Figure 28. At low periods (0.01 seconds), the response from the conductive anomaly is very weak, with induction arrows pointing below the surface. At 0.1 seconds, the conductive anomaly response begins to show a weak central direction. Clearer induction arrows start to appear at 1 second, pointing toward the center. With increasing periods, the induction arrow magnitude weakens as the distance from the conductive anomaly increases. This can also be analyzed with the Phi phase tensor shown in Figure 24. At low periods (0.01 to 1 second), the conductive anomaly response is recorded, indicated by a larger Phi angle in the conductive anomaly compared to the resistive part. At 0.01 seconds, the Phi phase tensor already shows a large angle due to the proximity to the conductive anomaly. At 0.1 and 1 second, the Phi phase tensor response indicates the presence of the conductive anomaly.

4.5 MT Data Modeling

4.5.1 1-D Interpretation

The 1-D model has resistivity values that vary with depth (Figure 29). The period range used for the 1-D model in Model 01 is from 0.01 to 1000 seconds, whereas for the other models, the 1-D model is only applicable at a period of 0.01 seconds. The 1-D modeling is performed by first conducting forward modeling, followed by inversion to produce a resistivity model that accurately depicts the subsurface resistivity values. The 1-D interpretation serves as an initial approach for modeling and interpretation in the preliminary stage. The inversion

results for Model 01 show that the 1-D modeling is consistent with the synthetic MT curve parameter analysis. The layer thickness from the 1-D inversion more accurately represents the synthetic model conditions compared to the 2-D inversion model. The layer thickness obtained is 1 km for each layer.

The analysis of Model 02 reveals the presence of both 1-D and 2-D dimensionalities. The 1-D inversion modeling results for Model 02 show a lateral distribution of resistivity values consistent with the synthetic model. However, the elevation does not match the synthetic model, with the 1-D model indicating elevations greater than -3000 masl, while the synthetic model reaches only up to - 2400 masl.

The 1-D inversion results for Model 03 show that the lateral distribution of resistivity values aligns with the synthetic model, but the elevation is not accurate. The conductive anomaly elevation produced by the 1-D model is greater than 5000 m, whereas the synthetic model indicates around -1400 m.

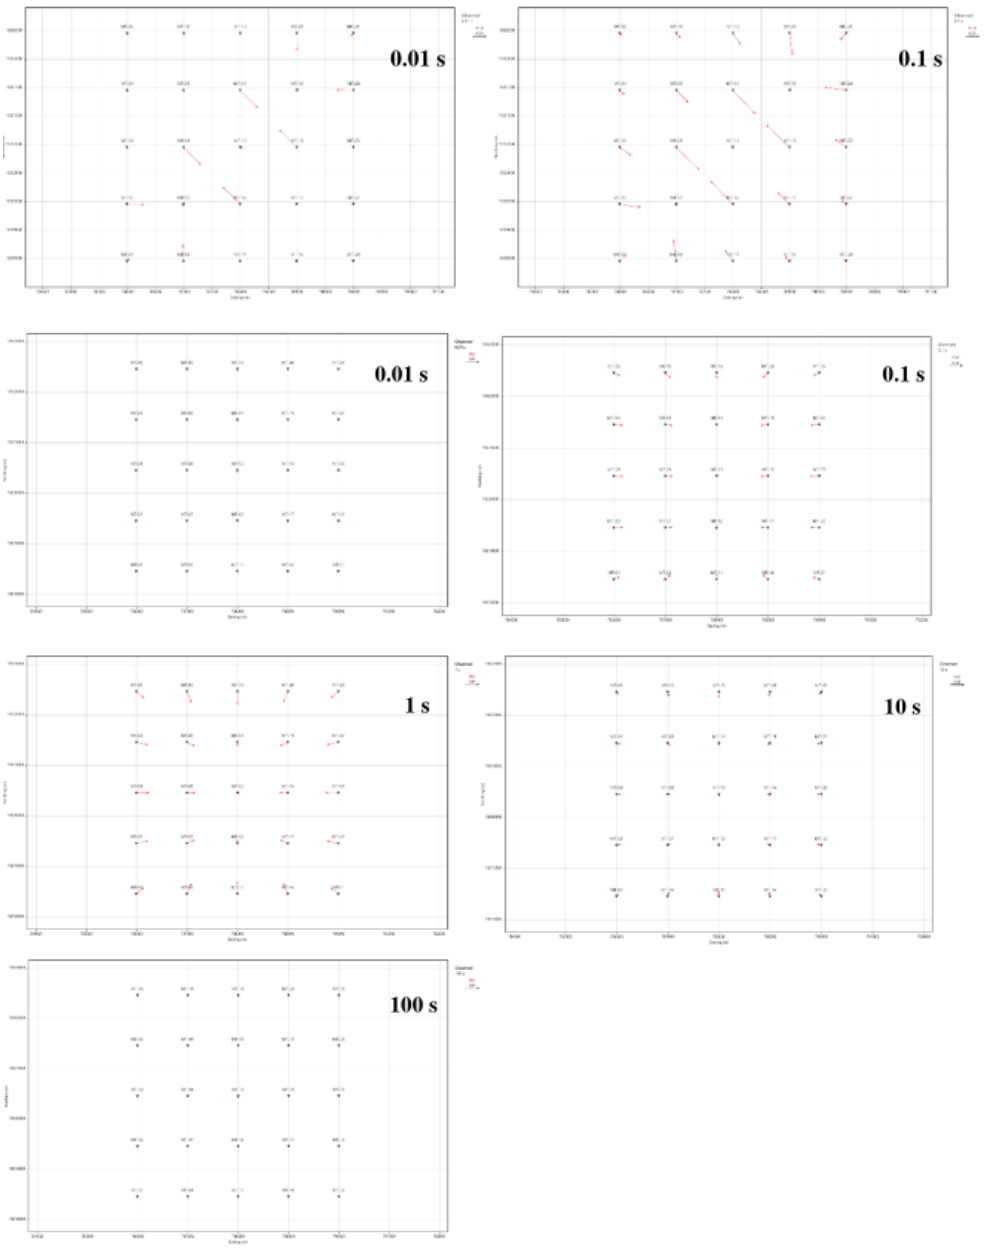

Figure 28: Induction Arrow of Model 04.

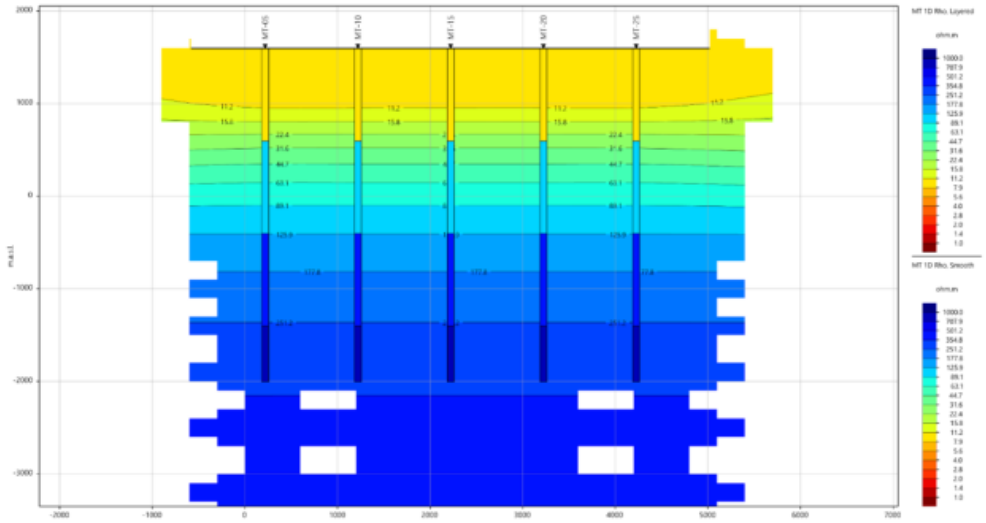

Figure 29: 1-D model for model 01.

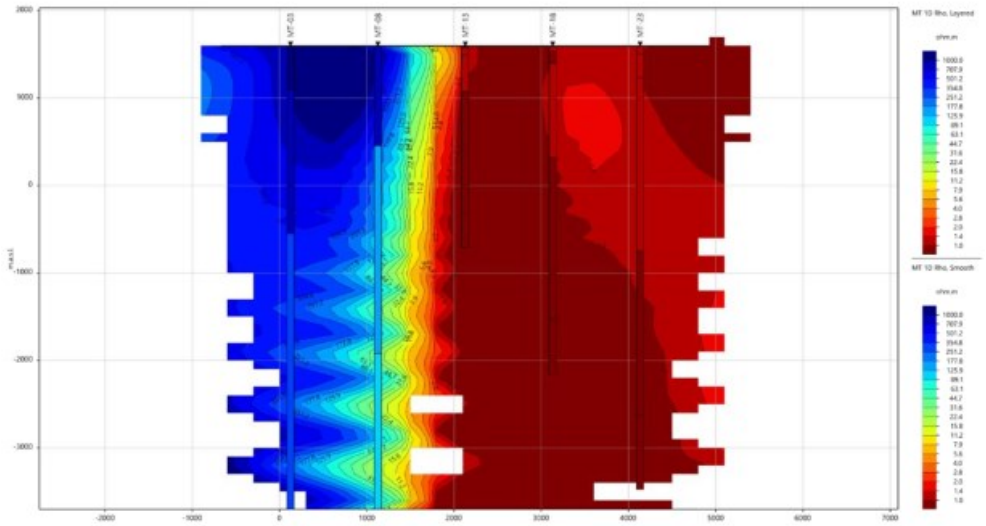

Figure 30: 1-D model for model 02.

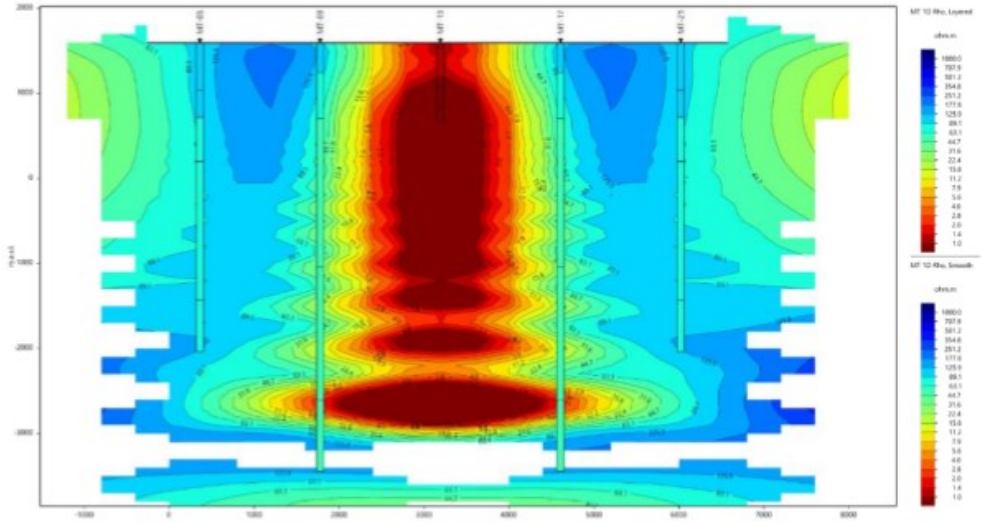

Figure 31: 1-D dodel for model 03.

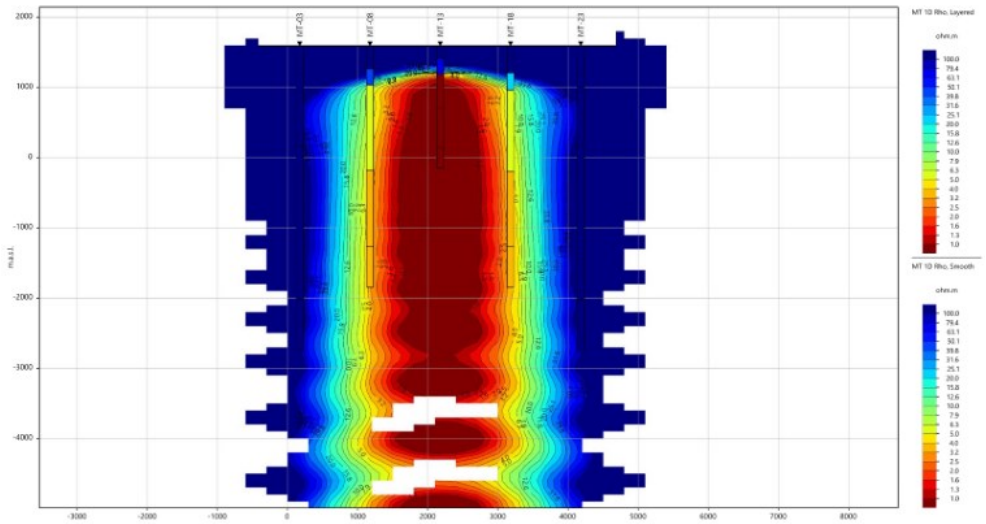

Figure 32: 1-D model for model 04.

In Model 04, the lateral distribution of the conductive anomaly matches the synthetic model, but the depth does not align with the synthetic data. The depth of the conductive anomaly from the 1-D modeling is more than -4000 masl.

4.5.2 2-D Interpretation

In 2-D modeling, trial and error are performed to find the appropriate inversion parameter size that matches the subsurface conditions. The geometry and inversion parameter size significantly affect the resistivity distribution results. 2-D MT modeling is carried out using the same transect to observe subsurface resistivity distribution with respect to distance and depth. In constructing the 2-D model, the geometry of each cell affects the resistivity distribution results, as do the background resistivity values and inversion input parameters.

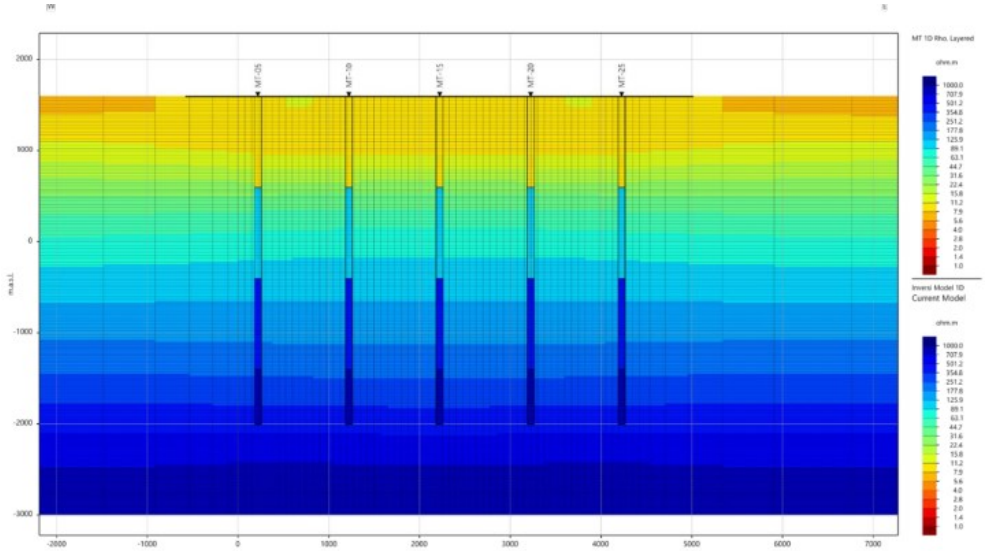

Figure 33: 2-D model for model 01.

Based on the MT curve parameter analysis, Model 01 has 1-D dimensionality. When 2-D inversion modeling is applied to Model 01, the layer elevation from the 2-D inversion does not match the synthetic model. For example, the first layer's thickness does not reach 1 km. The geometry used in the inversion includes horizontal cell widths of 500 m, an elevation range of 1600 to -2400 m, padding of 1000 m with a padding factor of 1.5, and vertical cell thickness of 25 m. The inversion parameters used include the entire period range (0.01 to 1000 seconds) and a background resistivity value of 100 Ωm.

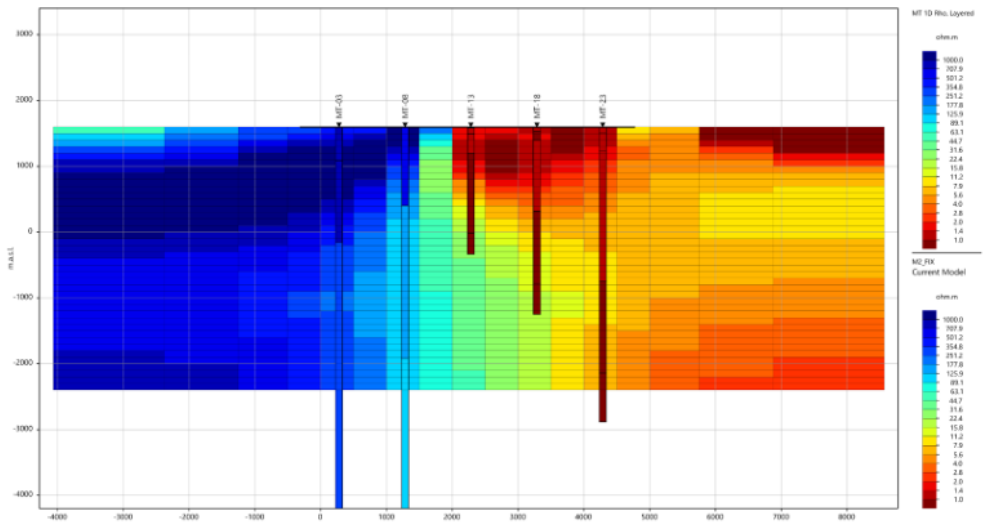

Figure 34: 2-D model for model 02.

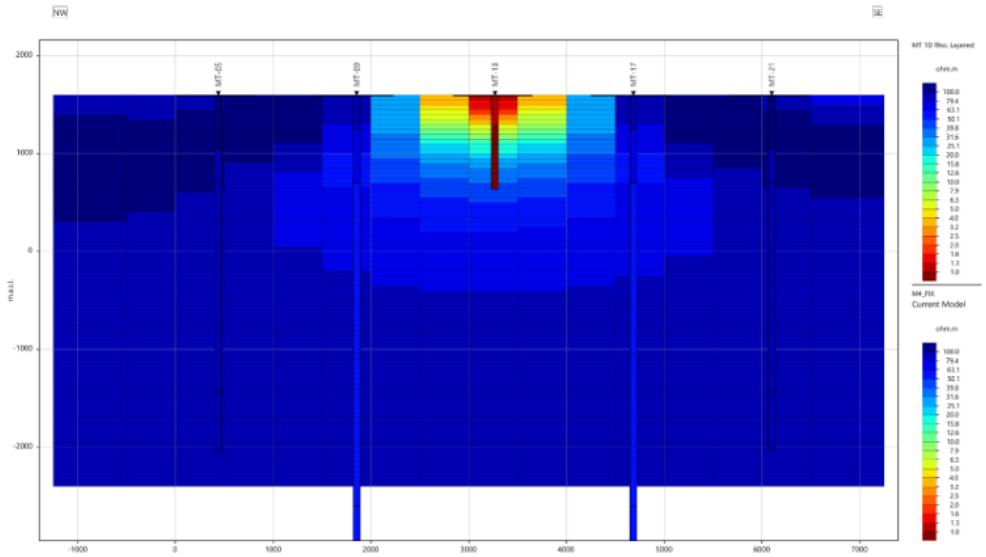

Figure 35: 2-D Model for Model 03.

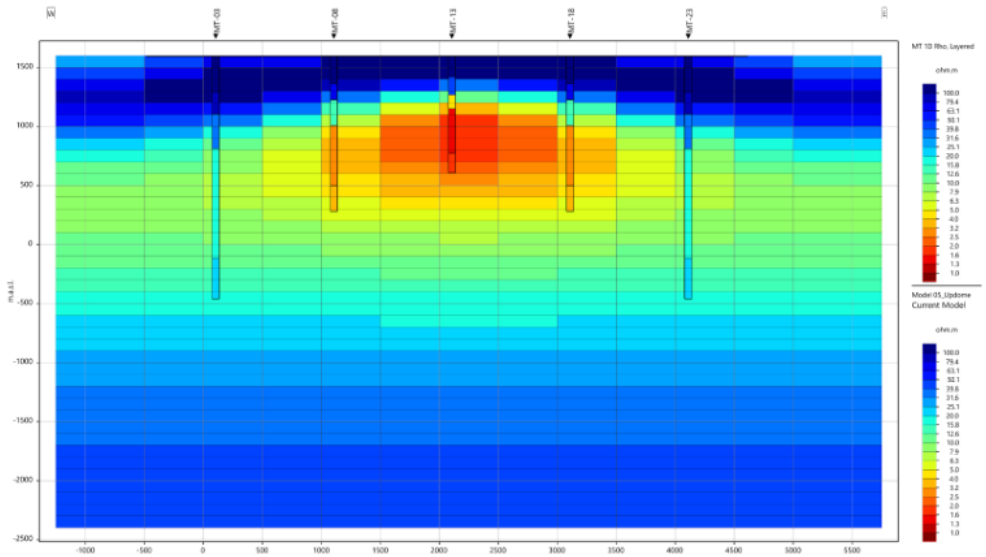

Figure 36: 2-D model for model 04.

The MT curve parameter analysis for Model 02 indicates 2-D dimensionality. The lateral resistivity distribution aligns with the synthetic model, and the 2-D inversion depth also represents the synthetic model depth. The geometry used in the inversion for Model 02 includes horizontal cell widths of 500 m, an elevation range of 1600 to -2400 masl, padding of 1000 m with a padding factor of 1.5, and vertical cell thickness of 100 m. The inversion parameters used include the entire period range (0.01 to 1000 seconds) and a background resistivity value of 100 Ωm. The MT transfer function used is TM mode, as the geoelectrical strike direction aligns with the magnetic field. Additionally, Model 02 has 2-D dimensionality due to the simple lateral resistivity distribution and geometry.

For Model 03, the 2-D inversion results with a transect perpendicular to the geoelectrical strike up to a period of 0.1 seconds do not accurately represent the conductive anomaly distribution in elevation. In the synthetic model, the conductive anomaly depth is around 2 km from the surface, but the 2-D inversion results are only reliable up to 0.1 seconds, as the 2-D modeling limit is at this period. Therefore, 3-D inversion modeling is needed for more representative results. The geometry used in the inversion for Model 03 includes horizontal cell widths of 500 m, an elevation range of 1600 to -2400 masl, padding of 1000 m with a padding factor of 1.5, and vertical cell thickness of 100 m. The inversion parameters used include the entire period range (0.01 to 0.1 seconds) and a background resistivity value of 100 Ωm. The complex geometry and resistivity distribution influence the dimensionality of the diagonal resistivity contrast.

In Model 04, the 2-D inversion results up to a period of 0.1 seconds show that the lateral resistivity distribution aligns, but the depth of the conductive layer does not match the synthetic model. The synthetic model indicates a depth of 2 km from the surface, but the 2-D inversion results only show a depth of 503 m. The geometry used in the inversion for Model 04 includes horizontal cell widths of 500 m, an elevation range of 1600 to -2400 m, padding of 500 m with a padding factor of 1.5, and vertical cell thickness of 100 m. The inversion parameters used include the entire period range (0.01 to 0.1 seconds) and a background resistivity value of 100 Ωm. The MT transfer function used is TE mode, as the geoelectrical strike direction aligns with the electric field. 3-D inversion modeling is needed for more accurate data modeling, similar to Model 03, where the complex geometry and resistivity distribution influence the dimensionality of the anticline resistivity contrast.

5. CONCLUSION

The research conducted to analyze the MT curve parameters from 3D synthetic MT data concluded that the TE and TM curves separate when crossing the geoelectrical strike, whereas they align when the resistivity values are the same. If the polar diagram is circular, further processing can be done up to 1-D; if elliptical, processing can extend to 2-D; and for a peanut shape, processing can be up to 3-D. If the beta phase tensor value is zero, the dimensionality is 1-D, and if it is more than three, the dimensionality is 3-D. The dimensionality of the polar diagram is closely related to the beta angle in the beta phase tensor. If there is no change in the polar diagram shape, the Phi phase tensor value is homogeneous at each period, and the induction arrow points to the surface, there is no linear zone. However, if the polar diagram shape changes, the Phi value varies at each period, and the induction arrow points towards the conductive layer, a linear zone can be identified. Conductive anomalies are indicated by the direction of the induction arrow pointing towards the conductive layer, and the phase tensor value will be higher than that of other stations with higher resistivity values.

Radon Thoron in Fault-Controlled Geothermal Prospect: A Study Case in Sumatra

Fraga Luzmi Fahmi, Jodhi Pramuji Giriarso, Fuad Nur Hussein, and Mulyanto

Pertamina Geothermal Energy, Grha Pertamina, Pertamax Tower 5th floor,
Jl. Medan Merdeka Timur No.11-13 Jakarta, Indonesia

fraga.fahmi@pertamina.com

Keywords: radon, thoron, RAD8, fault-controlled geothermal system, Sumatra

ABSTRACT

Radon-thoron survey was measured using Durridge RAD 8 radon detector of 63 locations in Pertamina Geothermal Energy's geothermal green field site at central region of Sumatra, which is being explored for geothermal prospecting. The object was to determine the geothermal system's permeability based on radon surface anomaly. The study area was located in a major fault of the Sumatra Fault System (SFS), and this geological structure controlled the evidence of surface manifestation, suggesting a fault-controlled geothermal prospect. The sampling distance was 500 m. As a result, anomalies here were scattered along the fault and corresponded mainly with the surface thermal manifestation and granitic rocks at the surface. The results suggested the high anomaly of radon and thoron was related to the heat flow of the system, indicated by the surface manifestation distribution. Another cause isthe granitic rock that is exposed near the surface, may result higher radon emanation. A tectonic graben area covered by paddy soil usually had measured radon levels of near zero because of the slow diffusion of radon in stagnant water. Measurements along the fault zone show variations in radon measurement values that correlate with the appearance of manifestations.

1. INTRODUCTION

Geothermal energy has received much attention as a renewable and sustainable energy source, with the potential to play a critical role in meeting global energy demands and mitigating the consequences of climate change. The assessment of geothermal resources frequently relies on various geological, geophysical, and geochemical indicators, with the detection of naturally occurring noble gases, such as radon (^{222}Rn-222) and thoron, emerging as a valuable tool for evaluating geothermal potential. Radon soil gas investigations have had varying success rates in geothermal exploration (Dyck, 1968; Wollenberg, 1974; Nielson, 1978; Whitehead et al., 1983, Cox, 1980; Whitehead et al., 2007; and Prasetio et al., 2023). Previous study on Sumatra was conducted by Haerudin et al. (2016), located on Way Ratai, one of geothermal prospect in southern part of Sumatra.

2. LOCATION AND GEOLOGICAL SETTING

The study area is a geothermal prospect under exploration phase located along the Sumatra Fault System (Figure 1). According to Sieh and Natawidjaja (2000), this prospect is located on the edge of 1N segment and terminated with 1O segment, a part of 19 segments of Sumatra Fault System (SFS). This fault termination creates a pull-apart basin on the southeast area of the geothermal prospect. The surface manifestation appears along the fault, as hot springs and warm springs. No steam features or fumarole were identified on this prospect. The distribution of the faults follows the pattern of the Sumatra Fault System with NW-SE fault pattern. Previous study by PGE (2016) suggests this prospect as a geothermal fault-controlled system, where the deep-seated fault is controlled the heat flow from the heat source to the surface as a boiling hot spring. The study area is located on the Tertiary volcanic rocks, granite rocks, and sedimentary rocks in southeast area as Quaternary alluvium covering the area of pull-apart basin (PGE, 2016).

3. METHODOLOGY

3.1 Radon and Thoron Measurements for Geothermal Prospecting

Radon is a noble gas that is colorless, odorless, and not easily chemically compounded with other natural nuclides. There are three isotopes of radon in nature, namely ^{219}Rn (Actinon) with a half-life of 4 seconds derived from the Actinium decay series, ^{220}Rn (thoron) with a half-life of 55.6 seconds derived from the ^{232}Thorium decay series and ^{222}Rn with a half-life of 3.824 days. The ^{222}Rn isotope is the decay product of ^{226}Rn in the ^{238}U decay series, decaying by emitting alpha (α) particles. ^{222}Rn detection was widely used as a natural tracer for several applications such as groundwater dynamics studies, surface water and groundwater interaction studies, and fault zone investigation studies in earthquake and geothermal system studies.

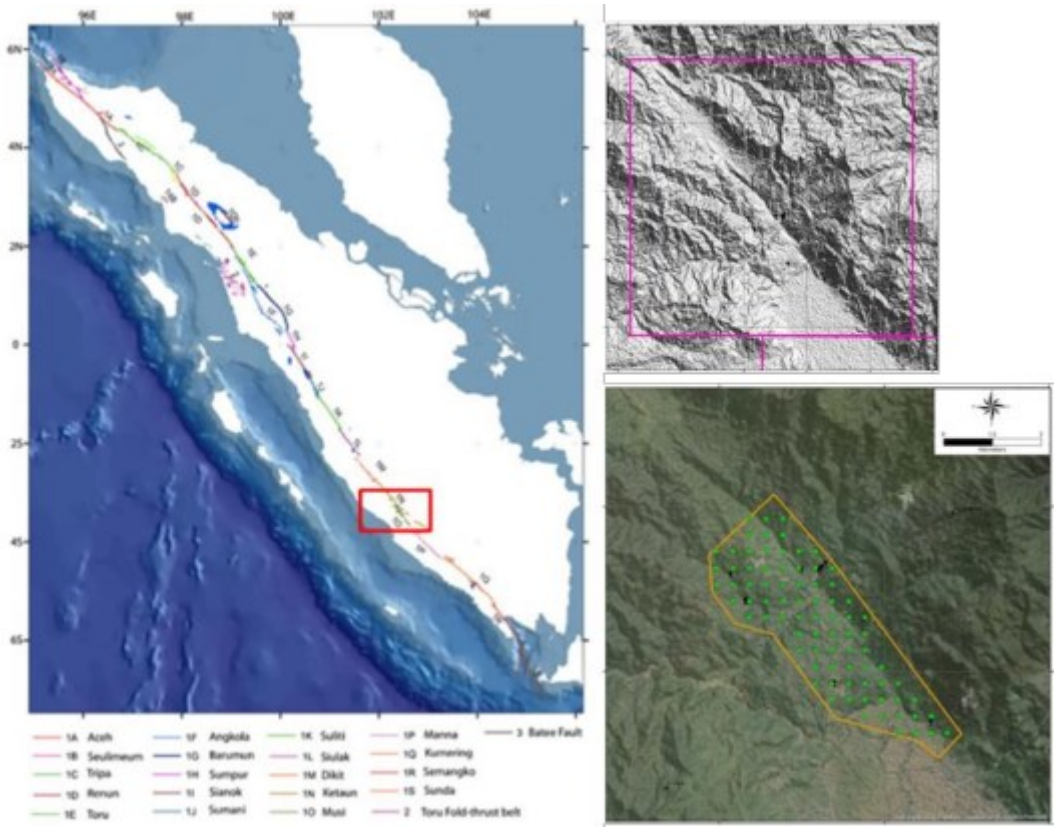

Figure 1: The location of this study related to the Sumatra Fault System (SFS), the picture shows the Sumatra Fault segment from Sieh and Natawidjaja (2000). The green dot lines indicate the distribution of data acquisition along the Sumatra Fault.

Radon can be a useful indicator in geothermal exploration because its presence can signal the indication of permeable zone due to its mobility tendency and its inert property of noble gas. Radon soil gas study allows geothermal geoscientists to locate and delineate fault-controlled geothermal systems. This data is critical for targeting geothermal wells and evaluating the viability of a geothermal resource (Figure 2).

3.2 Field Data Acquisition to Measure Radon and Thoron Soil Gas

The soil gas radon (^{222}Rn) and thoron (^{220}Rn) were measured in the field using Sniff method with a Durridge RAD8 radon detector and a soil gas probe located approximately 60-80 cm below the surface (Figure 3). To reduce air pollution, proper flushing was performed for 5 minutes before and following sampling. The radon (^{222}Rn) and thoron (^{220}Rn) measurements were performed with humidity levels below 10%. Previous study for radon soil gas from many researchers uses RAD7 as radon detector. Since early 2023, Durridge company has released a new version of the radon detector called RAD 8. In this study, Pertamina Geothermal Energy (PGE) was the first user of RAD 8 in Indonesia who apply RAD 8 as a soil gas detector in a geothermal geoscience study. A total of 63 point locations were chosen for radon soil gas measurements with consideration of geological setting and surface thermal manifestation distribution. The field data acquisition was conducted at October to November 2023. The challenges during data acquisition was heavy rainfall, extreme terrain, and heavy vegetation of forestry area.

4. RESULT AND DISCUSSION

4.1 Radon and Thoron Statistics

The soil gas radon (^{222}Rn) and thoron (^{220}Rn) findings were statistically analysed using a probability plot, a technique extensively used in exploratory geochemistry (Reimann et al., 2005; Sinclair, 1974; Ciotoli et al. 2016; and Prasetio et al., 2023). In principle, making a probability graph will determine the normality of the data, which refers to the trend line in the graph. A series of data that deviates from the normal line or has a different trend line is considered an anomaly. Thus, the threshold value can be determined, which is the value that limits the two trend lines in the probability graph. This study determined two thresholds to divide the data into low anomaly, background, and high anomaly.

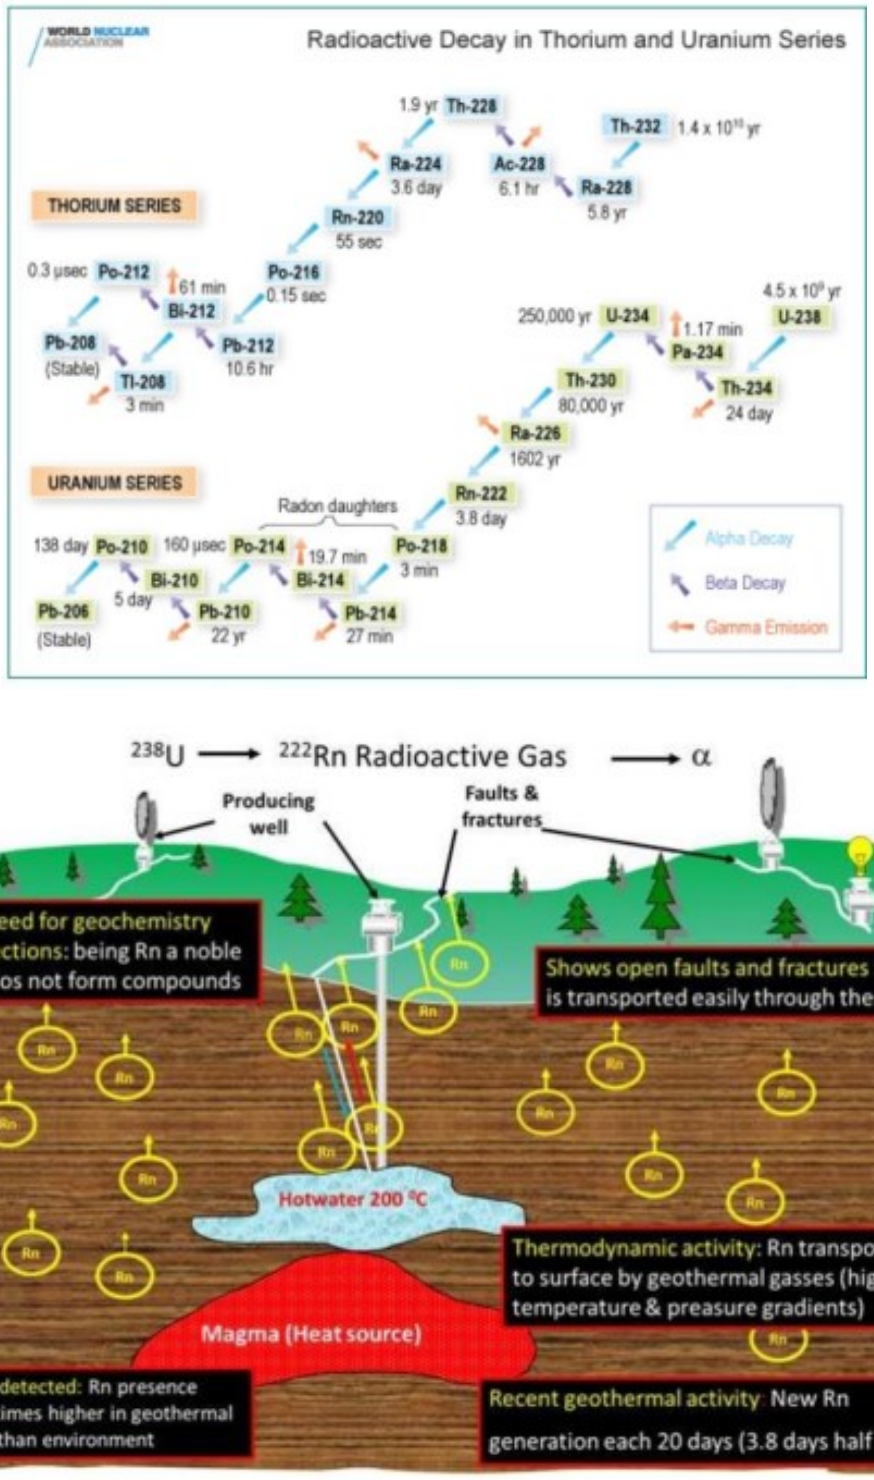

Figure 2: Top: Radioactive decay in Thorium and Uranium series as the source of radon in nature. Bottom: Radon for geothermal. exploration prospecting (Balcazar et al., 2014).

The normal probability plot tool in NCSS 2023 statistical software was used to examine the data. To explain the statistic of radon and thoron statistic, a series of normal probability plot from radon, thoron, and radon + thoron can be viewed from the graph on Figure 4. Radon (^{222}Rn) concentrations of soil gas in the research area range from 15,80 Bq/m3 to 4.132,00 Bq/m^3, with an average of 607,86 Bq/m^3. Thoron (^{220}Rn) concentrations of soil gas in the research area range from 20,00 Bq/m^3 to 16.180,00 Bq/m^3, with an average of 3.331,21 Bq/m^3. Radon + thoron values range from 122,00 Bq/m^3 to 18.480,00 Bq/m^3, with an average of 3.741,84 Bq/m^3 (Table 1). Geothermal and volcanic sites typically have values ranging from 1.500 to 250.000 Bq/m^3 (Inguaggiato et al., 2000; Bonforte et al., 2013; Mismanos and Vasquez, 2015).

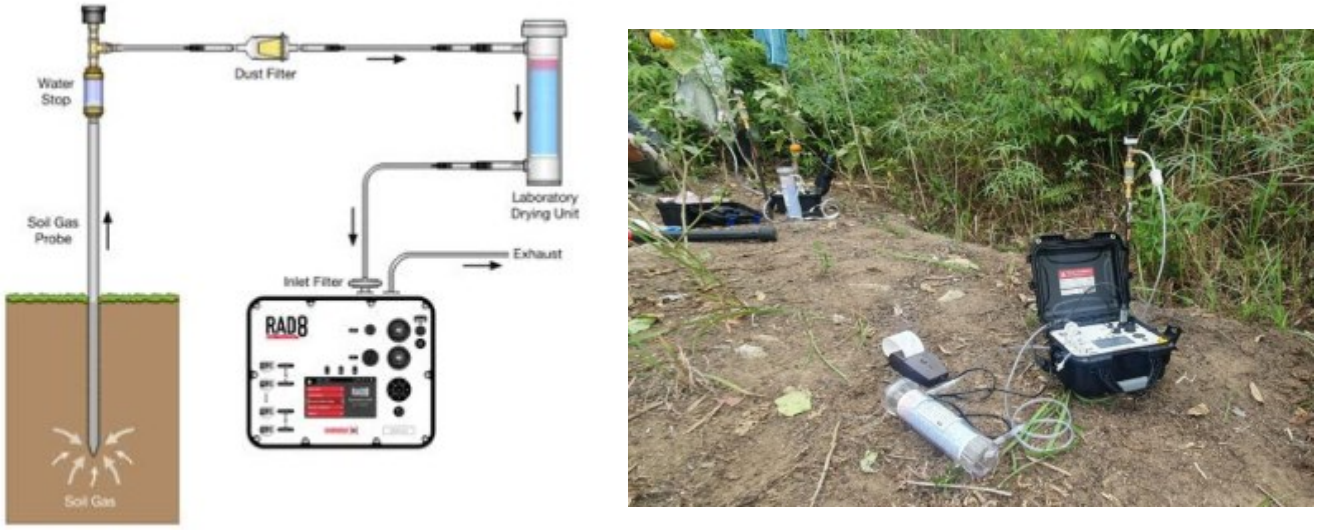

Figure 3: Soil gas probe and Rad8 radon detector configuration for field data acquisition (left), Rad8 during operation (right).

Table 1: The main statistics of soil gas data of radon, thoron, and radon + thoron (Bq/m^3).

Count of Data Samples	Soil Gas Data	Mean	Standard Deviation	Standard Error	Minimum	Maximum	Range
63	radon (Bq/m^3)	607,86	769,24	96,92	15,80	4.132,00	4.116,20
63	thoron (Bq/m^3)	3.331,21	3.226,59	406,51	20,00	16.180,00	16.160,00
63	radon + thoron (Bq/m^3)	3.939,07	3.741,84	471,43	122,00	18.480,00	18.358,00

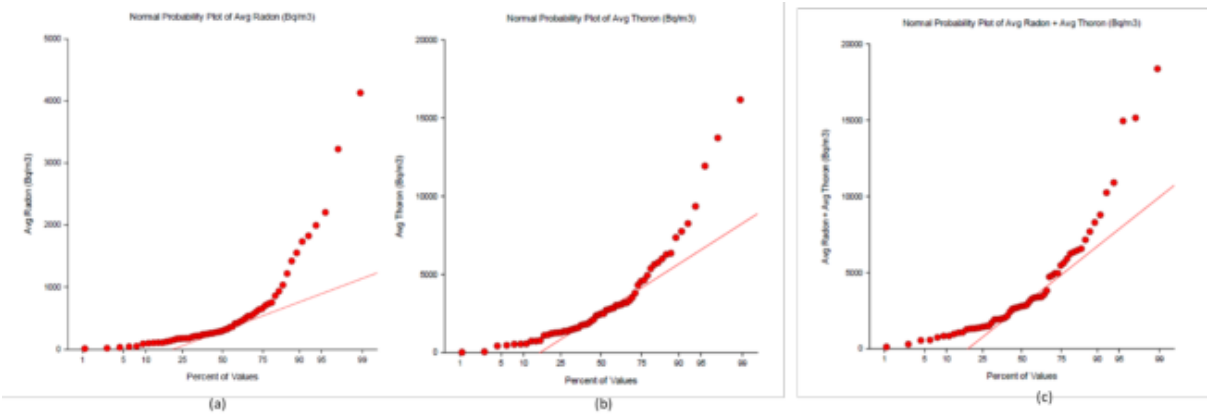

Figure 4: The graph of normal probability plot of radon (a), thoron (b), radon + thoron (c).

4.2 Distribution Maps of Radon and Thoron

The distribution map or contour of soil gas concentration was created to analyze the vicinity of high soil gas concentration to fault structures using Kriging interpolation to assess the lateral distribution of radon (^{222}Rn) and thoron (^{220}Rn) soil in the research region, which was then mapped over existing structures, which was done by Surfer and ArcGIS software (Figure 5, Figure 6, Figure 7). The structural geology data was derived from a previous study conducted by PGE (2016).

Site locations with radon (^{222}Rn) and thoron (^{220}Rn) background values were found in the central, south, and northwest area, despite the presence of major fault structures (Sumatra Fault System) along the northwest to southeast. High and anomalous values were primarily identified in the north-northeast and southeast of the research area, which is located around the AP and BR hot spring complex. Based on the lateral distribution of radon, thoron, and radon + thoron, all show generally similar patterns. The occurrence of a lateral distribution of high radon values is more widespread in the north-north-east area than the lateral distribution of thoron values, although in terms of measured values thoron is higher than radon. From the distribution of the anomaly map, it

can also be concluded that radon and thoron anomaly values do not show the same high values along the Sumatra Fault System, as seen from the low radon and thoron emanation values from measurements in the central area. High values of radon (> 2.000 Bq/m^3) and thoron (> 10.500 Bq/m^3) do not always correlate with the appearance of geothermal manifestations. From the maps in Figure 5, Figure 6, and Figure 7, it can be identified that radon values around the K2 & K3 hot spring and AK warm spring, as well as L warm spring show insignificant radon and thoron values. The surface geology data and geothermal conceptual model in Figure 8 may correlate with the radon and thoron distribution data, where high radon and thoron values are found in locations around hot springs and granitic rock outcrops at the surface. These granitic rock outcrops on the surface follow the pattern of high radon and thoron, it can also be correlated that radon and thoron may indicate heat flow from fault-controlled geothermal systems. High radon and thoron values appear around the upflow zone following with the appearance of boiling hot springs and neutral chloride water. The low radon and thoron values in the south-southeast area may correlate with the surface rock type of moist paddy soil. Many researchers have concluded that radon values are low if the measurement location is on a water-saturated soil surface because the presence of shallow water on the surface can block radon readings on surface radon detectors. The radon and thoron distribution pattern at the surface was modeled using Leapfrog software with the same cross-section direction as the geological model (NE-SW), which is perpendicular to the Sumatra Fault System (SFS) pattern (Figure 9).

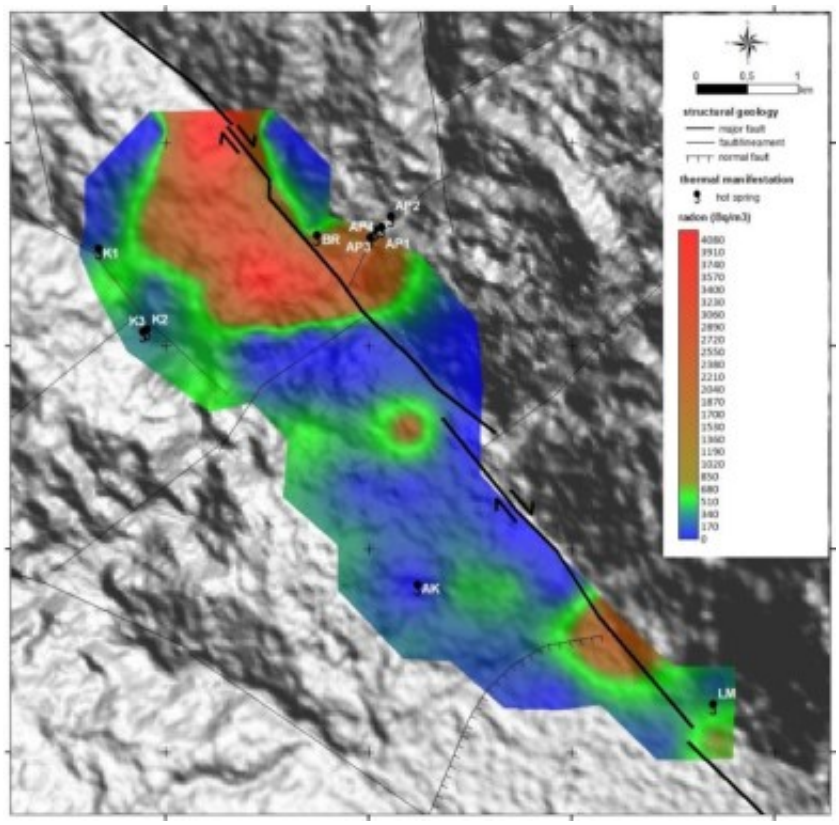

Figure 5: Anomaly map of radon.

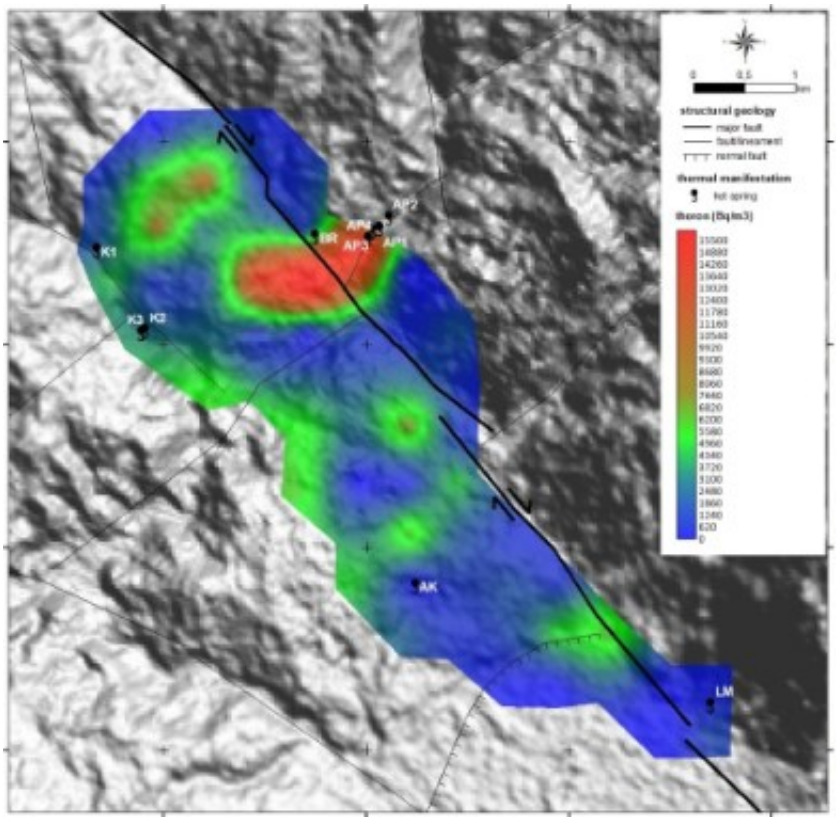

Figure 6: Anomaly map of thoron.

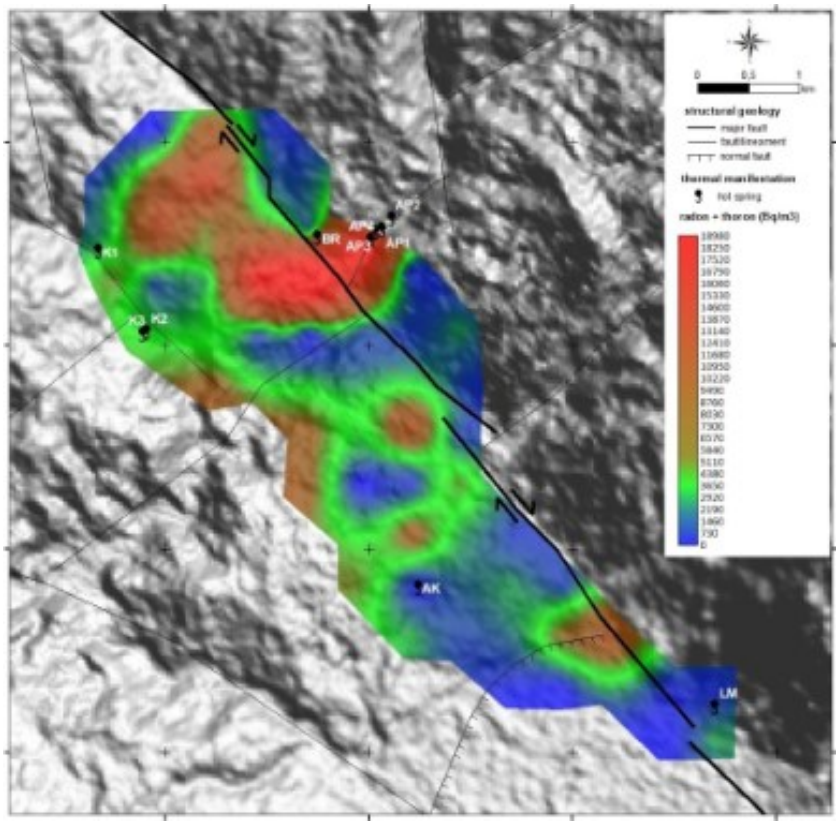

Figure 7: Anomaly map of radon+thoron.

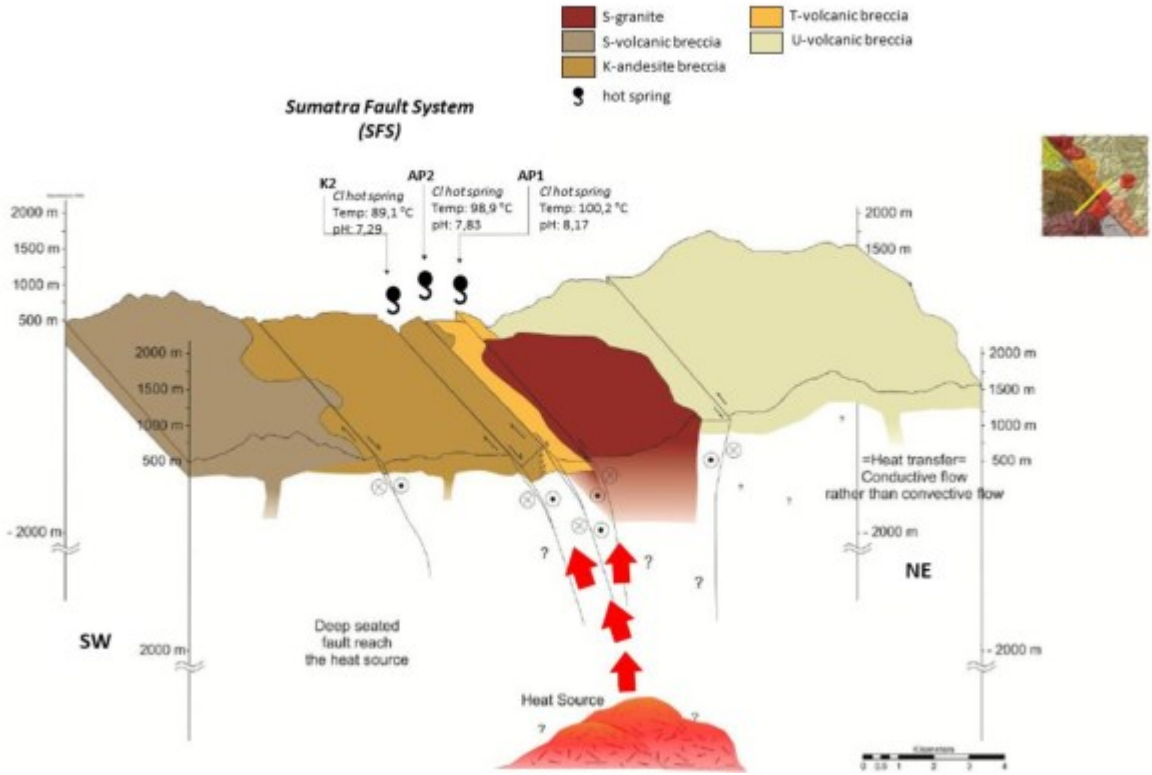

Figure 8: 3D-geological cross section and geothermal conceptual model of study area (modified from PGE, 2016).

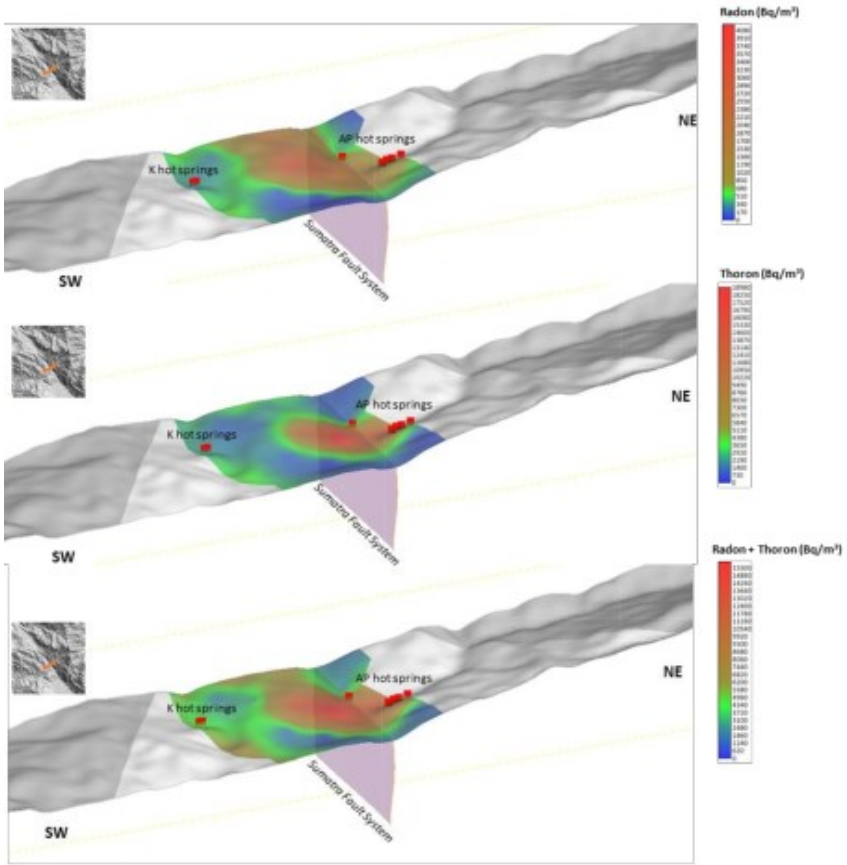

Figure 9: radon, thoron, and radon+thoron anomaly map cross section with terrain model. The cross sections (NE-SW) are perpendicular to Sumatra Fault orientation (NW-SE fault pattern).

5. CONCLUSION

The soil gas of radon (^{222}Rn) and thoron (^{220}Rn) and thoron distribution in this study area showed high concentration in the northern to northeastern of study area, which related to some fault segments of Sumatra Fault Sytem and appearance of natural boiling hot spring and chloride water, which represents as upflow zone of this geothermal system. The high values of radon also correlate with the lithological distribution of granitic rock in the surface, while the low radon and thoron values in the south-southeast area may correlate with the surface rock type of moist paddy soil.

ACKNOWLEDGEMENTS

The authors would like to express gratitude to our colleagues in Pertamina Geothermal Energy (PGE)'s exploration geoscience team who provided assistance during field and laboratory works. The authors want to thank to the management of PGE for supporting and allowing this study to be published.

Keywords: scaling, geothermometer, geochemistry, Dieng

ABSTRACT

Scaling is a mineral or mineral combination that forms and precipitates in response to pH, pressure, and temperature changes. Scaling is one of the challenges in the geothermal industry, particularly in medium enthalpy geothermal systems with high silica content, such as Dieng. This situation becomes disruptive when minerals deposit in brine pipeline and injection wellbores, reducing the flow rate of the fluid. To prevent scaling, it is crucial to understand mineral geothermometers, geochemistry, and pressure temperature in well and surface facilities.

This case study goes over the appearance of scaling in well testing activities. This data from well testing activity is essential as a key to understanding the development of scaling before the well is generated and hooked in to the power plant. The data came up from Well Testing activity, PTS survey, TFT and XRD analysis of scaling samples. It's interesting to note that when WT is conducted, the stuffs formed in the borehole and well testing facilities. Based on Well Testing Activity, the well can generate a total mass flow of approximately 136 kg/s at an enthalpy of roughly 1470 kJ/kg at WHP 45 bara. The liquid level was measured during the PT shut-in survey, which somewhat is located at 500 mASL. Based on the geochemistry data, geothermometer, and SSI analysis were obtained to gain a more comprehensive result to analyze potential scaling issues, as there are scaling issues when the well is flowing. Scaling in the research area typically takes the form of silica, metal sulfides, and so on.

The objective of this research is to investigate the influence of the mineral geothermometer, fluid geochemistry, and PT on scaling deposition in geothermal fields with high enthalpy characterization in two-phase fluid well. It is hoped that the findings of this study will help to identify scaling depositional characteristics and locations related to solution solubility and saturation. Further research is required to overcome or reduce the formation of scaling by modifying the level of pressure and other changes to the well testing facility in the well.

1. INTRODUCTION

Located on the Dieng Plateau in Central Java, Indonesia, the Dieng geothermal field stands as a testament to the region's unique geological characteristics and renewable energy potential. Nestled amidst the volcanic complex of the Dieng Plateau, this field boasts a diverse array of geothermal features owing to its location within the volcanic arc of the Sunda-Banda magmatic arc. Sileri, one of the areas in Dieng, for instance, governs and hosts the two phase-liquid dominated reservoir with neutral fluid as it marked by presence of high chloride and silica concentration. Chloride content is ranging from 8000 to 24000 ppm and silica content from 600 to 1300 ppm, respectively. The first Commercial Operation Date (COD) for Dieng Unit-1 was in 2002 with 1x60 MW installed capacity. Right now, the power plant had produced less electricity than the initial capacity because one of the problems is scaling.

In 2020, GDE started to develop the second power plant unit for Dieng Field. The development program of Dieng Unit 2 aims to obtain capacity of approximately 55 MWe plus 10% steam buffer. After drilling, production well need to be tested. This paper will be focused in one of the well that tested in development program of Dieng Unit 2, Well 1. Well 1 is production well that already drilled in Sileri area. One of the issues in well testing activity in Dieng is about scaling related in wellbore or well testing equipment. This case study goes over the appearance of scaling in well testing activities. This data from well testing activity is essential as a key to understanding the development of scaling before the well is generated and hooked in to the power plant.

The research framework of this study begins with an overview of the Dieng geothermal area, highlighting its geological characteristics and the prevalent types of scaling, such as halite, sylvine, and amorphous silica. The next phase involves conducting detailed analyses, including geothermometer to assess subsurface temperatures, geochemical analysis to determine the composition of geothermal fluids, and pressure-temperature profiling to

understand the dynamic conditions within the wellbore. These analyses provide a comprehensive understanding of the scaling processes and the conditions that favor their formation. The final phase of the study focuses on evaluating and implementing anti-scaling and descaling methods, such as high-pressure separation and chemical injections of inhibitors or acids, to develop effective strategies for preventing scaling in the Dieng geothermal wells and surface facilities. This holistic approach aims to enhance the efficiency and longevity of geothermal operations in the Dieng area.

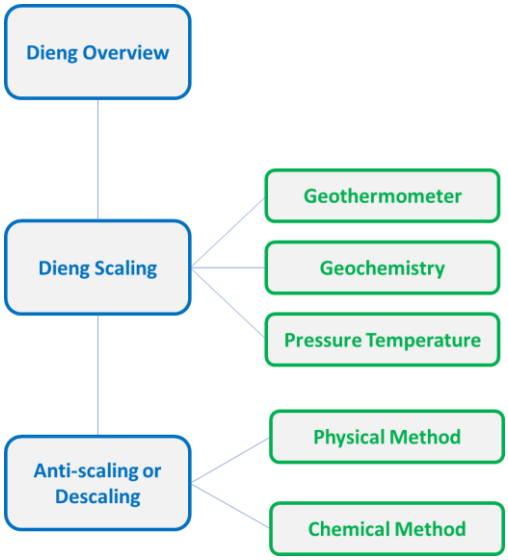

Figure 1: The research framework of this study.

2. DIENG SCALING TYPE

2.1 Overall Scaling Dieng

Scaling is a mineral or mineral combination that forms and precipitates in response to pH, pressure, and temperature changes. Scaling is one of the challenges in the geothermal industry, particularly in medium enthalpy geothermal systems with high silica content, such as Dieng. This situation becomes disruptive when minerals deposit in brine pipeline and injection wellbores, reducing the flow rate of the fluid. To prevent scaling, it is crucial to understand mineral geothermometers, geochemistry, and pressure temperature in well and surface facilities. In Dieng, scaling can form from wellbore until turbine. While well testing activity, scaling still found even the activity still in a short time. Some of mineral scaling already found in Dieng such as silica, metal sulfide, halite, calcite, and etc.

2.2 Scaling in the Well Testing Activity

The scaling process in geothermal wells can have significant implications for the effectiveness and efficiency of well testing activities. In a recent well testing conducted in a new geothermal well, scaling was found in various equipment used during well testing, such as in pipelines, mist pads in the LECM, and potential on the wellbore itself. The presence of scaling in the wellbore was identified by running a sample catcher in the hole to obtain scaling samples, which were then tested using X-ray diffraction (XRD) to determine the type of scaling present. This information is crucial for understanding the potential scaling issues that may arise in the future in the Dieng geothermal field, allowing for better mitigation strategies to be implemented to maintain the integrity and efficiency of geothermal well testing activities. By identifying and analyzing scaling in geothermal wells, GDE can proactively address scaling-related challenges and optimize the performance of geothermal wells in the long term.

3. GEOCHEMISTRY AND WELL TESTING RESULT

3.1 Geothermometer

From the Na-K-Mg geothermometer to determine the geothermal temperature in the Dieng Geothermal field, revealing a calculated temperature of approximately 340°C. However, it was noted that this temperature was higher than the actual temperature recorded in boreholes, which typically averaged around 304°C. This discrepancy raised questions about the accuracy of the geothermometer and the factors that could potentially influence the results.

One possible explanation for the higher temperature readings could be attributed to the presence of fluids with differing chemical compositions within the geothermal reservoir. These variations in fluid chemistry can affect the equilibrium between the geothermal minerals and the fluids, leading to deviations in temperature estimates. Additionally, the complexity of the geological structure and fluid flow dynamics in the Dieng Geothermal field could also play a role in influencing the temperature calculations.

Geothermometers estimate subsurface temperatures by analyzing the equilibrium state of minerals dissolved in geothermal fluids. Higher temperatures indicated by geothermometers suggest that the geothermal fluids have equilibrated at significant depths where temperatures are higher. As fluids ascend to the surface or shallower depths, they cool, leading to changes in mineral solubility. As the fluid cools, these minerals can precipitate out, forming scale in wellbores, pipelines, and surface equipment.

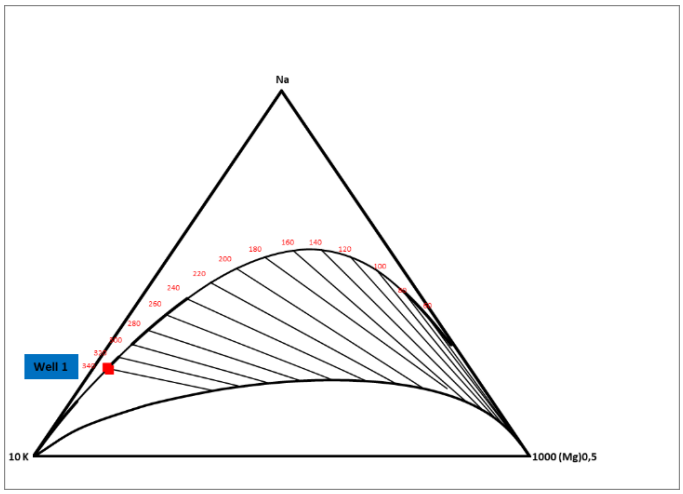

Figure 2: Na-K-Mg Ternary Diagram of the study area to estimate the temperature of reservoir fluids.

3.2 Geochemistry

Geochemistry analysis of reservoir fluid from Well 1 has revealed interesting findings. The first sampling showed that the fluid was still influenced by drilling fluids, with a high nitrogen/argon chemistry content. This is likely due to the use of aerated drilling fluid that incorporates air from the atmosphere during the drilling process. The presence of these gases indicates that the reservoir fluid may still be in contact with the drilling fluids, which could impact the overall geochemical composition of the fluid.

However, subsequent samplings at different times have yielded more promising results. The second and third sampling data show that the reservoir fluid has transitioned to a composition more characteristic of natural reservoir gases. The geochemical analysis suggests that the fluid is no longer heavily influenced by the drilling fluids, indicating that the reservoir gases are now the dominant component. This shift in composition is a positive sign, as it suggests that the reservoir fluid is evolving towards a more stable and natural equilibrium.

The analysis of the geochemical results from the reservoir fluid in the well 1 highlights the dynamic nature of fluid composition in a production well. The initial influence of drilling fluids has given way to a more natural reservoir gas composition over time. This evolution in composition is crucial for understanding the behavior of the reservoir and optimizing production strategies.

During the well testing activity at Well 1, geochemistry fluid sampling revealed a high Chloride content in the geothermal fluid. This elevated Chloride content poses a significant risk for scaling potential within the geothermal pipelines and injection wells. Chloride ions in high concentrations can react with minerals and metals present in the geothermal fluid, leading to the formation of scale deposits. These scale deposits can cause corrosion and blockages within the pipelines and injection wells, decreasing the efficiency of the geothermal system. In order to mitigate the scaling potential associated with high Chloride content in geothermal fluids, proper monitoring and treatment procedures must be implemented. Regular testing and analysis of the fluid chemistry, along with the use of scale inhibitors and corrosion inhibitors, can help prevent scaling issues and ensure the longevity and effectiveness of the geothermal infrastructure.

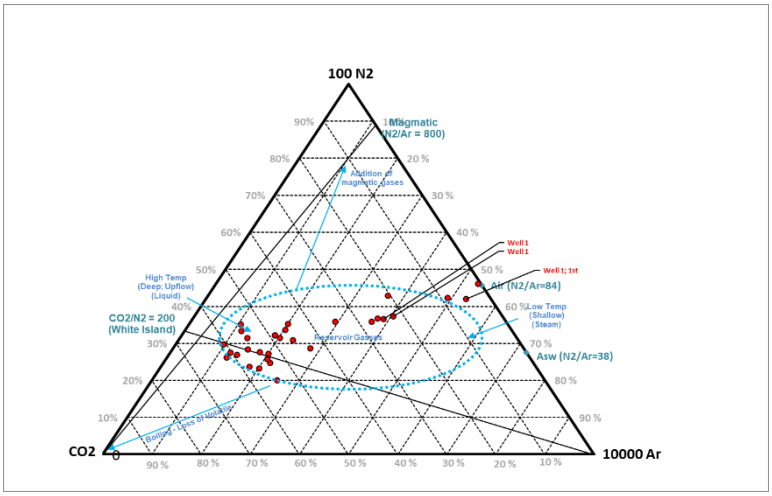

Figure 3: N2-CO2-Ar Ternary Diagram to explain gas chemistry.

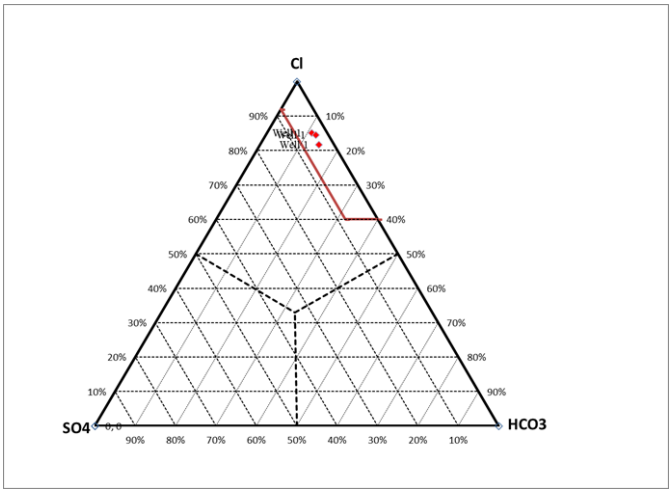

Figure 4: Cl-SO4-HCO3 Ternary Diagram about fluid chemistry.

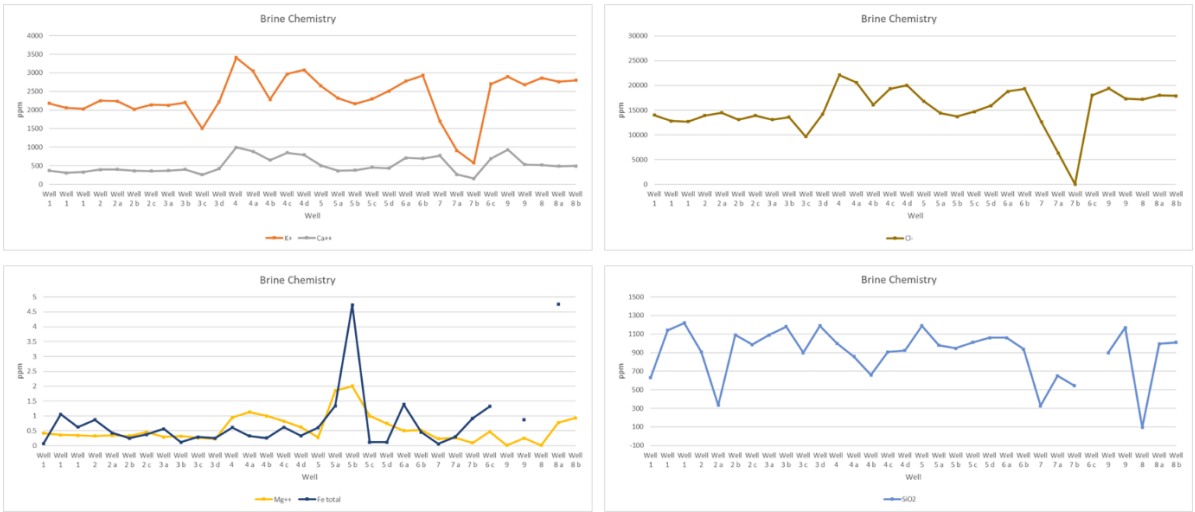

Figure 5: Brine chemistry of well 1 and existing wells.

The chemistry of geothermal brine plays a crucial role in determining the scaling potential within a geothermal well, with specific ions like potassium (K), calcium (Ca), chloride (Cl), magnesium (Mg), iron (Fe), and particularly silica (SiO2) being key indicators. In the case of the research well (Well 1), the SiO2 concentration is notably high, around 1200 ppm, while the concentrations of other ions such as K, Ca, Cl, Mg, and Fe remain consistent with those found in existing wells. This elevated silica concentration significantly increases the risk of silica scaling, which is one of the most common and problematic types of scaling in geothermal systems.

Silica tends to precipitate as the geothermal fluid cools during its ascent from the reservoir to the surface, especially when its concentration exceeds the solubility limit. In Well 1, the high SiO2 concentration suggests that silica scaling could occur in areas where there is a significant temperature drop, such as within the wellbore, in surface pipelines, or in heat exchangers. The scaling is likely to form as amorphous silica deposits, which can obstruct fluid flow and reduce the efficiency of geothermal operations. Although the other brine chemistry parameters are similar to those in existing wells, indicating a stable chemical environment for minerals like calcium carbonate or iron oxide, the unique challenge in Well 1 is the management of silica scaling.

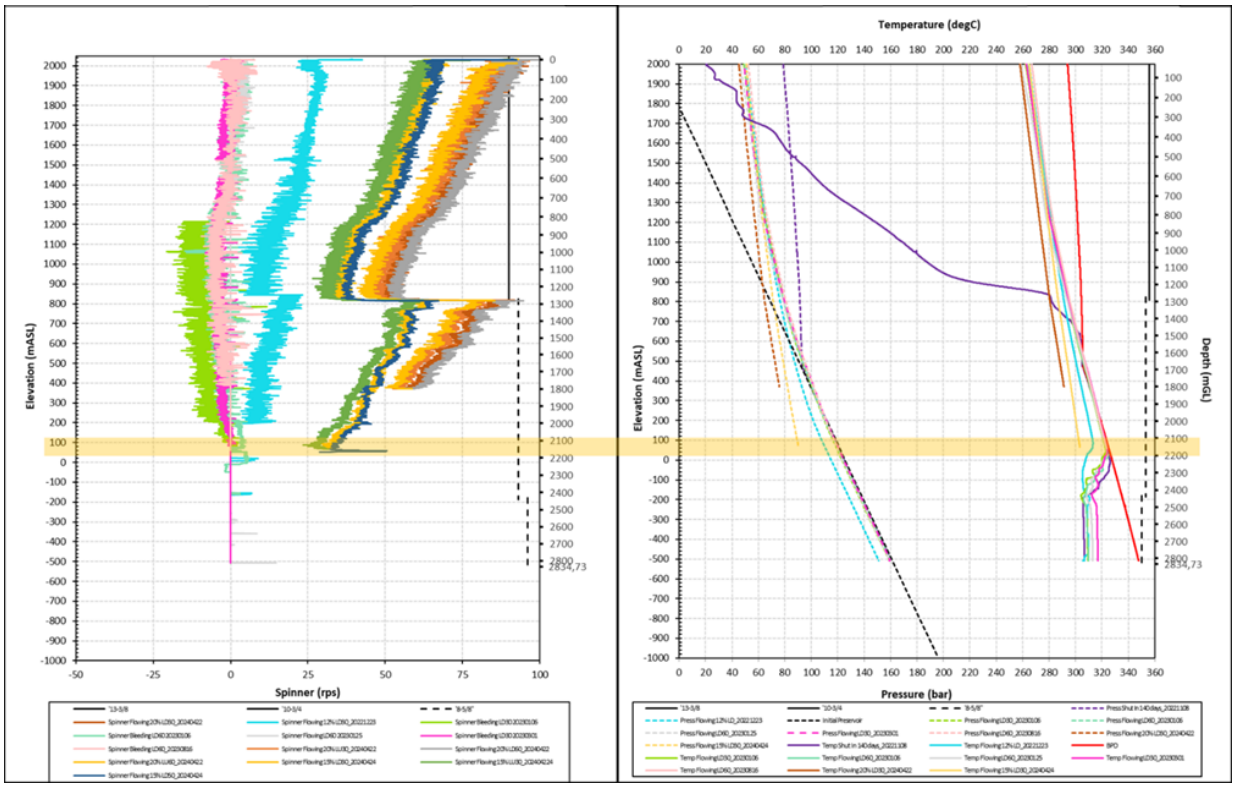

Figure 6: Pressure-Temperature-Spinner survey in the well 1.

3.3 Pressure-Temperature

A Pressure Temperature Spinner (PTS) survey conducted during bleeding and flowing in Well 1 revealed significant insights into the reservoir's behavior. The PTS surveys were performed at four different surveys to monitor the inflow and outflow feed zones within the reservoir section. The flashing point was identified at approximately 2157-2161 meters below ground level (mGL) or 65 meters above sea level (mASL), indicating a crucial zone where the pressure drops significantly enough for the liquid to vaporize. Temperature readings from the survey showed values higher than those recorded during the 140-day heating up period, suggesting increased thermal activity in the reservoir or well already in the stable condition.

Throughout the PTS surveys, a consistent issue was noted where the spinner readings were lost around 2000-2100 mGL. This anomaly occurred in every survey, indicating a potential obstruction or consistent interference at that depth. Additionally, scale samples were found on the spinner blades during each survey, which could be contributing to the spinner reading losses. These findings emphasize the need for further investigation into the cause of the obstructions and the thermal dynamics within the identified flashing point and feed zones. Based on Well Testing Activity, the well can generate a total mass flow of approximately 136 kg/s at an enthalpy of roughly 1470 kJ/kg at WHP 45 bara. The liquid level was measured during the PT shut-in survey, which somewhat is located at 500 mASL.

The flashing point in geothermal wells, where the geothermal fluid undergoes a phase change from liquid to vapor due to a drop in pressure, plays a crucial role in determining the scaling potential. As the pressure decreases and the temperature drops during the ascent of the fluid, especially near the flashing point, the solubility of dissolved minerals such as silica and calcium carbonate significantly decreases. This rapid change in conditions leads to the precipitation of these minerals, forming scale on the wellbore walls, pipelines, and surface equipment. The location and intensity of scaling are directly influenced by the pressure and temperature changes near the flashing point, making it a critical factor to monitor and manage in geothermal operations.

4. SCALING IN THE WELL TESTING EQUIPMENT

During well testing in Well 1, significant scaling was found in various pieces of equipment, which has implications for the operation and efficiency of the well. In the pipe flow line, scaling was discovered, indicating a buildup of mineral deposits that could potentially restrict fluid flow and reduce the efficiency of the well testing result. Amorphous silica scaling was also identified in the mist pad of the LECM. This is a critical issue because the mist pad is essential for preventing brine carryover, which can lead to operational inefficiencies and potential equipment damage. The presence of scaling on the mist pad compromises its ability to function correctly, reducing the overall efficiency of the LECM and posing a risk to the integrity of the entire system. Addressing this scaling is crucial to ensure the LECM operates effectively and prevents brine from contaminating other parts of the system.

Amorphous silica scaling occurs when dissolved silica in geothermal fluids precipitates out of solution, forming hard deposits. This process typically happens as the geothermal fluid cools and loses pressure, causing the solubility of silica to decrease. The chemical element involved in this scaling is silicon (Si), which combines with oxygen (O) to form silicon dioxide (SiO_2). Environments prone to amorphous silica scaling include well testing equipment where rapid temperature and pressure changes occur, such as LECM.

Additionally, scaling was found during Pressure Temperature Spinner (PTS) logging within the wellbore. The spinner was unable to spin properly due to scaling deposits, leading to inaccurate measurements and potential operational issues. A sample catcher was used to collect samples from the wellbore, confirming the presence of scaling. This scaling not only affects the accuracy of PTS surveys but also poses a risk to the longevity and functionality of the wellbore equipment. Regular descaling and monitoring are necessary to ensure accurate data collection and maintain the integrity of the well.

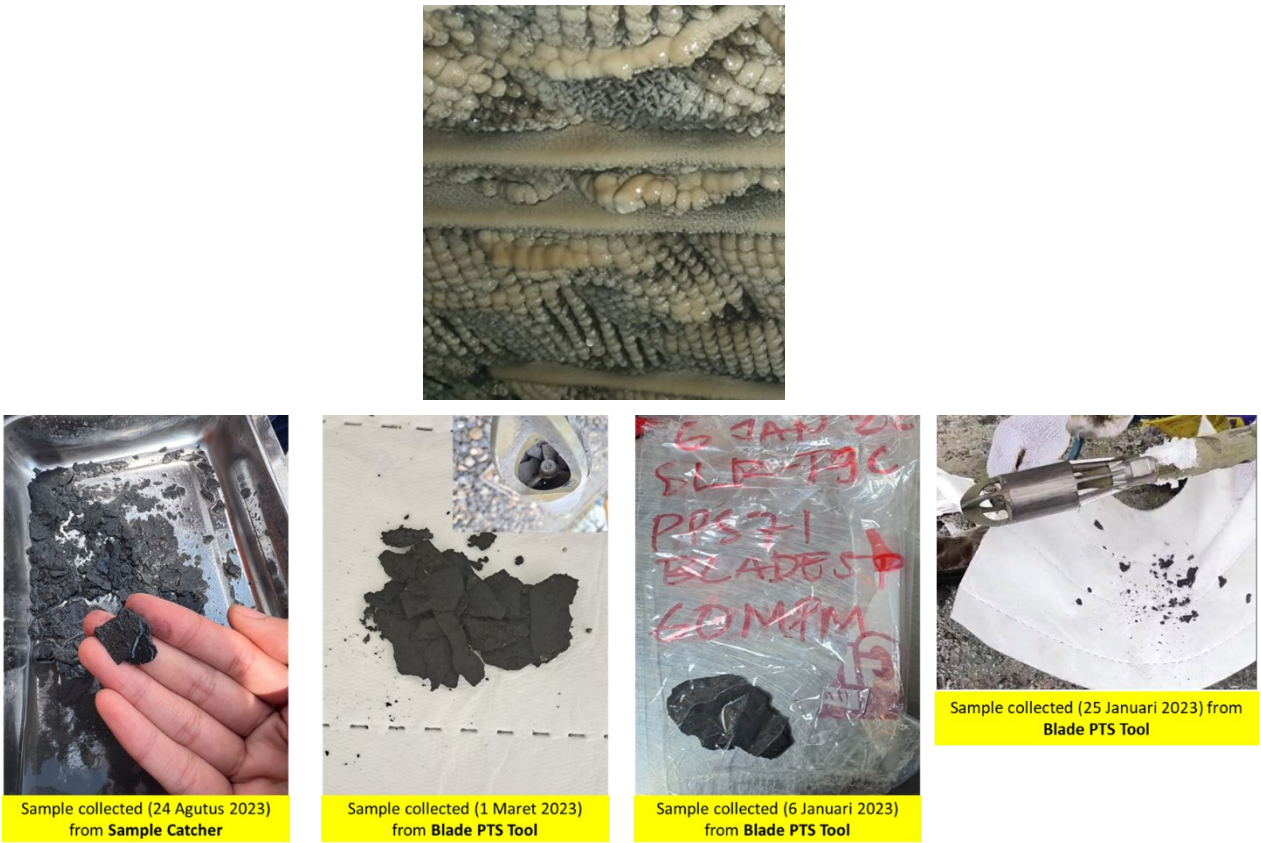

Figure 7: Scaling in the LECM (top pict), sample from sample catcher and blade PTS (bottom pict).

Data from Well 1 indicate that silica scaling index (SSI) issues occurred at temperatures below 200 degrees Celsius. Even with separation occurring at 21.2 bara, the conditions remain below the threshold for preventing silica scaling. This suggests that the thermal and pressure conditions within Well 1 are conducive to silica deposition, which can lead to significant operational challenges. The findings highlight the critical need to monitor and adjust these parameters to minimize the risk of scaling and ensure the well operates efficiently.

Furthermore, analysis of the LECM brine output and sampling conditions supports the presence of scaling. The brine, when plotted on a scaling potential graphic, consistently falls within the scaling zone. This indicates that despite separation efforts, the conditions within the LECM are still favorable for scale formation. The correlation between the low temperature and high-pressure environment and the observed scaling underscores the importance of implementing mitigation strategies.

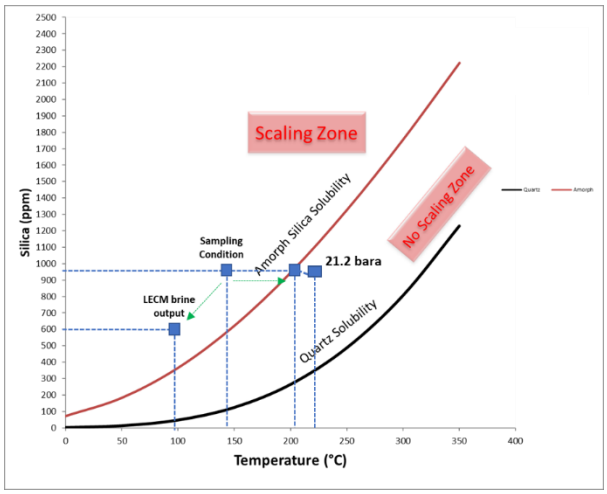

Figure 8: Silica-Temperature graphic related with scaling - no scaling zone.

XRD Analysis

XRD analysis of the scaling sample from the well 1 in the Dieng area revealed the presence of three primary minerals: halite, sylvine, and magnetite. Halite, or sodium chloride (NaCl), is commonly formed in geothermal wells due to the evaporation of saline water. As the geothermal fluid ascends and experiences pressure and temperature changes, the dissolved salts precipitate, leading to the formation of halite scales. These scales can obstruct fluid flow and reduce the efficiency of the well.

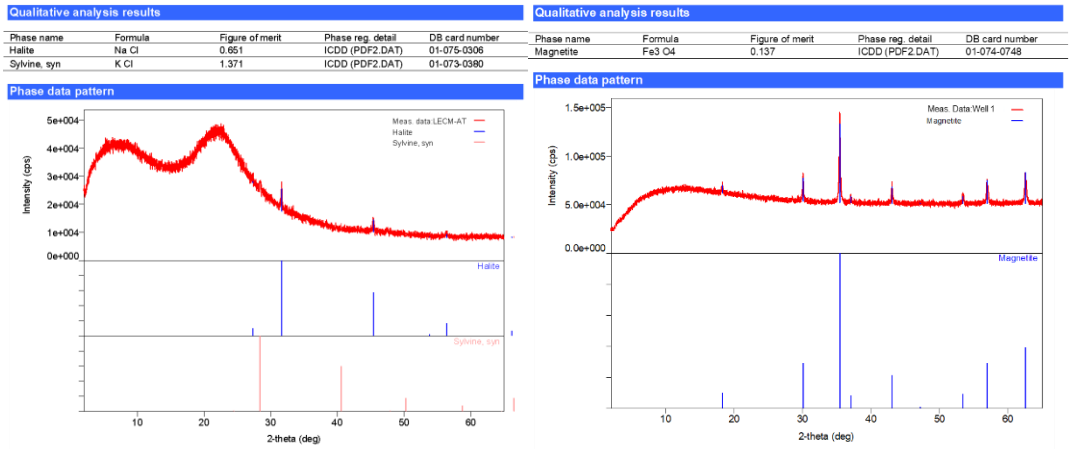

Figure 9: XRD qualitative analysis of scaling samples.

Sylvine, or potassium chloride (KCl), was also identified in the scaling sample. Similar to halite, sylvine forms as a result of the evaporation and concentration of geothermal fluids. The presence of sylvine indicates a high potassium content in the geothermal brine, which can further compound scaling issues by creating harder and more adherent deposits within the wellbore. These deposits can cause significant operational challenges, including increased maintenance requirements and potential well shutdowns.

Magnetite, or iron oxide (Fe3O4), found in the scaling sample, points to the corrosion of wellbore materials and the precipitation of iron from the geothermal fluid. The formation of magnetite scales can be particularly problematic as they are hard and dense, leading to severe blockages. The identification of these minerals through XRD analysis provides crucial baseline data for understanding the scaling processes in the Dieng geothermal wells. This information is invaluable for developing strategies to mitigate scaling and for predicting scaling patterns in newly drilled wells in the area.

5. ANTISCALING/ DESCALING

In geothermal wells, scaling can significantly impair the efficiency and functionality of the system. Mitigating silica scaling in geothermal systems involves two main approaches: physical methods and chemical methods. Each method targets the silica saturation index (SSI), a critical factor influencing silica precipitation. Increasing the pressure in the geothermal system can reduce the SSI.

According to the Fournier equation, maintaining higher pressures helps keep silica in a dissolved state, thereby preventing its deposition as scale. Modifying the pH of the geothermal fluid can shift the equilibrium of silica solubility. Lowering the pH tends to increase silica solubility, reducing the likelihood of scale formation. Chemical inhibitors can interfere with the nucleation and growth of silica particles, thus preventing scale formation.

5.1 Physical method

The value of SSI for mitigate silica scaling shall < 1. Increase pressure (to increase temperature) on the system to reduce value of SSI (silica saturation index) based on Fournier equation.

$$\log C = \left(\frac{-731}{10\,(T+273.15)}\right) + 4.52$$

$$SSI = \frac{A}{C} \quad (1)$$

Where:
T = Temperature system (Saturation pressure on the system)
C = Solubility of Amorphous silica (mg/kg)
A = Concentration of SiO_2 on the system from fluid chemistry analysis (mg/kg)

5.2 Chemical Method

1. pH Modification
   Injected acid either Sulfuric Acid or Acetic Acid on the system. It can delay polymerization of Silica occurs and thus rate of deposition of silica from the brine (Kingston Morrison, 1997). Sulfuric acid injection used on the many Geothermal Industries of the world because readily available, and relatively low cost. The key success on its method is depend on controlling or on the automation of injection due to sulfuric acid is a strong acid and the titration curve is steepest around pH 5, which is the normal target for pH modification. This means that if the acid is even slightly overdosed, the pH can go very low. Carbon steel piping tolerates acid conditions to about pH 4.6-4.8, but any lower pH can cause rapid corrosion of carbon steel (depending on the amount of silica scale already deposited in the pipe). Thus, even small fluctuations in brine flow can have a large change in pH, either leading to scaling, or corrosion. (Jacobs, 2020)
2. Inhibitor
   Many places on the world especially Indonesia is intensively developing chemical inhibitor to solving silica scaling mitigation without corrosion and health safety environment problem. Usually, they use water-based inhibitor. But it can't be said to be successful today, more research is needed to developing it chemical.

Even though we have done with value of SSI or delay of polymerization of silica, we should check on the pipeline physically view of deposition. We can install retractable coupon on the bypass pipeline to check periodically while the operation of production.

Commonly in Geothermal Industries on the surface facilities (from well head to power plant) we can separately handling Silica Scaling based on the location:

- 2-phase pipeline and production well
  Increase Well-head pressure (WHP) or throttle valve on the pipeline to reduce value of SSI on it place
- Brine pipeline
  Increase pressure separation on the separator to reduce value of SSI
- Injection well
  Reaming and Acidizing on workover activity can recover injection well from silica deposition either at the wellbore or the reservoir. But its activity is worst condition if we can't mitigate silica on the surface facility.
- Steam pipeline
  Silica deposition on the steam line is uncommonly because naturally silica is growing on the brine

phase. Silica deposition on the steam line is happen due to brine carry over to steam or silica is vaporized because normally geothermal steam is saturated steam change into superheated steam.

- Ensure efficiency of separator is >99.95%
- Ensure the quality steam outlet separator or demister/scrubber is <100%
- Loop seal installation on the separator to mitigate brine carry over to steam

5.3 Technology Selection

Based on pilot plant testing with JV Mannvit on 2021-2022 Higher pressure separation will be implemented on Dieng 2 steam field production to ensure value of SSC at 2-phase line and brine line is < 1 or minimum close than 1, so silica scaling on the injection facilities is still manageable without chemical injection. Dieng 2 power plant planned for 30 years operation, chemical injection either pH modification or inhibitor will add value of CAPEX and OPEX for 30 years operation. On other perspective pH modification with H_2SO^4 have a potential metal sulfide deposition due to H_2SO^4 reaction with metals content on the brine fluid.

- Average SiO_2 content D1 production wells = 1000-1100 ppm
- Projection of SSI for D2 operation = 0.95-1.05

From equation 1 previously, to get projection of SSI for D2

- Minimum pressure separation = 21.1 bar.a
- Temperature saturation = 215◦C

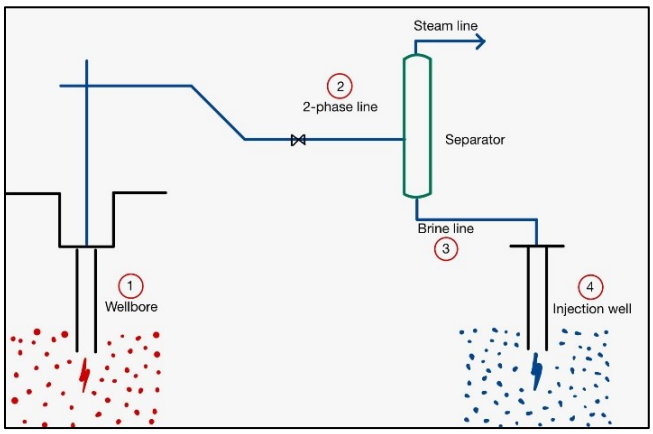

Figure 10: Common scaling location in Dieng (1,2,3,4) and higher-pressure separation will be implemented to ensure value of SSC at 2-phase line and brine line is < 1 or minimum close than 1.

6. CONCLUSION

Scaling in geothermal wells is intrinsically linked to the chemistry of the geothermal reservoir fluids. The types and concentrations of dissolved minerals such as silica, potassium, and iron play a critical role in the formation of scales. When geothermal fluids ascend and experience changes in temperature and pressure, their solubility characteristics alter, leading to the precipitation of minerals like halite, sylvine, and amorphous silica. These precipitates form hard deposits that can obstruct fluid flow, reduce efficiency, and cause significant operational challenges within the wellbore and surface facilities.

Additionally, the scaling process is heavily influenced by environmental changes within the wellbore and surface facilities. Variations in pressure and temperature, such as those occurring during fluid separation or rapid cooling, can trigger the formation of scales. The introduction of physical and chemical anti scaling method to control scaling demonstrates the dynamic nature of the wellbore environment and the necessity for continuous monitoring and adjustment of conditions. Understanding these relationships is essential for developing effective scaling prevention and mitigation strategies, ensuring the long-term efficiency and reliability of geothermal wells, particularly in areas like Dieng.

Keywords: Geothermal, fractures, permeability, fault, microearthquake, Wayang Windu, focal mechanism, double-difference

ABSTRACT

Deciding where to drill to improve the well success rate is one of the most important issues for geothermal field development. The biggest challenge in Wayang Windu as in many geothermal fields is understanding permeability heterogeneity which is commonly associated with structural irregularity. One geophysical approach to characterize the structural irregularity is monitoring seismic activity associated with fluid production and injection activities. Ten monitoring stations have been established to cover the most seismicity active areas of Wayang Windu field. Since 2021, more than 1400 absolute locations of high-quality micro-earthquake events have been recorded. High-quality microearthquake events must be identified by at least four stations, have at least eight phases, and have an azimuthal gap of less than 210 degrees. With the help of the double-difference (hypoDD) software, 662 events were successfully relocated and grouped into the north and south clusters with better location uncertainties. The north cluster, which is connected to the steam zone, is comparatively shallower and denser than the south cluster. Both clusters show the encapsulated fault-controlled event distributions, i.e., Kijang and Cibitung-1 faults at the north; Cibolang and Sukaratu faults at the south. Processing of the focal mechanism was applied to the chosen hypoDD events, requiring at least four stations with a signal-to-noise ratio of at least five. A Python program was used to process the focal mechanism. The outcome demonstrates a variation of the maximum stress orientation. Further analysis of the stress regime has revealed variation: in the north-west the stress regime having more reverse-faulting, while in the northern and southern production areas are both tend to have strike-slip and normal-faulting type.

1. INTRODUCTION

Located roughly about 40 kms south of Bandung, capital province of West Java, Indonesia, the Wayang Windu geothermal field has been commercially producing steam since 2000. The field now has 230.5MWe of installed capacity totaling 110 MWe from Unit-1 and 117 MWe from Unit-2, and 450 kg/s of steam is needed to maintain 230.5MWe of generation.

Figure 1: Location of geothermal fields in West Java, Indonesia.

There are several high terrain andesitic strato-volcanoes geothermal system in the area such as Darajat, Kamojang, Tampomas, Tangkuban Perahu, Salak, Karaha-Talaga Bodas, and Patuha. The strato-volcanoes are associated with the Sunda Volcanic Arc. It was resulted from the activity of subduction where Australian plate underneath Eurasian plate at the southern of Java.

Numerous seismicity monitoring projects have been carried out at Wayang Windu field. In 1998, the first microearthquake monitoring was carried out to track the induced seismicity of the field's southernmost wells, which located in the STW and STF pads. In 2005, three wells which located in the NTD, STS and NTQ pads were subjected to an additional round of induced monitoring to follow the seismicity in the central area. One well in the NTB pad was used in 2007 to track generated seismicity in the north. The massive reservoir monitoring was also carried out in 2012 as more than 30 continuous monitoring stations covering the field. The monitoring continued until the last equipment was dismantled in 2016.

Currently, there are 10 permanent seismic monitoring stations covering the field since 2020. Each of monitoring stations equipped with GEObit GEOthree data logger and force-balance C100 sensor that was put at 5 m depth. The sensors have a wide response of 10s – 98Hz, and 1500 V/m/s sensitivity. The sampling rate was set to 500 sps.

Data acquisition is conducted weekly, this include replacing the batteries of each station. SEISGRAM2K program (http://alomax.free.fr) is used for phases picking, this include P-phase polarity determination, while the absolute hypocenter location inversion was carried out using HYPOINVERSE program (https://www.usgs.gov). Relative location Double Difference was then carried out by utilizing HYPODD software (https://www.ldeo.columbia.edu/~felixw/hypoDD.html). The focal mechanism inversion was completed within python environment. The study will focus on the microearthquake focal mechanism result of 2021-2023 monitoring activity and its correlation with the updated geological structure, stress regime and geomechanics study.

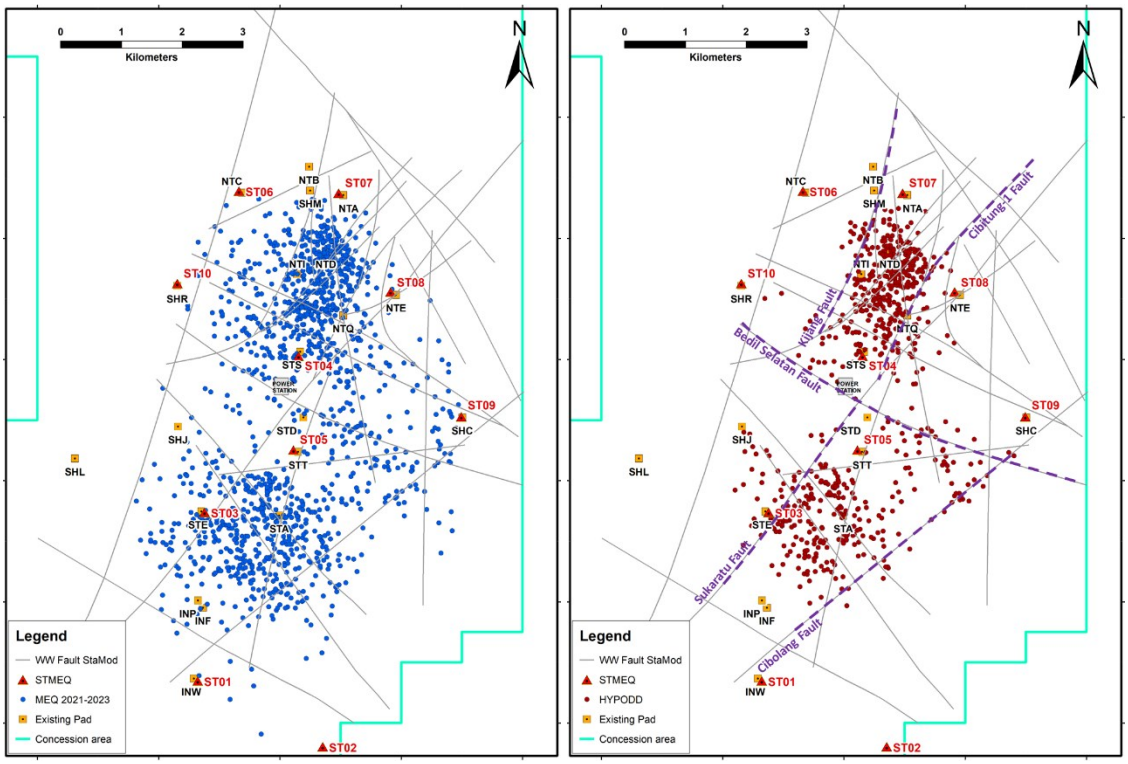

Figure 2: Hypocenter distribution during 2021-2023 monitoring period, [Left] Absolute; [Right] HypoDD.

2. SEISMICITY

Microearthquakes are small earthquake that has magnitude less than 3 (Lee and Stewart, 1981). Microearthquakes commonly occurs in reservoirs as a result of injection or exploitation activities that may be due to the change in the stress distribution. Microearthquake occurrences can also be caused by localized volcanic and tectonic activities.

2.1 Microearthquake Distribution

Wayang Windu geothermal field has been producing steam for more than 2 decades and thousands of microearthquake events have been recorded in the area since then. The distribution of seismic monitoring stations is designed to monitor the reservoir proven area. The deployment of 10 monitoring stations was distributed into two stages. The first five was deployed in 2020, and another five in 2021. Almost all stations are located in the

well pads except one that is placed further south at the edge of concession area (ST02). The well pads occupied are production pads i.e., STT (ST05), NTC (ST06), NTA (ST07), and NTE (ST08); injection pad, STW (ST01); SlimHole pads i.e., SHC (ST09), and SHR (ST10); and idle wells i.e., STS (ST04) and STE (ST03).

Figure 2 showing the distribution of microearthquake events overlaid with the interpreted fault in the area. The field's geological structure was better understood in 2019 thanks to an extensive LIDAR survey. New insights into geological structure were obtained by combining the high-resolution Digital Terrain Model (DTM) with earlier LANDSAT data, gravity processing, and modeling outcomes (Purnomo, et al., 2023).

There are more than 2000 microearthquake events recorded since the deployment of seismic monitoring stations, but only about 1400 events that are detected by minimum 4 stations (8 phases) and maximum azimuthal gap of 210º are accepted and kept for advance processing. The HypoDD processing was conducted to enhance the accuracy of hypocenter determinations. As a result, 662 hypocenter locations were refined, revealing the presence of two distinct clusters. This improved accuracy is crucial for detailed seismic analysis and understanding the underlying geological structures and fault mechanisms in the study area.

Two significant clusters have been identified: the northern and southern clusters (Figure 2). The northern cluster, which is the most productive area, is confined between the Kijang and Cibitung-1 faults, whereas the southern cluster is located between the Cibolang and Sukaratu faults. Both clusters are situated in regions dominated by production wells. In terms of seismicity, the Bedil Selatan fault separates the shallower northern cluster from the deeper southern cluster. Tritium tracer injection tests were performed in the central area in 2014 and 2016 and confirmed vertical connectivity between the deep liquid reservoir and the current main production area, the Northern steam cap (D. Malik, et al., 2020).

2.2 Signal to Noise Ratio

The advantages of placing the monitoring stations within the pads are easy access, more secure, and no additional budget needed for land leasing; while the disadvantage tends to have more noisy data, thus reducing signal to noise ratio (SNR). The SNR was calculated from the ratio of P-phase signal and the background noise about 0.5 second before the P-phase amplitude. SNR ≥ 5 was taken as the good SNR for focal mechanism processing. Figure 3 shows the statistic of events detection and SNR of each station since all ten stations are installed. It shows that station ST07 and ST08 are both have the lowest SNR and event detection, while ST06, ST09 and ST10 are three stations with the highest SNR and event detection. The ST02 is unique, because it was installed rather late, Nov 2021.

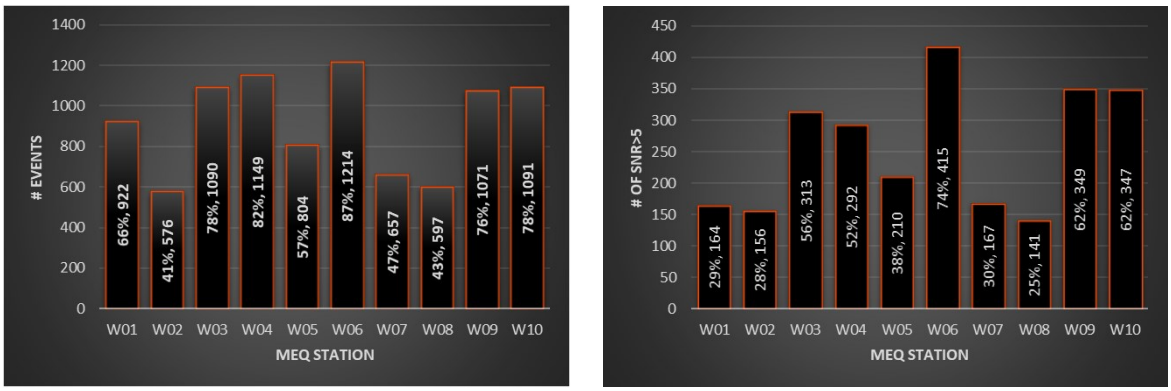

Figure 3: (Left) Number of events detected on each station during 2021-2023 monitoring period. (Right) Number of SNR ≥ 5 of events detected by each station.

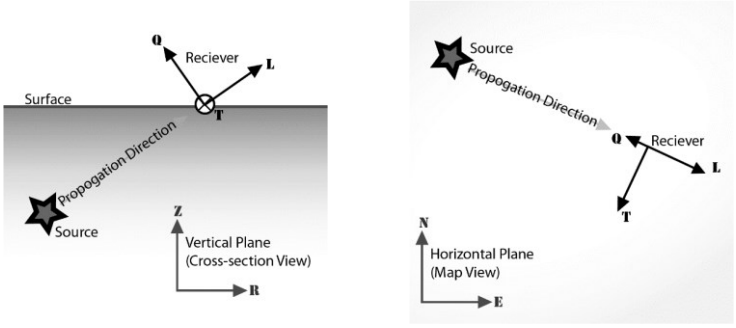

Figure 4: The illustration of LQT orientation system (https://service.iris.edu/).

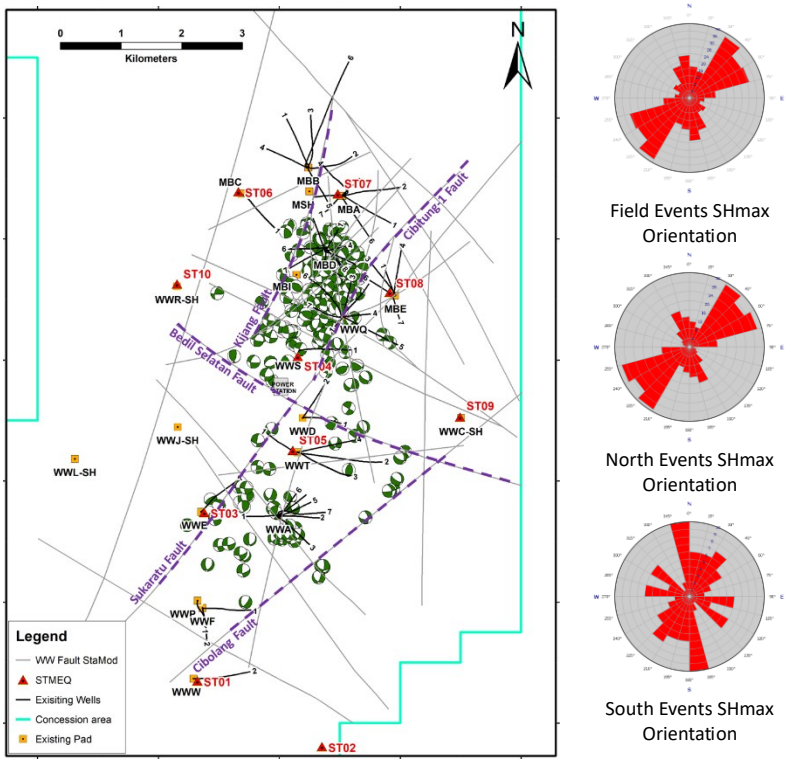

Figure 5: [Left] Distribution of focal mechanism, [Right] Rose diagram of SHmax orientation.

3. FOCAL MECHANISM

A total of 223 hypoDD microearthquake events were chosen for investigation of the focal mechanism. The selection of events is based on a minimum of eight phases and a signal-to-noise ratio of more than five, as observed by a minimum of four stations. During the computation of the hypoDD, azimuth and takeoff angle were calculated simultaneously. P, SV, and SH amplitudes were obtained by rotating the event waveforms into the LQT orientation system, where L aligned with the P wave propagation direction, Q with the SV phase movement, and T with the SH phase movement (Figure 4).

The microearthquake (MEQ) focal mechanism are distributed into two main clusters: north and south (Figure 5). The northern cluster, which is confined by Kijang and Cibitung-1 fault, is characterized by shallower events compared to the southern cluster. This difference in depth correlates with the distinct reservoir type in the area: the north is a vapor-dominated zone, while the south is a two-phase zone. Consequently, most of the steam production originates from the northern area, highlighting its significance in geothermal energy extraction. The focal mechanism analysis reveals that the SHmax orientation in the northern cluster is NE-SW, while in the southern cluster, it is NNW-SSE.

The SHmax orientation varies between the clusters (Figure 5), indicating distinct stress regimes essential for understanding fracture dynamics and optimizing geothermal extraction. The geological faults significantly influence the seismic activity and reservoir behavior, with the northern cluster being more productive.

The SHmax orientations are crucial for assessing regional stress fields and their impact on seismicity and reservoir behavior. This understanding helps predict potential fault slips, improving risk management in geothermal energy production. The stress orientation data guides drilling and stimulation activities to enhance resource recovery while minimizing seismic risks.

4. CONCLUSION

The investigation into the focal mechanisms of 223 hypoDD microearthquake events has provided valuable insights into the seismicity and subsurface characteristics of the study area. The selection of events was rigorous, based on a minimum of eight phases and a high signal-to-noise ratio, ensuring the reliability of the data. The computation of azimuth and takeoff angles, along with the rotation of event waveforms into the LQT orientation system, allowed for precise determination of P, SV, and SH amplitudes.

The findings emphasize the northern cluster's importance for geothermal energy extraction, suggesting focused exploration and production strategies of Wayang Windu. The different stress regimes in the clusters highlight the

need for region-specific analysis. Continuous monitoring and analysis are essential for optimizing geothermal production.

Future research should deepen the understanding of the relationship between seismicity, reservoir characteristics, and geothermal production. Advanced modeling techniques and higher-resolution data can offer more insights into subsurface processes and improve understanding of the geothermal field. Additionally, evaluating signal-to-noise ratios at monitoring stations can further enhance data quality and interpretation.

In summary, the focal mechanism analysis of hypoDD microearthquake events has revealed critical information about the Wayang Windu geothermal field's seismicity and subsurface structure. These findings enhance the understanding of regional geology and stress fields, providing useful information for geothermal energy extraction, reservoir management, and well targeting.

Keywords: Geothermal resource assessment, Indonesia, Numerical reservoir models, Renewable energy, Geoscientific data

ABSTRACT

The National Energy General Plan (RUEN) of Indonesia targets the production of 10 GWe from geothermal by 2030 and further increases to 17.5 GWe by 2050. Robust assessments of Indonesia's undeveloped geothermal resources are required to help prioritize systems for development.

A new method for resource assessment has been developed by the Geothermal Institute at the University of Auckland, which leverages modern geothermal modelling tools and cloud computing. This approach provides more realistic estimates of the potential of a geothermal resource than the traditional stored heat method and has been applied to commercial and research projects.

This paper discusses the application of this method to six undeveloped geothermal systems in Indonesia. The study was understaken in collaboration with the Geological Agency (GA) of Indonesia and the Directorate-General of New Renewable Energy and Energy Conservation (EBTKE) as a step towards establishing a new framework for the systematic assessment of Indonesia's undeveloped geothermal resources. The resource assessment framework was applied to each of the six systems; Ciremai, Kepahiang, Kotamobagu, Maritaing, Massepe, and Papandayan. This included the development of new digital conceptual models and numerical reservoir models for each system using geoscientific data from The Geological Agency. The resource assessment results for each field are presented in a standard format, and it is envisioned that they could be made publicly available in a database of Indonesia's geothermal resources in the future.

1. INTRODUCTION

Indonesia is positioned along the boundaries of active plates and boasts an impressive geothermal potential estimated at 23.36 GW distributed across 356 locations. Recognizing this vast potential, the Indonesian government has set targets to increase geothermal energy production to 10 GWe by 2030, with further expansion to 17.5 GWe by 2050 (Rencana Umum Energi Nasional, 2017). However, despite these promising prospects, the current exploitation of geothermal resources in Indonesia remains limited. Currently, 16 geothermal fields are operational, collectively generating 2,342 MW, representing less than 15% of the targeted capacity for 2050 (Alhusni et al., 2023).

The exploration and development of new geothermal resources face many challenges. The early stage of exploration is particularly risky due to the limited availability of data and the substantial investment required. Consequently, stakeholders must ensure that the potential of a geothermal resource is sufficient to justify the investment. This is typically assessed by estimating the potential electrical power output of the geothermal field.

Traditional methodologies for estimating geothermal resource potential are plagued by high levels of uncertainty, primarily due to reliance on numerous assumptions and a lack of consideration for the physical processes within the reservoir and wellbore. A new framework has been developed that incorporates a more realistic energy extraction scenario using numerical modelling and cloud computing to address these limitations (Croucher et al., 2020; Dekkers et al., 2022; O'Sullivan & O'Sullivan, 2016). This innovative approach reduces the uncertainty in power output calculations and enhances investor confidence by providing a more reliable assessment of geothermal potential.

This paper presents the application of this novel approach to six undeveloped geothermal systems in Indonesia. Conducted in collaboration with the Geological Agency (GA) of Indonesia and the Directorate-General of New

Renewable Energy and Energy Conservation (EBTKE), this study marks a significant step toward establishing a systematic framework for assessing Indonesia's untapped geothermal resources.

2. METHODOLOGY

Numerical modelling for geothermal reservoirs has been carried out since the 1970s (Stanford Geothermal Program, 1980; O'Sullivan, 1985; O'Sullivan et al., 2001; O'Sullivan and O'Sullivan, 2016). In this paper, we propose a new method for assessing the potential of geothermal power output using numerical modelling, available data and innovative algorithms. This method requires simulations of a large number of different reservoir models, making it highly dependent on computational speed. Fortunately, highly parallelized geothermal simulators like Waiwera, developed by the University of Auckland and GNS Science (Croucher et al., 2020), can leverage high-performance computing resources to make this new method feasible.

The advantage of the resource assessment method presented in this work is that the geothermal power estimations are based on numerical reservoir simulations. These simulations include reservoir physics, wellbore physics and realistic energy extraction scenarios. The method of resource assessment also produces robust estimates of the uncertainty using well-established uncertainty quantification techniques (Dekkers et al., 2022).

2.1 Steady state models

The first step for our resource assessment is to use the 3D digital conceptual model to set up a numerical model where the geology, alteration zone, structural settings and potential deep upflow locations define a large set of model parameters. We then generate an ensemble of possible models by randomly sampling model parameters from statistical distributions based on realistic ranges. These sample models are simulated to a steady state before any production simulations are carried out. Over 2000 sample models were generated for each of the systems presented in this paper to estimate the power output of each geothermal system.

2.1.1 Uncertain parameters

Generally, when we develop a new numerical model, we start with an initial guess based on expert knowledge of rock permeabilities and upflow rates. These parameters are then manually calibrated using the available data. During the exploration stage of a geothermal field, the calibration process is rapid because few data is available. However, the lack of data means there is significant uncertainty in the model parameters. To represent this uncertainty, an ensemble of reservoir models is created by randomly sampling model parameters from realistic probability distributions. The distribution of each parameter is centred around the calibrated model parameters. Collaboration by geothermal stakeholders to specificy a standardised list of required exploration data could help reduce uncertainty in the future by providing more data to condition the sample models.

2.1.2 Conditioning on the clay cap

The second step of our approach is to filter the steady state models based on the location and temperature of the clay cap. This process is called "conditioning" and involves discarding sample models that do not fit the available reservoir engineering data. We do this using approximate Bayesian computation (ABC) (Beaumont, 2019; Marin et al., 2012) as described in Dekkers et al. (2022). Thus, to apply our methodology, some data giving the location of the clay cap is required, e.g., MT survey data, clay mineralogy from drilling cuttings or downhole temperatures. A clay cap is formed by alteration of the rock structure due to heating. Temperatures of approximately 200 °C are needed to form a clay cap. After the clay cap is formed, the hot fluids do not flow easily through the clay cap due to its low permeability. Thus, the location of the clay cap can be used as a proxy for the temperature distribution at the top of the geothermal system. The resistivity boundary and estimates of the location of the top of the reservoir are used in a similar way to traditional stored heat calculation. However, a stored heat calculation neglects the physics of subsurface fluid flow and does not make use of the full three-dimensional interpreted clay cap. Expert interpretation of resistivity is still required in both a traditional stored heat calculation and our new approach to account for phenomena such as relic alteration and clay sediments. The temperature threshold for conditioning can also be modified where mineralogy indicates it is appropriate.

2.2 Production models

After filtering the steady state models to an ensemble containing only those that match the geophysical data, we apply an innovative method to run production scenarios that maximize the power output of each sample model. We use the steady state model as an initial state for the production model and then simulate 25 years of future production extracting energy using a typical flash power plant configuration. This method can be easily modified to accommodate different power plant designs and operating conditions depending on the geothermal system that is being analyzed.

One of the challenges with using uncertainty quantification of geothermal models for resource assessment is that the optimal production strategy is different for each model sample. Typically, the design of future scenarios for a

geothermal model is done manually by geothermal reservoir modellers and then optimized to achieve maximum energy extraction. However, this manual approach is clearly not viable with thousands of sample models.

The innovative method we have developed is an iterative algorithm that can select the best targets for production and reinjection for any given sample model. The iterative algorithm continues selecting targets until the additional energy produced is less than 5% of the previous iterative step, indicating diminishing returns on adding new wells.

Wellbore modelling is used to represent the behaviour of each of the production wells. Before running the iterative algorithm, wellbore models are run for all possible target depths under all the likely range of thermodynamic conditions. This process can be completed on a standard desktop computer within 2-3 days. Vertical, single-feed wells with typical completion designs are assumed in this work to demonstrate the approach. However, the parameters of production wells, including the completion design and number of feeds, could easily modified. Additionally, areas where wells can (or cannot) be sited (e.g., due to factors such as topographical constraints or consent boundaries) can be easily specified.

It is important to remember that the objective of this method is to calculate the production potential for each sample model efficiently using a realistic extraction scenario. It does not aim to design the perfectly optimal extraction scenario for each sample model or the system in general. Designing an optimal extraction scenario for the system is expected to take place during the development of the production stage once exploration drilling and early production testing have taken place. The details of the iterative algorithm of our innovative method are provided in Dekkers et al. (2022).

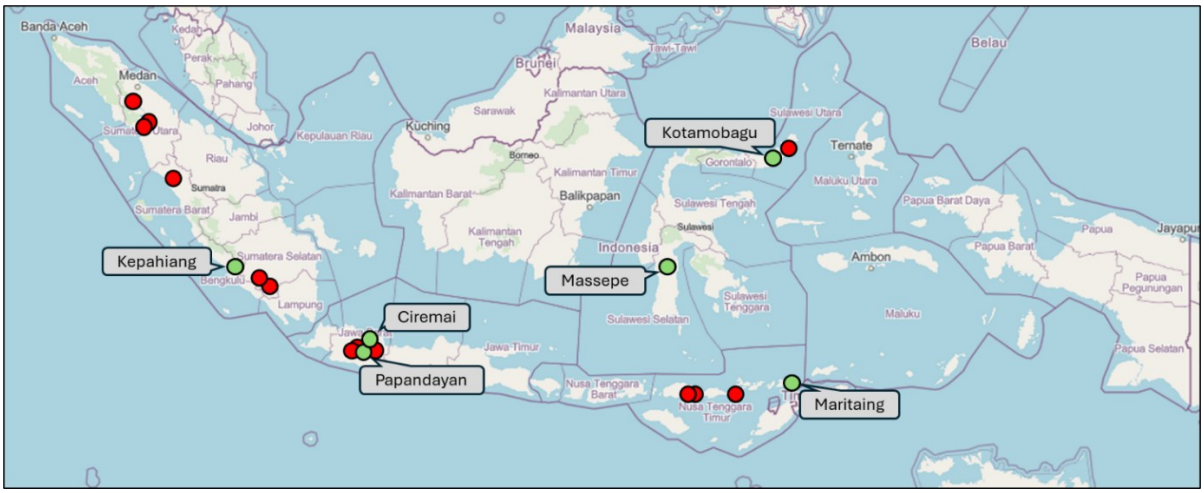

Figure 1: Exploitation stage geothermal fields (red) and six undeveloped geothermal fields (green).

3. UNDEVELOPED GEOTHERMAL FIELDS

Indonesia has an abundant amount of geothermal potential mainly due to its location at the junction of several tectonic plates. Its location produces volcanic arcs and tectonically active zones along many of the islands across the country. Sunda Arc, which is the subduction product between Indo-Australian plate and Eurasian plate, hosts from Sumatra to Java and then through to Nusa Tenggara (MacPherson & Hall, 2002; Varekamp et al., 1989). Modern volcanoes in the area were formed during the Quaternary period and have mainly generated basaltic andesite to andesite effusive and explosive products (Pacey et al., 2013). Different to the islands in Sunda Arc, the regional area of Sulawesi Island was formed by interactions of three different plates, namely Eurasian, Indo-Australian, and Pacific plates (Hall, 2002; Hamilton, 1979; Katili, 1975; Nugraha et al., 2022). A unique K-shape feature in Sulawesi is the evidence of robust tectonics and volcanics activity since Miocene to Late Pliocene (Katili, 1978).

This study applied the new resource assessment framework to six undeveloped geothermal fields namely Ciremai and Papandayan (Java); Maritaing (Nusa Tenggara); Kepahiang (Sumatra); and Massepe and Kotamobagu (Sulawesi) (Figure 1). The sections below discuss the newly developed numerical and 3D geological model for each geothermal field. Data from Geological Agency of Indonesia, the Directorate-General of New Renewable Energy and Energy Conservation (EBTKE) and previous publicly available research were used to support this paper.

3.1 Ciremai

The Ciremai geothermal field, located in West Java, Indonesia, is a volcanic-type geothermal system with promising potential for energy development. Situated around the prominent stratovolcano Mount Ciremai, the field covers an area of approximately 38,560 hectares, making it a possible target for Indonesia's geothermal development strategy. The geological setting of Ciremai is characterized by a complex stratigraphy that includes the Cinambo Formation, Halang Formation, Ciherang Formation, and various volcanic deposits dating from the Tertiary to Quaternary periods (Djuri, 2011; Silitonga et al., 1996). The area is dominated by the northwest-southeast trending fault system, which serves as the primary conduit for geothermal fluids (Sukaesih et al., 2021) (see Figure 2). Notable geothermal manifestations include the Cilengkrang, Sangkanhurip, and Ciniru hot springs, which provide surface evidence of the geothermal activity beneath the surface.

The hydrogeology of the Ciremai geothermal field reveals a complex interaction between volcanic aquifers, fracture zones, and recharge areas. The system is influenced by two primary flow mechanisms: a porous media system and a fracture-driven volcanic aquifer system resulting in a relatively low water table. Recharge occurs in the highlands, discharging at lower elevations (250-650 meters above sea level) through numerous springs (Irawan & Puradimaja, 2006). This hydrogeological framework is vital for understanding the geothermal system and is integral to developing accurate conceptual and numerical models (Irawan et al., 2009).

3.2 Kepahiang

The Kepahiang geothermal field is located within the volcanic complex of Mount Kaba in Bengkulu Province, Sumatra, Indonesia. The site covers the Kepahiang and Rejang Leboh regions at altitudes ranging from 250 to 1600 meters above sea level. Characterized by its volcanic nature, the area hosts various volcanic products and manifestations, such as fumaroles, solfataras, and hot springs, which indicate active geothermal activity (Kusnadi et al., 2011). The primary geological formations include the Kaba Tua and Kaba Muda eruption products, along with surrounding volcanic structures such as Bukit Lumut, Taba Penanjung, and Bukit Malintang (Sugianto & Hadi, 2011).

Based on the geophysical surveys, the dynamics of the system are controlled by key fault structures, including the Sempiang and Bogor faults, which facilitate the movement of geothermal fluids (Arsadipura et al., 2011; Nurdiyanto et al., 2022) and the reservoir is estimated to be under a thick clay cap layer (1500-2500m), which is in the Old Kaba Volcanic (Nurdiyanto et al., 2022). The complex hydrogeology of the area is further influenced by volcanic activity, with fluid recharge occurring from the slopes of Mt. Kaba and surrounding areas. These factors contribute to the rich geothermal manifestations observed in the region (Kusnadi et al., 2011).

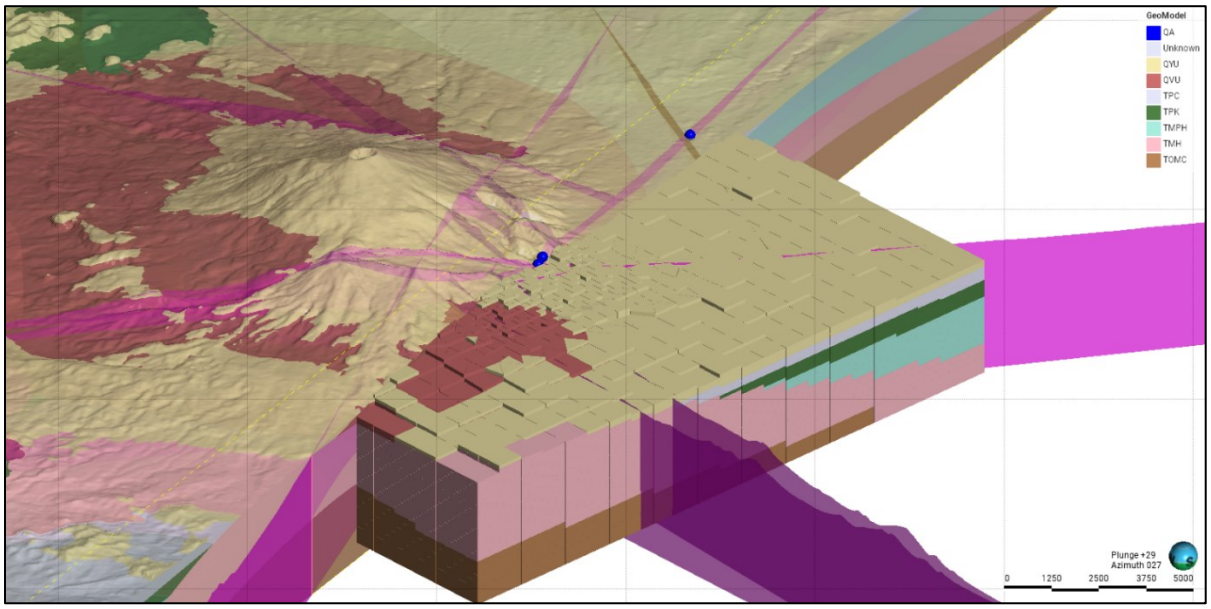

Figure 2: Ciremai geological model alongside the numerical model. Magenta planes represent NE-SW and NW-SE faults. Blue dots represent alkali chloride surface manifestations.

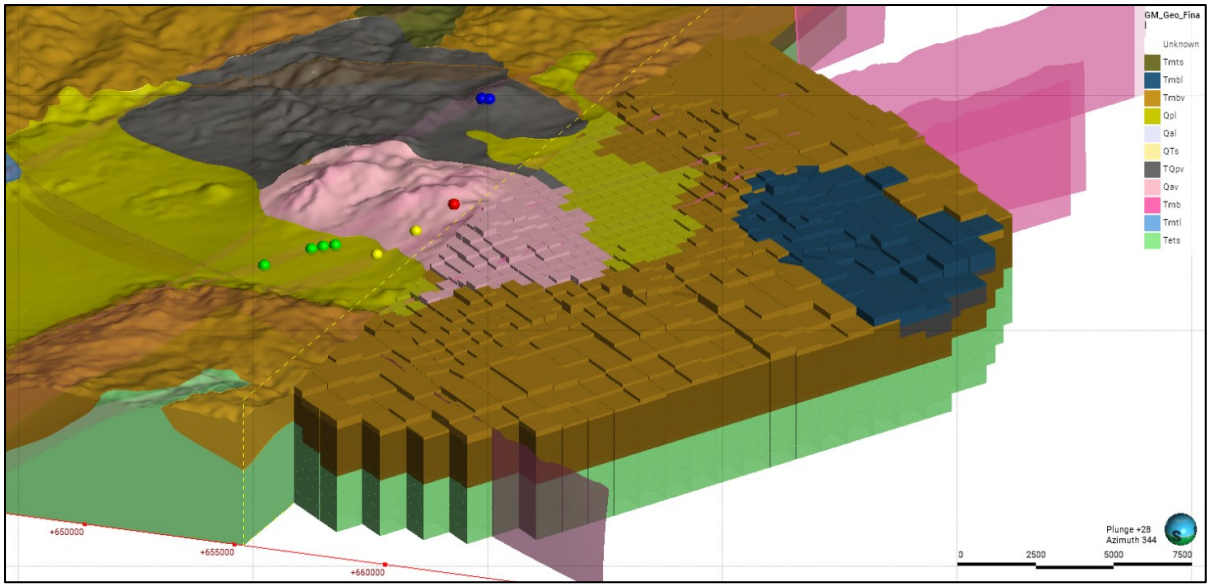

Figure 3: Kotamobagu geological model alongside the numerical model. Magenta planes represent NE-SW and NW-SE faults. Colored dots represent survey manifestations as acid sulphate (red), sulfate-chloride (yellow), and bicarbonate (green), and alkali chloride (blue).

3.3 Kotamobagu

The Kotamobagu geothermal field is located in North Sulawesi, Indonesia, approximately 200 km southwest of Manado City. This geothermal site, situated within the Minahasa region, is known for its significant potential as a geothermal energy resource. The field is characterized by a complex geological setting, with stratigraphy including sedimentary rocks of the Tinombo Formation, Bilungala Volcanics, Tapadaka Formation, and Pinogu Volcanic deposits. Recent volcanic deposits from the Ambang Volcanics also play a crucial role in the geothermal system (Apandi & Bachri, 1997) (see Figure 3). The field's geology features formations from the Eocene to the Holocene, reflecting a dynamic volcanic and tectonic history shaped by regional geological processes.

A previous conceptual model has been made and geochemical surveys have identified key features of the Kotamobagu geothermal system (Riogilang et al., 2011b, 2011a; Riogilang, Itoi, & Taguchi, 2012; Riogilang, Itoi, Tanaka, et al., 2012). The presence of fumaroles and hot springs around the Mt. Muayat area indicates an active, liquid-dominated reservoir with temperatures ranging from 230°C to 320°C (Riogilang et al., 2013). The system is influenced by NE-SW and NW-SE trending fault lines, which serve as pathways for geothermal fluids and control the distribution of manifestations across the field. These fault structures are critical for understanding the geothermal dynamics and potential resource area within the Kotamobagu site.

3.4 Maritaing

The Maritaing Geothermal Field, situated on Alor Island in East Nusa Tenggara province, Indonesia, holds a modest geothermal potential. The field is located approximately 800 km from the Ulumbu field and about 700 km from Maritaing. The area encompasses 3 km² and is characterized by a reservoir temperature estimated at 170-200°C as indicated by Na-K geothermometer analyses through a partial-equilibrium Kura hot spring (Setiawan et al., 2015). Preliminary studies have focused on its geological, geophysical, and geochemical properties. The geological composition mainly includes volcanic and sedimentary rocks such as andesite lava, pyroclastic flows, conglomerates, and limestone. These formations are part of the Alor formation, which consists of various lava and breccia layers interspersed with tuff.

The geological structure of the Maritaing field features prominent NW-SE and NE-SW trending faults, forming the Maritaing depression and acting as fluid controls for the Kura hot springs (Supriyadi et al., 2015). Faults in this region are crucial for the geothermal system's dynamics, as they facilitate the movement of fluids and recharge the reservoir. A recent gravity survey shows high amplitude values in the complete Bouguer anomaly signal, suggesting the presence of andesitic lava rocks (Boling et al., 2024). The magnetotelluric (AMT and TDEM) surveys have revealed low-resistance zones (<10 Ohm.m) indicative of altered rock formations acting as a caprock (Rahadinata et al., 2017).

A previous conceptual model (Setiawan et al., 2015) proposes that the geothermal system is linked to young magmatic activity, with meteoric water infiltrating the Maritaing Depression and heating up due to residual magmatic heat. This results in a convective hydrothermal system, with hot fluids emerging at the surface as hot

springs. A new 3D geological model was developed to give better understanding of the system (Aloanis, 2024) (see Figure 4).

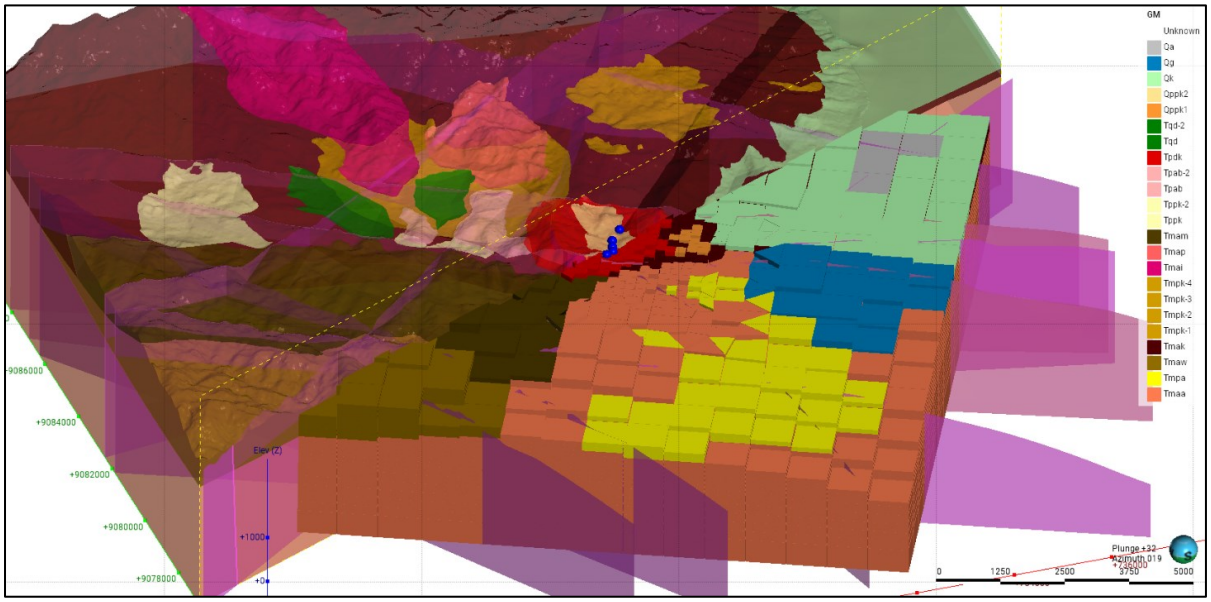

Figure 4: Maritaing geological model alongside the numerical model. Magenta planes represent NW-SE and NE-SW faults. Blue dots represent alkali chloride surface manifestations.

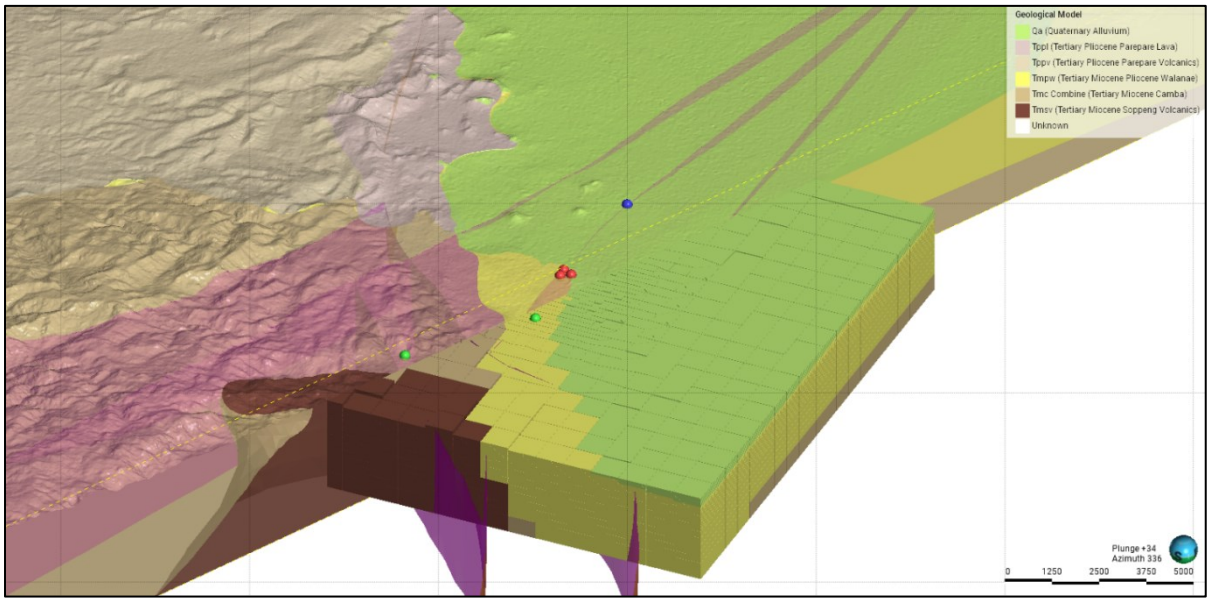

Figure 5: Massepe geological model alongside the numerical model. Magenta planes represent the N-S faults. Colored dots represent survey manifestations such as bicarbonate sulphate (red), bicarbonate (green), and alkali chloride (blue).

3.5 Massepe

The Massepe Geothermal Field, located in South Sulawesi, Indonesia, presents a promising opportunity for geothermal energy development due to its potential. Geographically situated within the Sidenreng Rappang Regency and approximately 194 km from Makassar City, the Massepe field is characterized by diverse geological formations and notable geothermal activity. The region consists of volcanic, intrusive, and sedimentary rocks dating from the Tertiary to Quaternary periods (Sukamto, 2012). Key stratigraphic units include the Soppeng, Camba, Walanae, Parepare formations, and more recent alluvial deposits (Risdianto et al., 2008). Notably, the geological structure is dominated by the north-south trending Massepe fault, which acts as the primary conduit for geothermal fluids and plays a crucial role in the hydrothermal system. The hydrogeology of the area includes recharge zones in the hilly regions where meteoric water infiltrates and interacts with deep-seated geothermal

fluids, leading to surface manifestations such as the Pajalele and Alakuang hot springs (Risdianto & Soetoyo, 2008) (see Figure 5).

The geophysical surveys provide detailed subsurface features. The Bouguer anomaly resulted from the gravity survey show low-mid-high values, which associated with altered and less dense volcanic rock, sedimentary rocks, and shallow andesitic intrusions rocks, respectively (Risdianto & Soetoyo, 2008). The resistivity anomalies confirm the geological structures, particularly in the north-south Massepe Fault, which contribute to the emergence of hot springs at Pajalele and Alakuang. The low resistivity anomaly (<20 Ωm) suggests to be the upflow zone of the system, while the values between 20-60 Ωm thought to be the reservoir zone which clustered around the Pajelele hot spring, extending towards the Alakuang and Warede hot springs (Joni et al., 2019).

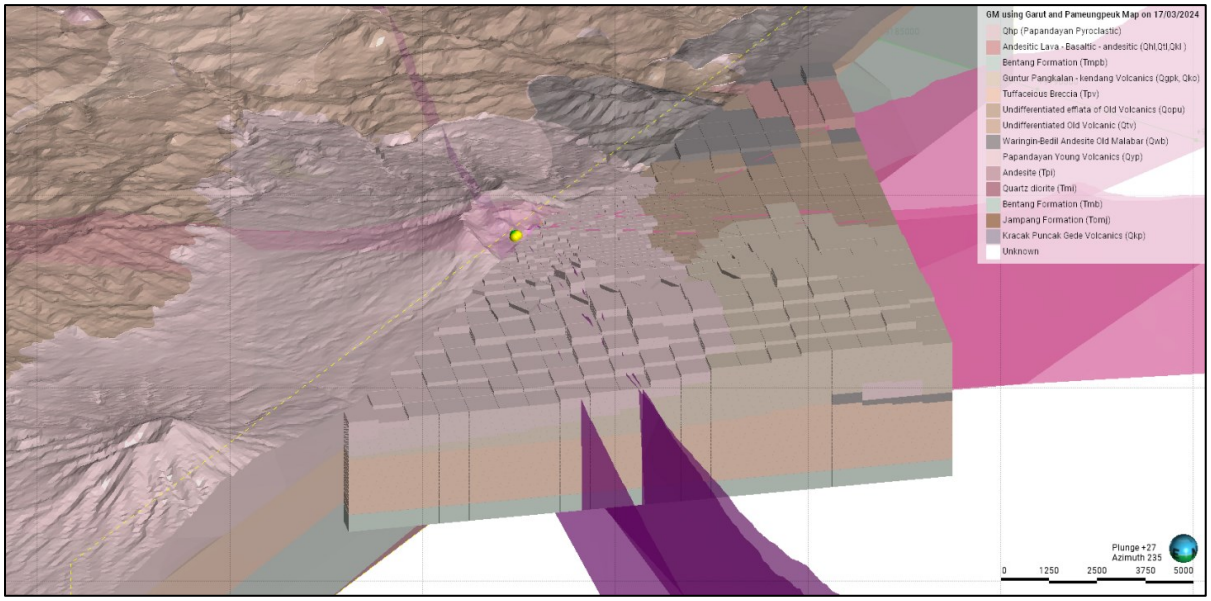

Figure 6: Papandayan geological model alongside the numerical model. Magenta planes represent NW-SE and NE-SW faults. Yellow dots represent acid sulphate manifestations.

3.6 Papandayan

The Papandayan geothermal field, located in West Java, Indonesia, offers potential for geothermal energy development. Mount Papandayan, a prominent stratovolcano, rises from 1,100 to 2,665 meters above sea level and is situated between Bandung and Garut District. The site has been studied since the early 2000s, with investigations focusing on lithology mapping, geologic structures, ground deformation, alteration, and fluid analysis from thermal features, which include solfataras, fumaroles, mud pools, and hot springs (Alzwar et al., 1992; Byrdina et al., 2018; Mazot et al., 2008; Nasution et al., 2008; Z. Abidin et al., 2003). The field's geological framework comprises several rock formations, ranging from Quaternary Holocene volcanic deposits to Tertiary Miocene formations such as the Bentang and Jampang formations. These formations are linked to ongoing volcanic activity, which provides a heat source that elevates the temperature of permeable rocks, creating geothermal reservoirs (see Figure 6).

A key feature of the Papandayan geothermal system is its complex fault structure, which significantly influences fluid flow and geothermal activity. The fault system in the area includes NE-SW and NW-SE trending faults that create pathways for geothermal fluids, impacting the distribution and intensity of thermal features (Sulastri et al., 2014). The presence of a clay cap dome below the area with many acidic thermal features, particularly in the Mas Crater, presents a challenge, as it is not feasible for drilling.

4. RESOURCE ASSESSMENT RESULTS

The resource estimates were made using the method outlined in Section 2 with the calibrated natural state model of each geothermal field as the initial input. Key parameters such as rock permeabilities, porosities and heat upflows were sampled from distributions to establish realistic parameter ranges for developing an ensemble of sample models. Note that these distributions could also be constrained by any available lab analysis data. Each sample model was then run to achieve a steady state before undergoing the filtering process. The models that successfully converged to a steady state were conditioned based on their temperature distribution at the base of the clay cap. These selection criteria required models to reach temperature between 180-200°C beneath the

alteration zone, indicating an accurate representation of the geothermal conditions during the formation of the clay cap.

The accepted models were subsequently used to estimate the maximum power output using the production scenario algorithm outlined in Section 2. By combining the predictions from the thousands of sample models, the uncertainty range of the power output can be quantified and expressed probabilistically using P10, P50, and P90 estimates.

A 25-year production scenario was applied to each of the six undeveloped geothermal fields in this study (Alia, 2024; Aloanis, 2024; Fuad, 2024; Nagoro & O'Sullivan, 2023; Rahmansyah, 2024; Syahrul, 2024). All scenarios had a separator pressure of 6.5 bar and a conversion rate of 2.5 kg/s of steam per MWe.

Stored heat calculation from published sources by EBTKE (Direktorat Panas Bumi, 2017), The Geological Agency (Badan Geologi, 2019), and Rahmansyah (2024) are also presented in this study as direct comparison with the result obtained from numerical methods. The stored heat calculation estimates the total thermal energy output and accounts for the recovery factor, conversion efficiency, and parasitic load (Zarrouk & Simiyu, 2013). Depending on the field, 10-20% can be used for the recovery factor and conversion efficiency. Monte Carlo simulation is typically used to quantify the uncertainty for parameters including reservoir size, average reservoir temperature, and porosity. This allows P10, P50, and P90 estimates to be made using the stored heat method. Table 1 presents the resource estimation results using both approaches for each of the geothermal fields studied.

Table 1: Result of the resource assessment using a traditional stored heat approach and the numerical modelling framework applied to six undeveloped geothermal fields. Stored heat calculations carried out by EBTKE (Direktorat Panas Bumi, 2017) [1], Rahmansyah (2024) [2], and The Geological Agency (Badan Geologi, 2019) [3].

Geothermal Field	Stored Heat Estimate (MWe)			Numerical Modelling Estimate (MWe)		
	P90	P50	P10	P90	P50	P10
Ciremai[1]		150		28.6	37.5	55.1
Kepahiang[1]		180		36.6	50.2	63.1
Kotamobagu[1]		225		70	160	270
Maritaing[1]		17		10.2	16.7	22.9
Massepe[2]	24.4	39.4	55.4	25.8	34.5	43.4
Papandayan[3]	16	21	26	12.3	18.5	28.4

The results in Table 1 show that the stored heat method yields higher resource estimates than the numerical model approach for the fields considered in this study. However, the stored heat estimates are subject to important limitations, primarily due to their high sensitivity to key input parameters and simplifying assumptions. The stored heat method neglects the importance of a heterogeneity typical of geothermal systems by using average temperature to represent the entire reservoir. Numerical reservoir models can capture reservoir heterogeneity. The stored heat method also assumes simplified reservoir geometries and ignores reservoir physics, which further bias thermal energy estimates. Importantly, the recovery factory parameter used in stored heat calculations is very uncertain and cannot reflect the complexities producing from different geothermal systems.

Our numerical modelling approach presented in this work provided robust estimates of the potential power output for each geothermal field, as the methodology accounts for reservoir and wellbore physics and fluid flow dynamics. The approach also allows additional insights into the nature of the geothermal resource. For example, it was found that accurately modelling the water table level was critical for the Ciremai system. The initial numerical resource assessment yielded a very low power estimate due to the system having a very deep water table. The deep water table strongly affects the reservoir pressure in the system and the ability of geothermal wells to flow without pumping. Our research indicated that it was unlikely for conventional wells to self-discharge at the Ciremai system. Thus, a scenario involving drilling highly-deviated wells from lower elevations was considered. Development scenarios such as this can only be considered using numerical reservoir modelling techniques. The stored heat calculation for Ciremai can only account for the low reservoir pressure crudely through the recovery factor and most likely overestimated the resource potential as a result.

Similarly the Kepahiang system has a very deep top of the reservoir due to a thick conductor. The effect of the deep reservoir can be accurately estimated using our approach which models the production wellbore physics. The result is a more conservative estimate then the stored heat calculation which likely overestimates the recovery factor once again.

For Kotamobagu the results are quite similar with our numerical modelling approach estimating a lower resource potential. For this system the MT data and their interpretation are quite uncertain and as a result our interpretation of the target reservoir was slightly smaller than the resistivity boundary used in the stored heat calculation. The target reservoir zone could be expanded once more geoscientific data or exploration drilling more clearly identify its extent.

5. CONCLUSION

This study presents six case studies demonstrating a new framework for assessing the resource potential of geothermal systems. This framework uses early-stage exploration data to constrain numerical reservoir models and estimate the potential power output of a geothermal system. This approach can provide a more realistic estimate of geothermal resource potential than traditional methods, such as stored heat calculations, as it can represent the complex reservoir dynamics that affect how much energy can be extracted.

For each system, a new 3D geological model was constructed using publicly available data and data from the Geological Agency (GA) and the Directorate-General of New Renewable Energy and Energy Conservation (EBTKE). These 3D models provide a better conceptual understanding of each system and allow critical geological structures and features to be visualized. Subsequently, numerical models compatible with AUTOUGH2 and Waiwera were developed representing key aspects of the geothermal system, such as temperature distribution, heat transfer, and fluid flow.

The methodology then uses the calibrated models to generate an ensemble of sample models from sets of reasonable parameters, thereby representing the uncertainties inherent at the exploration stage. Our method is also adaptable, enabling refinement of production strategies as additional data becomes available and allowing for seamless updates when geological models are revised. The production algorithm calculates realistic maximum energy extraction scenarios for each of the thousands of sample models and can also be adjusted to suit specific project criteria.

The case studies presented show that our novel approach can be used to estimate the early resource potential of geothermal systems with diverse geological settings and thermodynamic conditions. They have also highlighted some typical flaws in estimates made using the stored heat method. The method can be implemented using only publicly available data (see Kotambagu) though the availability of comprehensive exploration data, including geoscience and exploration well data, is preferable, as it enhances the accuracy of the conceptual model and provides more data to constrain the numerical reservoir models.

By working with the Geological Agency (GA) and the Directorate-General of New Renewable Energy and Energy Conservation (EBTKE) to combine high quality geoscientific surveys and exploration data with our robust numerical modelling approach we hope this framework can help to address some of the challenges in estimating the capacity of geothermal resources during early exploration, and contribute to the broader goals set by the Indonesian government for expanding geothermal energy production.

ABSTRACT

An unexplored prospect within the Lahendong Concession or WKP is Mount Mahawu. Limited research publications and data constraints have prompted PGE to initiate geological and geochemical studies from 2019 to 2023. Mount Mahawu's geological structure is part of the Quaternary volcanic arc situated east of the Lokon Volcano complex, formed by tectonic subduction in North Sulawesi's northern arm, known as the Sangihe Arc. Classified as a Type-A volcano, Mount Mahawu features low activity fumarole within its central eruption crater and sits atop an older volcanic complex.

The geothermal system of Mount Mahawu is indicated by thermal manifestations extending from its central eruption area to the northern volcanic complex. These manifestations include hot water with temperatures of 88.7°C and neutral pH, Cl-SO4 hot water with a pH of 2 on the northeastern slope, and argillic alteration on the southern side. Weak fumarole emissions are observed in the central eruption crater.

The heat source is attributed to the Quaternary-aged volcanic activity of Mount Mahawu, associated with the active volcanic emergence of Mount Lokon. The cap rocks are the result of hydrothermal alteration of volcanic products such as basaltic andesite lava, pyroclastic breccia, and tuff, producing clay minerals dispersed around the geothermal hydrology system. The geothermal reservoir temperature, estimated using the cation geothermometer, is approximately 216°C.

This medium-enthalpy reservoir, as inferred from manifestation data, holds significant geothermal potential and presents an opportunity for further development.

1. INTRODUCTION

Lahendong Geothermal Concession (WKP) is a geothermal working area located in North Sulawesi, Indonesia. This area is managed by Pertamina Geothermal Energy (PGE) based on Minister of Energy and Mineral Resources Decree No. 2067K/MEM/2012 dated 18 June 2012. The Lahendong Concession covers an area of 106,800 hectares and has very promising geothermal prospects. In this area, there are two geothermal potentials that have been developed, namely Lahendong and Tompaso. Lahendong Unit I, which produces 20 MWe, began operating in 2001 and has operated consistently. Capacity development of 40 MWe was carried out in 2007-2009, and an additional 20 MWe began operating in 2011. Currently, Lahendong's total generating capacity reaches 80 MWe from 4 power plants, and Tompaso produces 2x20 MWe which is also included in this Concession. Apart from that, there is still other potential in this Concession that has not been explored, showing great opportunities for the development of geothermal energy in the future.

One of the other geothermal prospects in the WKP is located in the Mahawu Area. Based on a preliminary survey conducted by the Center for Geological Resources (PSDG) in 2013, two manifestations in the form of hot springs were found in the Kaleosan Area. These manifestations show great potential, and further and detailed research is needed to understand the geothermal system and evaluate the geothermal energy potential in this area. In 2023, PGE conducted geochemical and geological survey to assess preliminary evaluation of Mahawu prospect.

2. METHOD

Geological survey were conducted to find out the distribution of rock formations, identify tectonic features, and evaluate the physical characteristics of geothermal manifestations. Furthermore, geochemical survey were carried out to determine the fluid characteristics and conditions within geothermal reservoirs. This involves analyzing various parameters, including the type of manifestation and the concentration of solute to understand estimated temperature reservoir base on geothermometry.

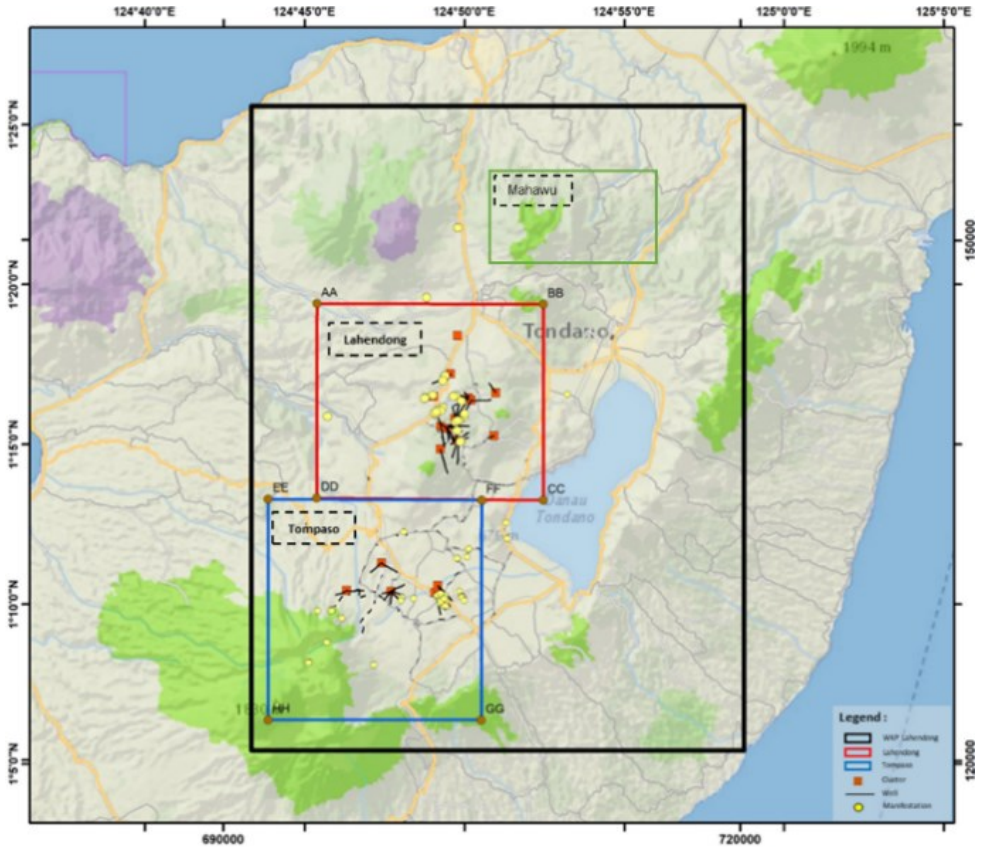

Figure 1: Geothermal prospect in the Lahendong Concession (Black square), Tompaso prospect at the South (Light blue square), Lahendong prospect (Red square), and Mahawu Prospect at the North (Green square).

3. REGIONAL GEOLOGY

The Mahawu Volcanic Complex is situated in the eastern part of the Northern Arm of Sulawesi Island, an area commonly referred to as the Minahasa Compartment (Siahaan et al., 2005). The Northern Arm of Sulawesi was formed by convergent tectonic processes, which include the subduction of the North Sulawesi Plate to the north and the East Sangihe Plate to the east, adjacent to Halmahera (Hall and Wilson, 2000). The subduction of North Sulawesi has been driven by the interaction between the Molucca Sea Oceanic Plate and the East Banda Arc since the Middle Miocene (Hamilton, 1979; Katili, 1975; Walpersdorf et al., 1998). The formation of geological structures in the Minahasa Compartment is primarily influenced by the tectonic evolution resulting from the interaction between the Sangihe Arc Subduction and the Halmahera Arc Subduction. This interaction has caused the Minahasa Compartment to move west to northwest (Walpersdorf et al., 1998) and rotate counterclockwise (Szentpeteri et al., 2015). On the surface, these tectonic processes have manifested in three major geological structures within the Minahasa Compartment: the Amurang-Malompar Fault, the Manado-Kema Fault, and the Tondano Volcanotectonic Depression Structure (Effendi and Bawono, 1997; Lecuyer et al., 1997). The Manado-Kema Fault borders the Minahasa Compartment to the north, while the Amurang-Malompar Fault borders it to the south.

The regional geological framework of the Mahawu and Klabat volcanic complexes in North Sulawesi is profoundly shaped by the tectonic dynamics within the Minahasa Compartment and result of significant volcanic activity during Quarternary period. The Mahawu Volcanic Complex, a stratovolcano located east of the Lokon-Empung volcano, exhibits complex geological features including pyroclastic cones and a crater lake formed from historical volcanic activity. Mount Klabat, the tallest volcano in Sulawesi, is distinguished by its summit crater lake, although it lacks recorded eruptions. These volcanoes are integral to the volcanic arc formed by the subduction of tectonic plates, underscoring their intricate geological and geothermal properties.

4. RESULT AND DISCUSSION

4.1 Local Geology

The delineation and relationship of volcanostratigraphic units were determined based on observations from a Digital Elevation Model (DEM), using references from previous publications and geological maps (Effendi et al., 1993; Effendi and Bawono, 1997; Wibowo et al., n.d.). There are 10 geological units in the study area, ranging from the oldest to the youngest: Tertiary Volcaniclastics, Tondano Tuff, Masarang Lava, Tombuluan Lava, Titingon Lava, Mahawu Lava, Klabat Lava, Klabat Pyroclastic, and Alluvium.

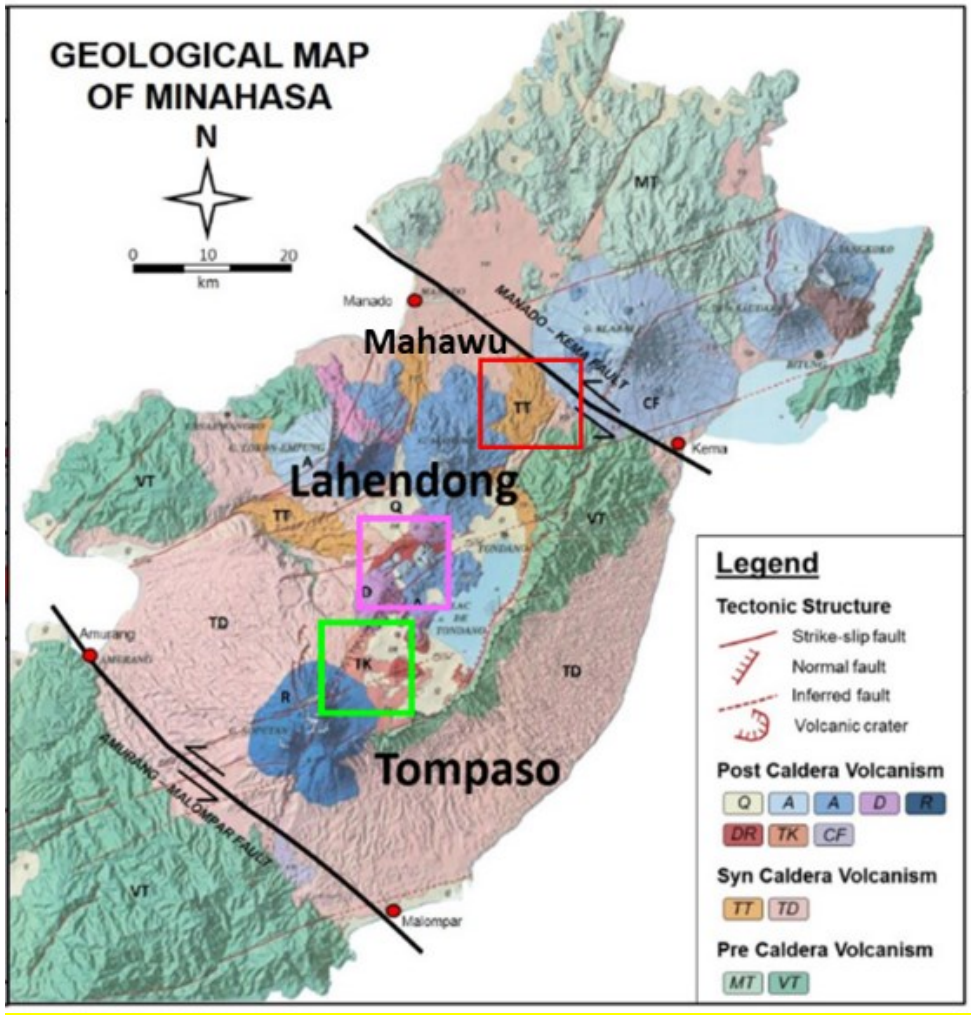

Figure 2: The geological map of the Minahasa Compartment (Lecuyer et al., 1988) shows the Tondano Volcanotectonic Depression, which is composed of pre-, syn-, and post-volcanic products of Tondano. The map also highlights two major strike-slip structures that bound the Minahasa Compartment to the north and south.

The oldest rocks found in the study area are products of the Tertiary volcanism, including breccia, andesite-basalt lava, and tuff (Effendi and Bawono, 1997). Additionally, mapping by Effendi et al. (1993) indicates that Quaternary volcanism began with the Tondano volcanic episode, which produced widespread tuff, pumice, and ignimbrite with flow structures. This massive Tondano volcanism also contributed to the formation of the Tondano Caldera. Volcanic activity continued with eruptions from Mount Wawo, Mount Masarang, Mount Tombuluan, Mount Titingon, and Mount Klabat, and Mount Mahawu, which remains active to this day, with the last recorded eruption occurring on November 16, 1977 (Global Volcanism Program, 2024). Futhermore, the volcanic products found in the Mahawu Volcanic Complex are generally lava with compositions ranging from basalt to dacite, as well as pyroclastic flow and lahar deposits (Siahaan et al., 2005; Yamin et al., 2015).

The determination of the geological structures in the Mahawu area was based on several previous publications (Effendi et al., 1993; Wibowo et al., n.d.) and interpretations using Digital Elevation Model (DEMNAS) data. The geological structures in the Mahawu area generally have a northwest-southeast orientation, aligning with the direction of subduction, as well as northeast-southwest and, to a lesser extent, north-south orientations. The major

faults in the study area are the Kuwil Fault and the Taedei Fault (Wibowo et al., n.d.), which are part of the sinistral strike-slip Manado-Kema Fault, one of the major northwest-trending faults that delineate the Minahasa Compartment to the northeast (Effendi and Bawono, 1997; Lecuyer et al., 1997). The presence of these faults is also believed to control the occurence manifestations observed in the study area.

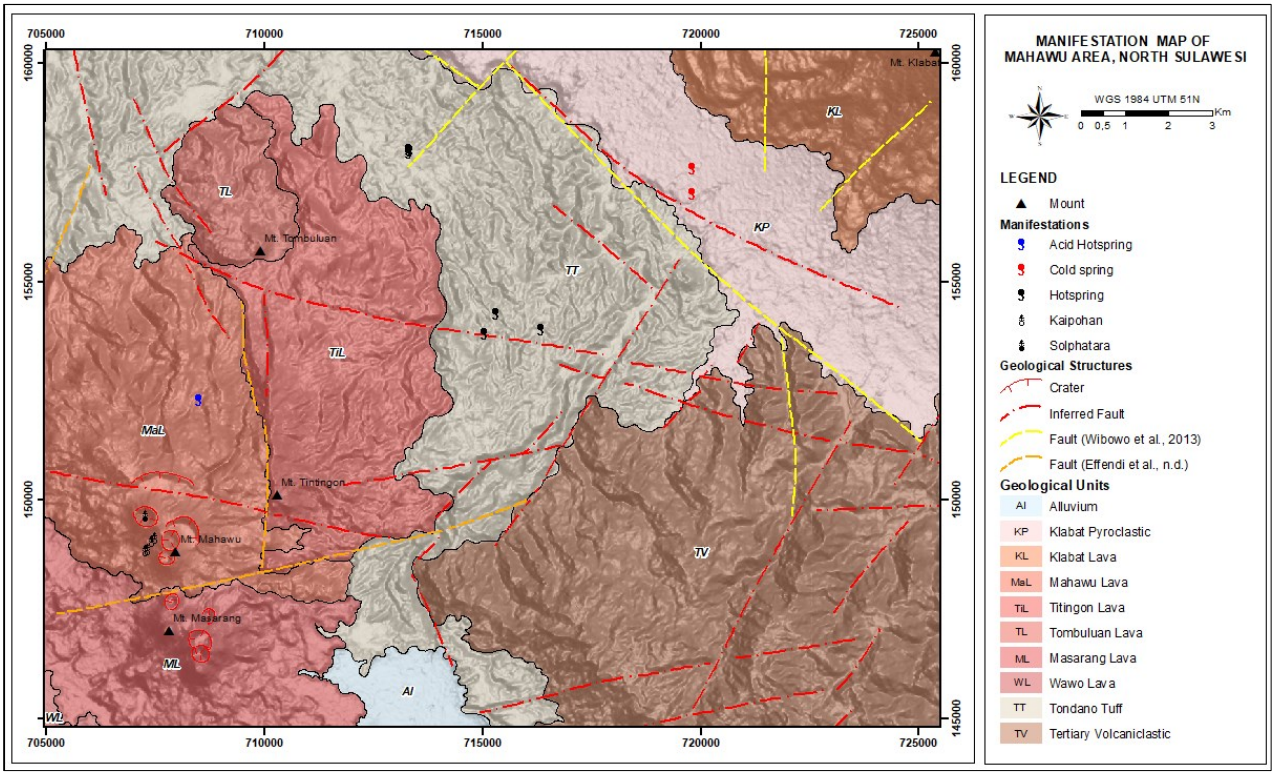

Figure 3: Geological map of the Mahawu-Klabat area with geological structures shown in yellow dash (Wibowo et al., 2013), orange dash (Effendi et al.), and red dash representing inferred faults.

Table 1: Physical parameter of surface manifestation.

No	Lokasi	Jenis_mani	Id/Code	Ambience Temp	Manifestation Temp	PH	Total Disolve Solid

4.2 Water Geochemistry

The prospect area is featured by manifestations around the crater of Mount Mahawu and hotsprings at northeast. Additionally, hotsprings located between Mount Mahawu and Mount Klabat were the key targets for this survey. Data collection for manifestations was conducted concurrently in 2023. The manifestations and cold springs in the Mahawu prospect can generally be categorized as follows:

- Mount Mahawu Group: Includes altered ground or kaipohan to the south of Mount Mahawu, Solfatar at the crater of Mount Mahawu, and acidic hot springs (MHW-1) on the northeastern flank.
- Sampiri-Kaleosan Group: Comprises hotspring manifestations in Sampiri (SAM1, SAM2, SAW1) and Kaleosan (KLS- 1, KLS-3). No thermal activity was found in Air Madidi.

The Mahawu Prospect is generally characterized by hotsprings and some acidic hot springs, with no active fumaroles (kaipohan and altered ground) and the crater of Mount Mahawu. Hotsprings are distributed across the northeast region of the Mount Mahawu complex. Field observations indicate that the spring water temperatures range from 28-57°C with pH values between 2.9 and 8. Anion, cation, and isotope sampling was conducted in the hotsprings based on these observations.

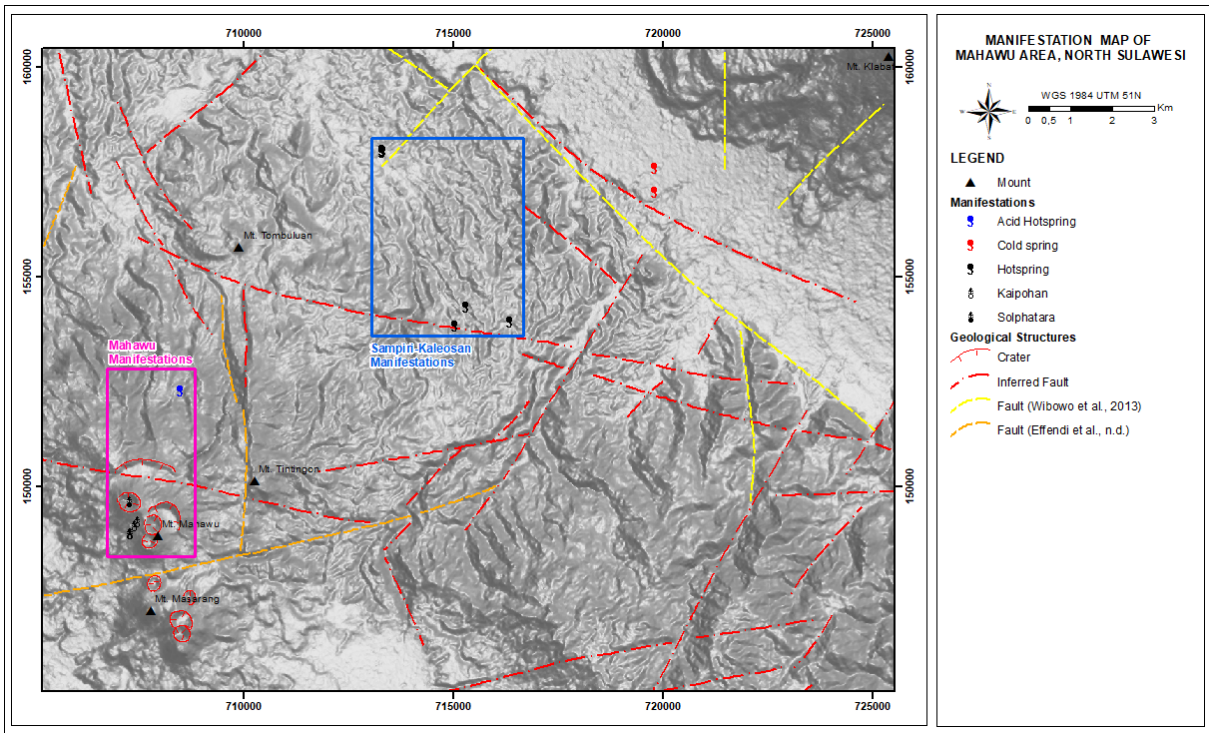

Figure 4: Map distribution of data and manifestations of the Mahawu prospect. The Mahawu complex is marked in pink, and the Sampiri and Kaleosan complex is marked in blue.

4.3 Geochemistry Evaluation

Based on the geochemical survey carried out in 2023, cold spring samples were taken from various locations and then analyzed by a third party laboratory. Table 1 presents the results of the water chemistry analysis. Initial quality control of the data was performed using ion balance calculations before further evaluation. Acid fluid manifestations with an ion balance value exceeding 5% (e.g. MHW-1, MHB-1, MHW-4) were included in the geochemical interpretation due to evidence of oxidation. Other manifestations with an ion balance value below 5% exhibited good data quality.

The ternary diagram of Cl-HCO_3-SO_4 indicates that manifestations around the Kaleosan area (KLS 1) exhibit water characteristics close to chloride/mature water. Acidic springs in Mahawu and the river from Mount Mahawu are classified as sulfate water types. In contrast, the cold springs in Air Madidi Village (AMD-1 & AMD-2) and the warm springs in Sampiri Village (SAM-1 & SAM-2) are classified as bicarbonate water types. Within the Mahawu geothermal system, chloride hot springs are found exclusively in Kaleosan village (KLS-1 to KLS-3), with a significant number of points around the Kaleosan River and some occurring directly in the river.

Data plotted on the Na-K-Mg diagram shows that all manifestations and springs in the Mahawu Geothermal system are classified as immature water. This suggests significant mixing with meteoric water during the transportation from the reservoir to the surface. Only the sample from the KLS-1 manifestation is positioned on the partial equilibrium line, indicating a stronger influence from the reservoir compared to other hot springs.

The Cl/B (Conservative element) diagram reveals two distinct groups of springs: the Kaleosan trend (KLS 1 and KLS 2) and the MHW acid manifestations. The Kaleosan group shares similar characteristics with the Sampiei and Sawangan manifestations, as well as several springs from Mount Mahawu. Conversely, the hot springs in Mahawu and those to the north of Mount Mahawu (MHW 1) exhibit an acidic pH, likely due to sulfate condensation in meteoric water, while maintaining high chloride levels indicative of a magmatic origin.

Isotope analysis provides insights into the fluid properties and processes of the manifestations and springs in this area. The Oxygen-18 ($\delta^{18}O$) vs. Deuterium (δD) plot shows that both cold and hot springs, including those from Sampiri and Kaleosan, display a slight shift to the right of the Local Meteoric Water Line (LMWL). This minor

shift suggests a limited influence, as the water type in these locations is predominantly chloride and remains mixed with surface water. The samples do not indicate a significant influx of magmatic fluid; rather, there is a subtle shift to the left in the plot.

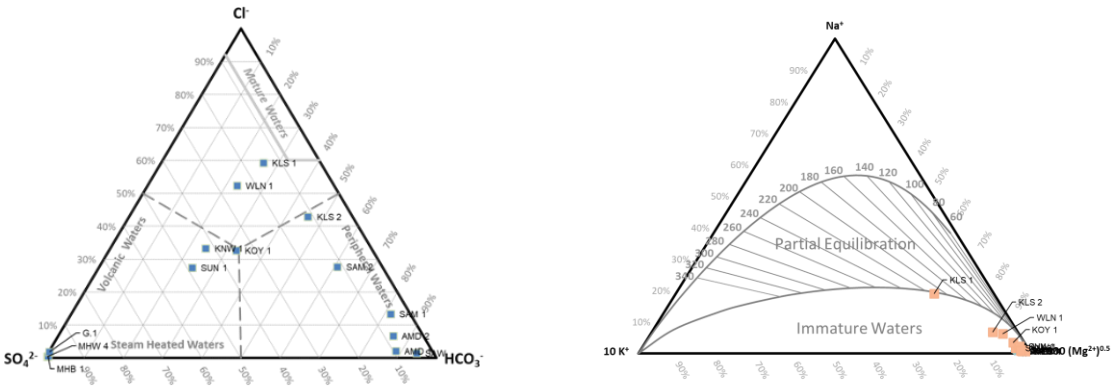

Figure 5: Ternary diagram of Mahawu water chemistry data.

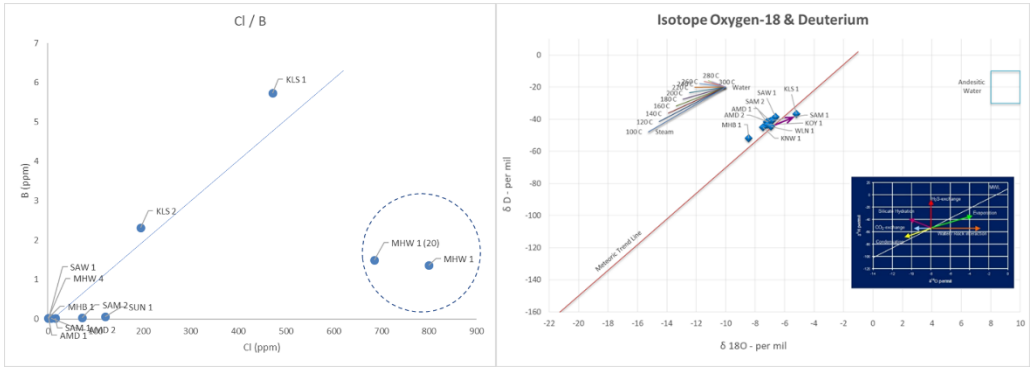

Figure 6: Diagram Cl/B of Mahawu water chemistry data (left) and Isotopes Oxygen-18 vs Deuterium data (right).

4.4 Geothermometry

Geothermometer is one of the methods in estimating reservoir temperature based on chemical composition from brine and gas samples. In this study, geothermometer approach is utilized to estimate the change in reservoir fluid temperature using solute geothermometer.

Silica geothermometer approach utilizes silica solubility as a function of temperature. While cation geothermometer is based on the equilibrium between minerals. Both geothermometer have different apporach. The fluid in the reservoir has reached equilibrium and when it rises to the surface, the Na/K ratio does not change much. The fluid migration to the surface might cause slight changes in temperature. Silica is very sensitve to temperature change, either because of pressure change or mixing with surface water. Therefore, the silica geothermometer method provides a lower temperature estimate compared to the cation geothermometer method which calculates temperature estimation at greater depth. When calculating geothermometry near the surface, the Na/K geothermometer should be corrected using calcium and magnesium conceentration for a more accurate temperature estimation.

Based on the results of water chemistry analysis, geothermometer calculations can be carried out to determine the temperature of the subsurface reservoir, while gas geothermometers cannot be used because there is no gas data that can be taken. All manifestations associated with the Mahawu system are not chloride water types that reflect fluid directly from the reservoir except for the Kaleosan Manifestation. Subsurface temperature can only be interpreted using 1 data which is still experiencing mixing based on the Cl-HCO3-SO4 and Na-K-Mg diagrams. The geothermometer results show a subsurface temperature range of 170 ºC – 216 ºC based on the Silica, Na/K, Na-K-Ca, and Na-K-Mg Correction geothermometer.

4.5 Tentative Conceptual Model

The hydrology of the Mahawu geothermal system remains a critical area of investigation. Based on the presence of chemical manifestations and existing data, the upflow is likely located beneath Mount Mahawu, where volcanic cones and craters exhibit minimal residual activity. In contrast, fumaroles to the south have undergone cooling and condensation. The northeast outflow direction is suggested by the presence of chloride manifestations in Kaleosan and chloride traces in the Sampiri area. Additionally, the presence of acidic hot spring manifestations on the northeastern flank of Mahawu is likely indicative of shallow fluid flow resulting from the oxidation of H2S gas within the groundwater aquifer. The prospect boundary towards Mount Klabat is defined by the Manado-Kema Fault, which is interpreted as a sealing fault. This is corroborated by the absence of other manifestations east of the fault, with only minor chloride traces observed in the cold springs of Air Madidi (AMD-1 & AMD-2). To develop a more robust conceptual model, further research into the distribution of clay caps and detailed geological structures is essential.

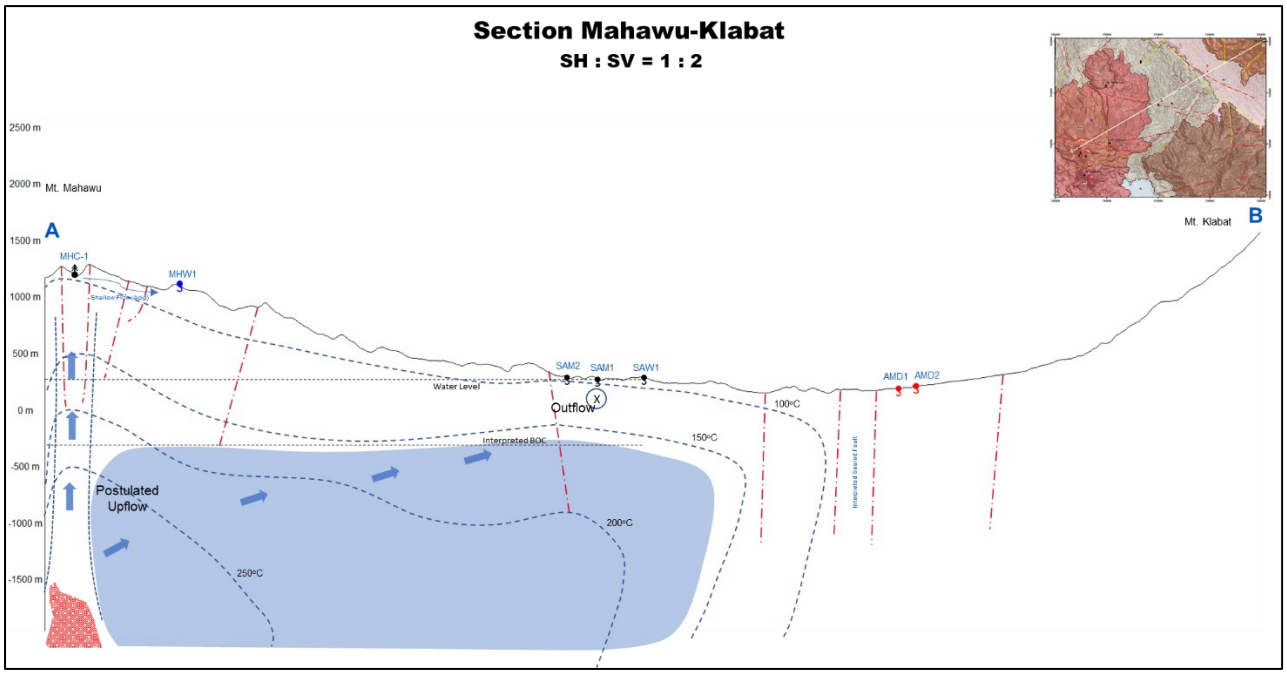

Figure 8: Tentative conceptual model which built from Geology and Geochemistry data of Mahawu Prospect.

5. CONCLUSION

The region's geological framework, shaped by the tectonic interactions of the Sangihe and Halmahera Arc Subductions, has resulted in a complex structural configuration within the Minahasa Compartment. These findings underscore the area's considerable geothermal prospects. The Lahendong Concession in North Sulawesi, particularly the Mahawu area, holds significant untapped geothermal potential, representing a promising frontier for future energy development. Comprehensive geological and geochemical surveys conducted from 2019 to 2023 by PGE have revealed substantial geothermal manifestations, including hot springs, acid hot spring, kaipohan, and low activity fumarole, indicative of a medium-enthalpy geothermal system with reservoir temperatures approximating 216°C. Continued exploration and in-depth studies are essential to harness the Mahawu area's full potential, which could play a pivotal role in augmenting Indonesia's geothermal energy resources.

Keywords: Atauro Island, inter-tidal hot springs, seawater intrusion, ternary diagram

ABSTRACT

Atauro is a volcanic island formed 3 Ma as a result of the magmatism from arc-continent subduction to collision between the Banda Arc and Australian Passive Margin, recognized from its 2 distinctive volcanic edifices in the southern part of the island with traces of northward-moving volcanism. The ancient volcanism leaves 4 hot springs as its traces, which is adjacent to the coastlines on the eastern part of the island. Therefore, it is strongly affected by the inter-tidal activity. Unfortunately, prior research on inter-tidal hot springs in this area are insufficient. Hence, it is necessary to understand the characteristics of these inter-tidal hot springs by using field observation and water geochemistry analysis, complemented by geothermometric studies with various ternary diagrams and calculations. There are four hot springs on the coastal plain of the eastern Atauro Island, namely, Makili, Pala, Biqueli 1, and Biqueli 2, which all are exposed only at low tide and submerged by seawater at high tide. The rocks around these hot springs are characterized by argillic alteration. The Pala hot spring's water emerged from joints in dacitic rock, while the water of the other three hot springs emerged from alluvial deposits on the coastal plain. The average water temperature of these hot springs is 73.88°C, with pH of 7.15, and the average of 19,525 mg/L for TDS and 39,837.5 µmhos/cm for EC. The Biqueli 2 hot spring has warm ground and a weak sulfuric odour, while the Biqueli 1 hot spring only has sulfuric odour but weaker than Biqueli 2 hot spring. Based on Giggenbach's Na-K-Mg ternary diagram shows that only the Biqueli 1 hot spring is in partial equilibrium with the estimated reservoir temperature 130-140°C, whereas the other three are immature waters. Based on the TCSH and TCLB diagram plots, all samples fall in the mature water zone with high Cl- content, with the average of 15,406.60 mg/L. Thus, considering the high Cl- concentration, along with TDS and EC parameters, indicates that all hot springs have been strongly intruded by seawater. Therefore, a correction using seawater fraction is required to normalize the water geochemistry data. Unfortunately, the seawater sample was not taken and currently there is no available geochemistry data of seawater around this island from previous studies, thus, the correction cannot be performed in this research.

1. INTRODUCTION

Atauro is a volcanic island located around 30 km north of Dili, East Timor. It is a part of the Inner Banda Arc and has 2 distinctive volcanic edifices on its southern part (Ely, et al., 2011). This elongated-shaped island indicates the northward changing volcanism due to the collision between Banda Arc and Australian Passive Margin (Ely, et al., 2011). Consequently, the volcanic activity ceased (Abbot and Chamalaun, 1981) and left several indications of hydrothermal activity and the existence of a geothermal system, such as altered rocks and hot springs. It is necessary to conduct assessments on these hot springs' potential, as it might be developed for a power plant or tourist attraction. Moreover, most of the inhabitants depend on electricity from a diesel-powered power plant, and the availability of which is based on a frequently limited fuel supply. Hence, geothermal energy might become an alternative to provide electricity in this island.

However, these manifestations are mostly located on the eastern shoreline of the island. Interestingly, the hot springs are situated in the intertidal zone and can only be seen when low tide. The absence of previous research on coastal hot springs in this region makes it difficult to understand the processes involved in the geothermal system, particularly the possibility of sea water intrusion, which might influence these manifestations. Therefore, it is necessary to conduct research on these hot springs to unravel their characteristics before determining their potential.

The aim of this paper is to understand the characteristic of inter-tidal hot springs in Atauro Island by utilizing geochemistry analyses of its surface hot spring water and field observation. There are 4 locations where the water samples were taken (Figure 1), namely, Makili (HSM), Pala (HSP), Biqueli 1 (HSB1), and Biqueli 2 (HSB2). Furthermore, water geochemistry data from these samples were plotted in Microsoft Excel using several diagrams, such as Schoeller (1965), Gibbs (1970), and Giggenbach's TCSH, TCLB, and Na-K-Mg (1991).

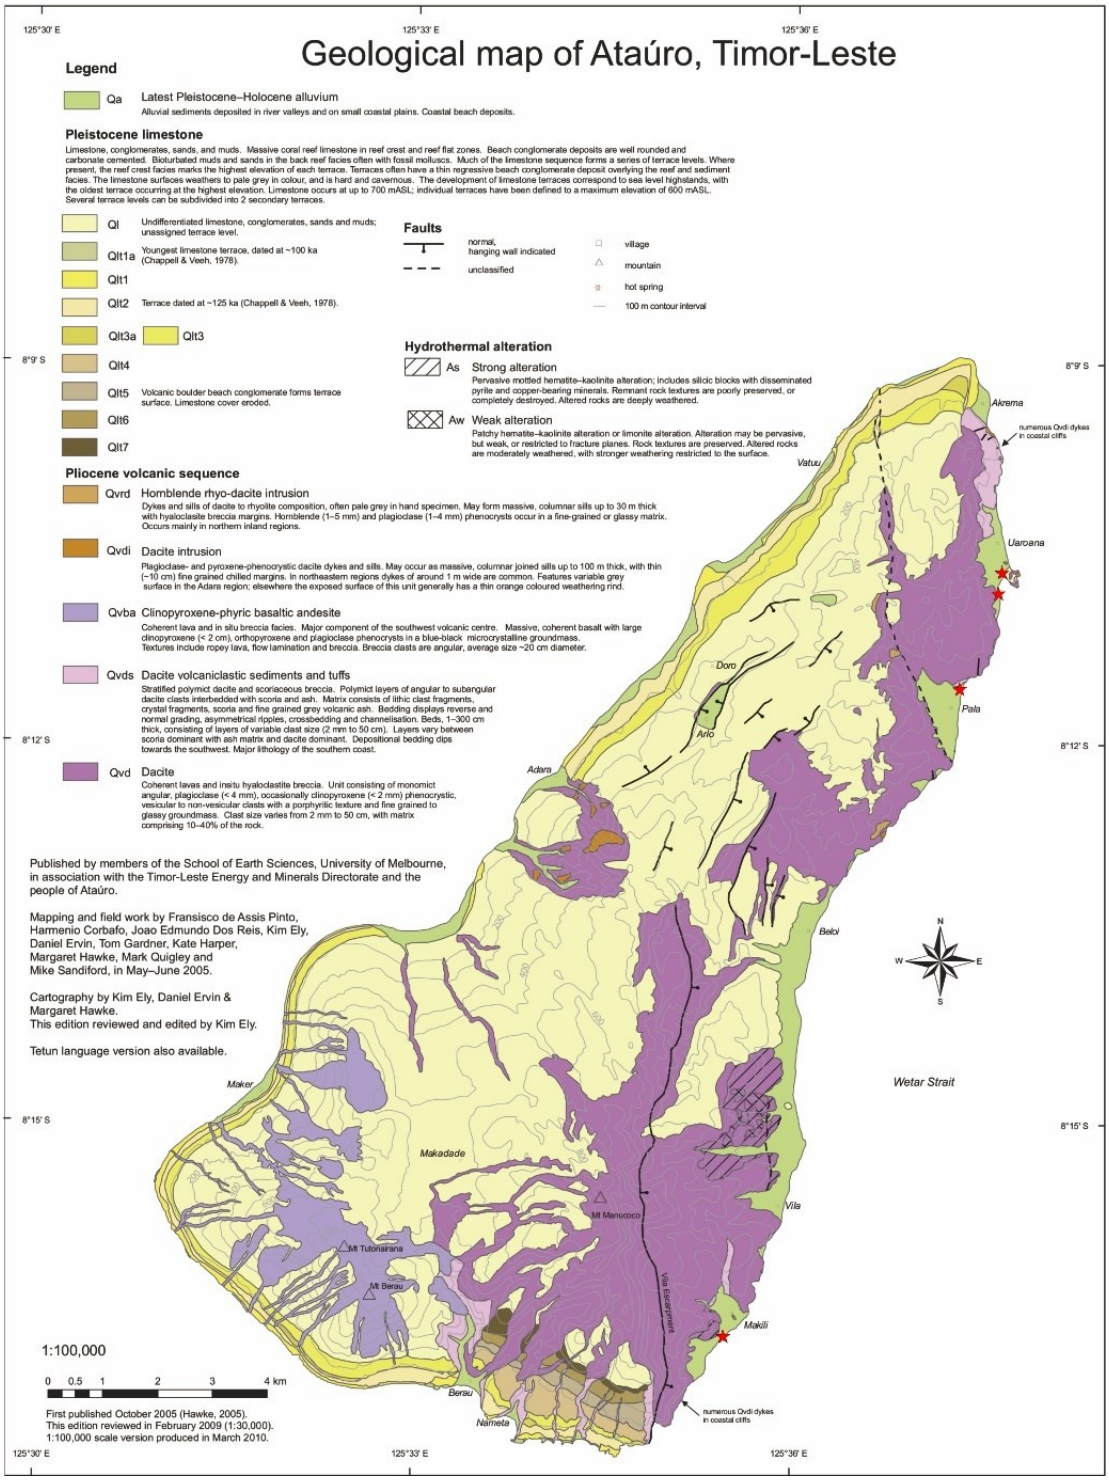

Figure 1: Geological Map of Atauro Island (Ely et al., 2011). Hot Springs are shown with red star symbol.

2. GEOLOGICAL SETTING

The research site is situated within the Southeast Asian tectonic framework, influenced by the convergent interactions of the Pacific, Eurasian, and Australian plates. Atauro Island, positioned in the neotectonic context (Figure 2), is located south of the Wetar Thrust and is impacted by the Timor Trough to its southeastern side (Harris, 2011). Geomorphologically, it is characterized by volcanic landforms and structural features (Chang, 2023).

The tectonic evolution of the study area commenced in the Late Miocene epoch, marked by the subduction-to-collision transition between the Banda Arc and the Australian continent. During the Late Miocene to Pliocene (4-6 Ma), this transition progressed gradually, leading to the uplift of Proto-Timor as a consequence of the shortening of the accretionary zone on the passive margin of the Australian continent due to active tectonic forces. In the Pleistocene epoch, compressional forces persisted, resulting in the shortening and uplift of Timor Island, accompanied by the development of back-arc thrusts and the Banda Volcanic Arc (Hall and Wilson, 2000; Spakman and Hall, 2010; Harris, 2011). The geological structures observed on Atauro Island include normal faults, strike-slip faults, and joints (Chang, 2023). In the context of tectonic evolution, the stratigraphic development in the research area is categorized into the Pliocene Volcanic Sequence, Pleistocene Limestone, and Pleistocene-Holocene Alluvial Deposits, with limestone overlaying volcanic highlands (Abbot and Chamalaun, 1981; Ely et al., 2011).

This tectonic setting has given rise to a volcanic arc that has been inactive since the Pleistocene epoch. However, hydrothermal alteration processes continue actively, facilitating the ongoing presence and potential development of geothermal resources (Abbot and Chamalaun, 1981).

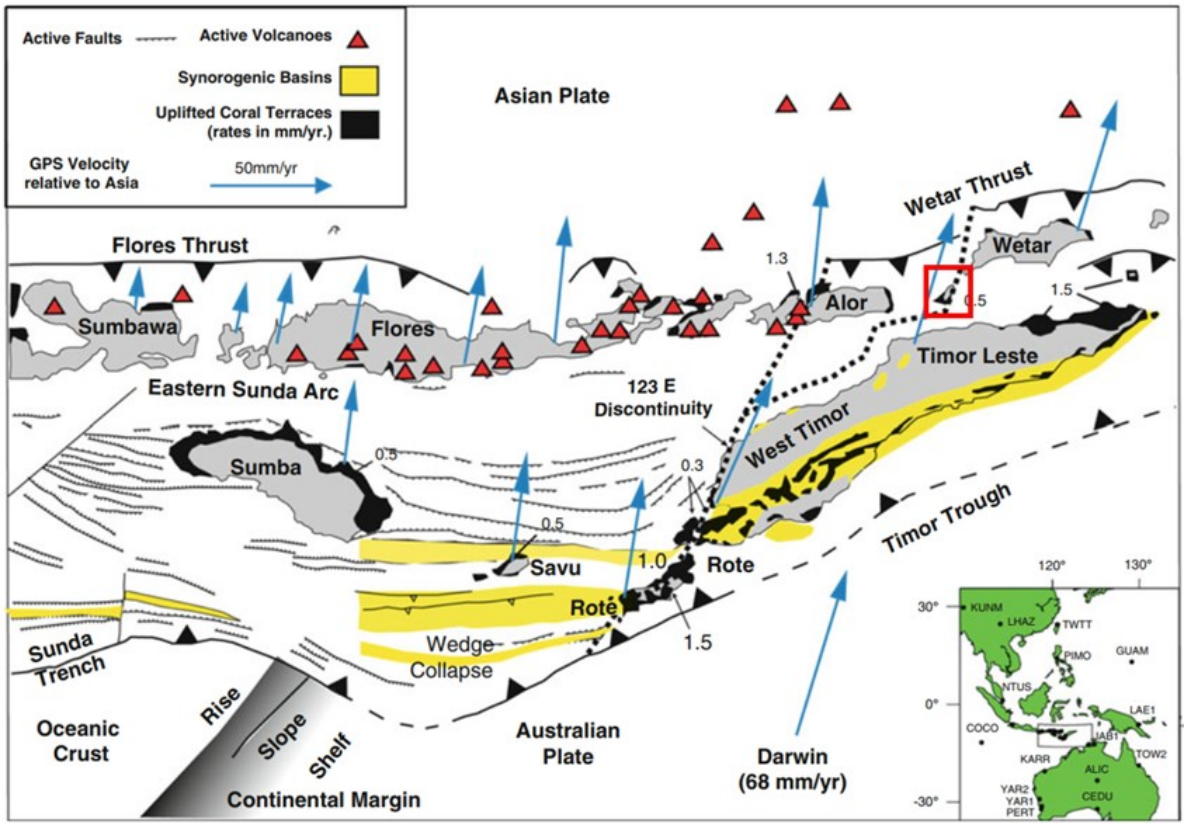

Figure 2: Neotectonic Map around the study area by Harris (2011). Research site is shown in red rectangle.

3. SAMPLING AND LABORATORY ANALYSIS

The sampling was conducted between 8:00 and 10:00 AM (UTC+9) during low tide in the wet season (February 2023). Water sample was collected directly from the water output (indicated by air bubbles) from each location and stored in a 900 mL polyethylene bottle that had been rinsed with groundwater and sample water. We ensured that the bottle was airtight an no water bubbles inside to prevent biological and chemical reaction. The temperature of the hot spring water was directly measured using Fann® Metal Stem Dial Thermometers (Part no. 206037), as well as pH value which was determined using Universal Test Paper. For temperature measurement, the thermometer's stem was dipped around 4 inches under water for 2 minutes, whereas the pH measurement was done by quickly dipping the test stripe (<1 second) and match it with the standard colour. Afterwards, the samples were sent to the Yogyakarta Centre for Environmental Health Engineering and Disease Control (BBTKLPP Yogyakarta) for water geochemistry analysis. The water samples were not filtered (using 0.45-micron membrane filter) except for Na, Li, K, and B parameter.

4. RESULTS AND DISCUSSION

4.1 Makili Hot Spring (HSM)

This hot spring was located at the coastal plain in Makili Village, at the southeastern part of the Island (UTM Zone 51S; 785907 m E, 9082818 m S). This location was accessible via 4-wheeled vehicle until Vila Village, followed by roughly 3,25 kilometres walk along the coastline. The Makili hot spring has a temperature of 187 – 192°F (86.1 – 88.89°C). Temperature measurements were taken at several points where the hot water emerged, characterized by the presence of water bubbles in several small puddles. In the area around the hot spring, there was a slight smell of sulphur and it felt warm with the presence of wet steam. The hot spring emerged from beneath alluvial ranging from fine sand to boulders (Figure 3). The boulders surrounding the hot spring had a reddish colour. It was an altered andesite rock from Mt. Manucoco, indicated by argillic alteration zone on the nearby hill (Chang, 2023).

Figure 3: Makili landscape around hot spring with altered hill in the background (left); small puddles where the hot water came out (middle); hot spring temperature (right).

Figure 4: Pala hot spring puddle (left); fracture where the hot water came out (middle); hot spring temperature (right).

4.2 Pala Hot Spring (HSP)

This hot spring was located in Pala Village at the northeastern side of the island (UTM Zone 51S; 790329 m E, 9094769 m S). This location was accessible by 4-wheeled vehicle and roughly 100 metres walk from the main road. The water came out from fractured rock (Figure 4), which was an altered dacitic rock (Ely, 2011) and had a trace of argillic alteration in the surrounding area. The temperature was measured on the fracture where the water flowed and it showed 149 – 151°F (65 – 66.1°C). This area had a slight smell of sulphur and little amount of steam observed.

4.3 Biqueli 1 Hot Spring (HSB1)

This hot spring was located in Biqueli Village (UTM Zone 51S; 790903 m E; 9096499 m S). This location was accessible by 4-wheeled vehicle and adjacent to the main road. The water came out under the bedding of an unconsolidated coastal deposit with sand-sized grains (Figure 5). This area had light steam and little smell of sulphur, and several brownish-orange alterations. The average of measured temperature was 145°F (62.8°C) on several water flow.

4.4 Biqueli 2 Hot Spring (HSB2)

This hot spring was accessible by 4-wheeled vehicle until the main road and roughly 150 metres walk (or by motorcycle ride) from the main road. The hot spring was located around 30 metres from the seawater, and the surrounding area was a peat land (UTM Zone 51S; 791101 m E, 9096855 m S). However, it become a pond when the high tide. The water flowed and formed a small river, with a quite strong smell of sulphur and steams that were observable (Figure 6). The measured temperature was 166°F (74.4°C) on a single spot that had bubbles, indicating a flow of fluid from beneath.

Figure 5: Biqueli 1small puddles where the hot water came out (left); Landscape around hot spring (middle); small puddles where the hot water came out with brownish-orange altered rocks (right).

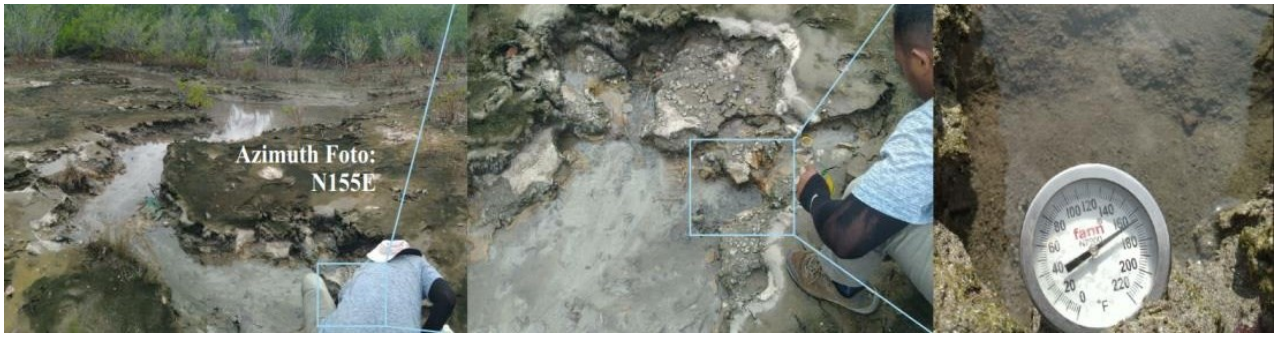

Figure 6: Biqueli 2 landscape around hot spring (left); small puddles where the hot water came out (middle); hot spring temperature (right).

4.5 Hot Spring Water Geochemistry

Chemistry of fluid is an important part in geothermal study and plays a crucial role as a tool to unravel the characteristic of a geothermal field. Four water samples were taken, one for each hot springs on the island, to analyse the chemical composition of geothermal system in Atauro Island. The result of chemical fluid composition of geothermal hot springs is given in Table 1.

Table 1: Major water geochemistry data from inter-tidal hot springs in Atauro Island.

4.5.1 Schoeller Diagram

Schoeller (1965) is one of the methods used for water chemistry analysis which based on cationic and anionic concentration comparative between groundwater samples. This diagram plots each ion concentration using six

ions such as Ca^{2+}, Mg^{2+}, $Na^{+} + K^{+}$, Cl^{-}, SO_4^{2-}, and HCO_3^{-} to represent groundwater type from its ionic dominations. Ionic concentrations are relatively similar on all four hot spring water samples, with the order of cationic concentration is $Na^{+} + K^{+} > Mg^{2+} > Ca^{2+}$ and for the anionic concentration is $Cl^{-} > SO_4^{2-} > HCO_3^{-}$ (Figure 7).

Schoeller diagram (Figure 7) shows there are spikes of Cl^{-} anion concentration values ranging from 338.4 Meq/L to 504 Meq/L for all four samples. These values, backed with DHL values of 33.350 µmhos/cm to 42.580 µmhos/cm from four samples (Table 1), represents saline water (saltwater). Classification standard of groundwater with electrical conductivity for fresh groundwater is less than 900 µmhos/cm (low EC), 900-2000 µmhos/cm for brackish water (medium EC), and higher than 2000µmhos/cm for saltwater (high EC) (Davis in Ruseffandi & Gusman, 2020). The presences of saline water indicated that there is sea water intrusion into the geothermal system, especially to the reservoir, which correlated to its location as all four hot springs are located in the inter-tidal of coastal zone and only exposed to the surface on low tide.

4.5.2 Gibbs Diagram

Gibbs (1970) constructed the diagram of TDS v/s $Na^{+}/(Na^{+}+Ca^{2+})$ and TDS v/s $Cl^{-}/(Cl^{-}+HCO_3^{-})$ as an instrument to study the water chemistry relationship due to the interaction with rainwater, aquifer material, rock weathering and evaporites crystallization as water flows in the subsurface. This diagram shows the origin and distribution of dissolved components from water-rock interactions and explained the variable that responsible for controlling groundwater chemistry (Rengarajan and Balasubramanian, 1990). Cation (a), anion (b), and TDS data from water samples plotted into the diagram (Figure 8) and it's shows that the chemistry of hot spring water in the study area are falls into the low precipitation or runoff zone and heavily influenced with seawater. This suggested that high concentrations of Cl^{-} anion from all four hot springs in Atauro Island most likely caused by sea water intrusion.

	Ca	Mg	Na+K	Cl	SO4	HCO3
HSM	1.91	98.57	199.2234	448.0	22.88067489	2.3
HSP	0.95	120.41	227.3171	338.4	17.57169209	1.9
HSB1	1.31	84.24	251.6043	504.0	26.33671859	2.1
HSB2	1.27	104.18	238.4630	448.0	37.76664626	2.1

Figure 7: Schoeller Diagram result for showing the domination of major anions and cations.

4.5.3 Water Type / TCSH / Cl-SO_4-HCO_3 Diagram

The ternary of Cl-SO_4-HCO_3 shows the proportions of the significant anion concentrations in the hot spring water samples. This diagram is used to tell or classify types of geothermal water present in the area, which distinguished into four types of thermal waters such as mature waters, peripheral waters, volcanic waters, and steam heated waters. (Giggenbach, 1991). Through this diagram based on the results of plotting the anions (Figure 9), shows that all hot springs water classified as mature water which is a type of water that high in Cl^{-} concentration and low content of sulphate and bicarbonate.

Ideally geothermal water with high value of Cl^{-} is an indication of water dominated by the geothermal reservoir system, but in this case the water came from the sea water intrusion as shown in Schoeller Diagram (Figure 9) and Gibbs Diagram (Figure 9). The Cl^{-} anion values from four hot springs are too high to be classified as a water from the geothermal reservoir. So, the anionic concentration from Maliki, Pala, Biqueli 1, and Biqueli 2 can't be used to determine the water type without further research and more comprehensive sampling procedures.

4.5.4 Water Source / TCLB / Cl-Li-B Diagram

This ternary diagram is used as an instrument to distinguish the geothermal water that influenced by absorption of high temperature steam from different sources (Powell and Cumming, 2010). The B concentration of fluids is

reflected to some degree the maturity of a geothermal system, in which because of its volatility it is expelled during the early heating up stages (Mnjokava, 2007). Result from plotting each element into the ternary diagram shows that all hot spring water samples fall at the top of the diagram (Figure 10). Low content of Boron and Lithium concentrations and high content of Cl^- concentrations is suspected influenced by sea water intrusion into the system. This result is consistent with Schoeller Diagram (Figure 10) and Cl-SO_4-HCO_3 ternary diagram (Figure 10) that also shown the indication of sea water intrusion.

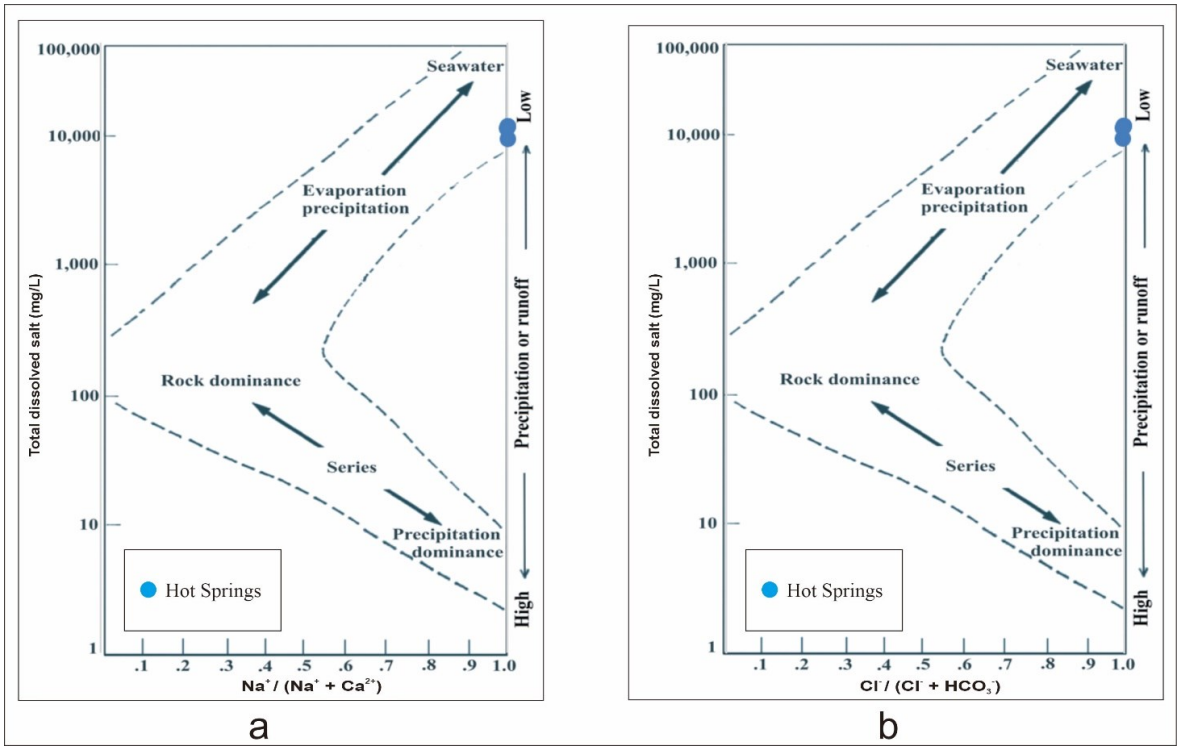

Figure 8: Gibbs Diagram shows the chemical relationship of water interaction.

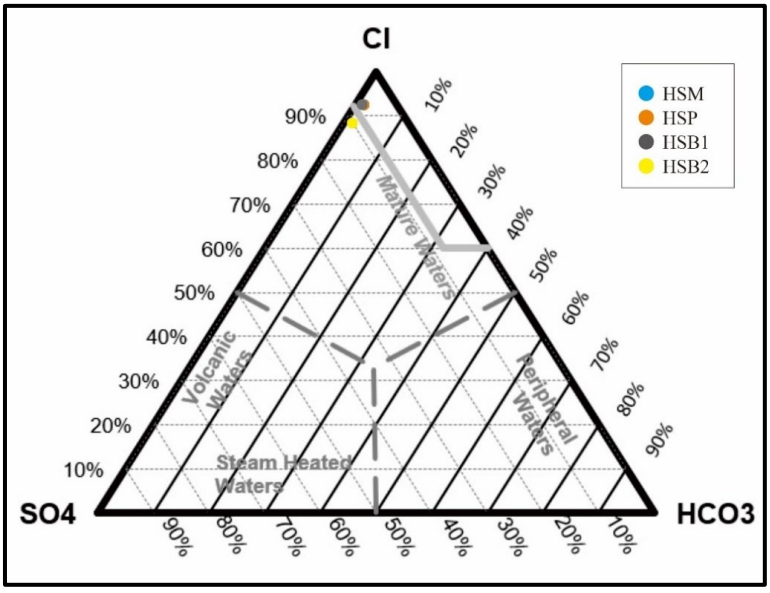

Figure 9: TCSH / Cl-SO4-HCO3 Diagram to determine the water type.

4.5.5 Equilibrium and Temperature

Na-K-Mg ternary is a diagram which used geoindicator ionic elements as a classification tool that divided water into three different classifications of water such as immature water, partially equilibrated water, and fully equilibrated water (Giggenbach, 1988). This diagram can be used to apply geothermometry only to partially equilibrated water and equilibrated water (Shah et al, 2021). The prediction of equilibrium temperature is based on the temperature dependency of full equilibrated assemblage of sodium and potassium minerals that formed

after isochemical recrystallization of average crustal rock under the geothermal interest condition (Giggenbach, 1988).

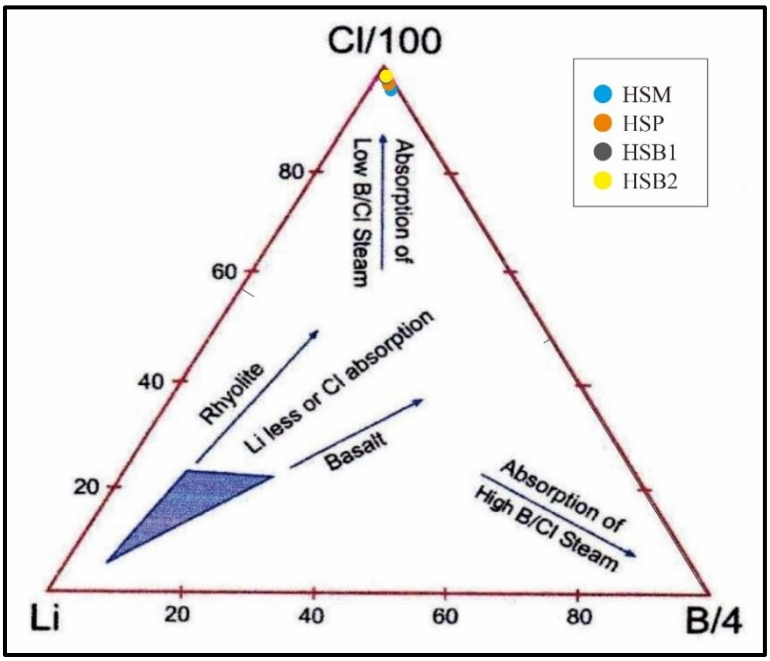

Figure 10: TCLB / Cl-Li-B Diagram to determine the water source.

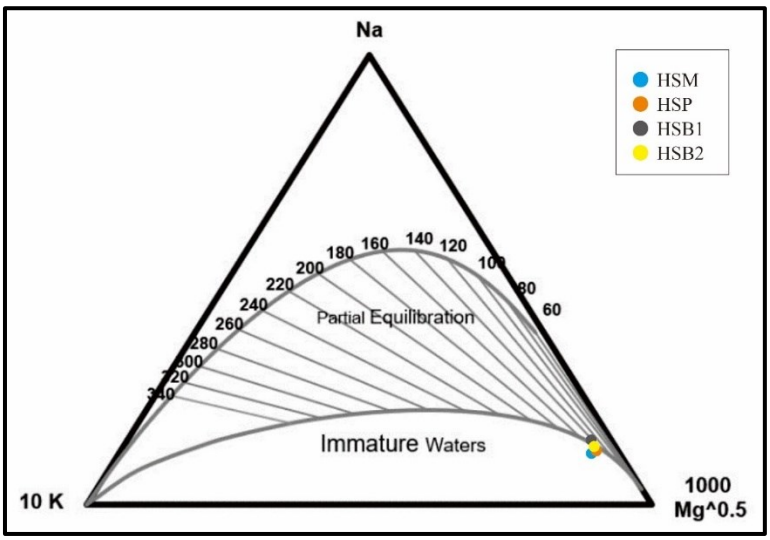

Figure 11: Na-K-Mg ternary diagram as a geoindicator to determine the equilibration.

According to Figure 11, the chemical data plotted from each hot springs shows that all hot springs have similar concentration that close to Mg concentration but only one sample falls just above the immature and partially equilibrated water boundary, which is HSB1 hot spring. The interpretation is that there is high concentration mixing of relatively cold meteoric water (groundwater) into the system, hence the high concentration of Mg ion. Hot springs that classified as immature water aren't suitable for temperature estimation (Giggenbach, 1988). However, the reservoir temperature from HSB1 hot spring that falls just above the boundary and classified as a partially equilibrated water is estimated to be 120 ^{0}C – 140 ^{0}C.

5. CONCLUSION

Field study on the Atauro Island revealed there are four hot springs as geothermal manifestations, namely, Makili (HSM), Pala (HSP), Biqueli 1 (HSB1), and Biqueli 2 (HSB2), which are located at the inter-tidal zone and only exposed on low tide. Furthermore, based on the ternary plots, HSM, HSP, and HSB2 hot springs are classified as immature water, whilst HSB1 is classified as partially equilibrated water with its estimated temperature of 120 ^{0}C – 140 ^{0}C. However, geochemistry data of the water samples from all hot springs shown that the hot springs are intensely mixed with cold groundwater and were suspected that there is a high amount of sea water intrusion into

the geothermal system. This occurrence was indicated by the high concentration of Cl^- anion, ranging from 338.4 - 504 Meq/L, with DHL values of 33.350 - 42.580 µmhos/cm. Therefore, obtaining the geochemistry of seawater around this island is necessary to normalize the hot spring water samples. Unfortunately, the seawater sample was not taken and currently there is no available geochemistry data of seawater around this island from previous studies. Thus, further research with the corrected hot spring water is required to remove the effect of sea water intrusion in order to conduct more accurate geothermometric analyses.

ABSTRACT

The emergence of hot springs in the Tempuran area, Magelang, Central Java is a natural phenomenon that has been utilized and manage as a public thermal bath by the locals. The appearance of these hot springs is a sign of the existence of a geothermal system in the area. The source of the geothermal system developing in this area is still unknown. This research aims to provide initial information specifically regarding the green field geothermal system present in the Tempuran area. This research uses high-resolution satellite gravity data from The Global Gravity Model Plus (GGMPlus) to analyze density of the sub-surface rocks. In addition, this research uses DEMNAS data as a basis for fault continuity analysis. This gravity data will be supported by field geological measurements and local geological structures measurement. The results of this research show that there is a low gravity anomaly around the hot springs (-0.31 mgal to -0.007 mgal) which indicates that the geothermal system aquifer is located in the Alluvium Quarter rocks. there is a high anomaly (0.1 mgal to 0.3 mgal) in the southern part of the study area which is the response of Oligo-Miocene volcanic rocks, and high anomaly (0.1 mgal to 0.3 mgal) in northern part of study area which is the response of Quarter Volcanic deposits. Using DEM data to obtain the general direction of the structure using morphotectonic methodology, the Tempuran area, Magelang has a general (major) direction of lineaments ranging from NW – SE with a minor direction N – S. This data shows that the geothermal system in the study area is most likely included in the geothermal system of Mount Sumbing.

1. INTRODUCTION

The Java arc is located along the southern edge of the Eurasian plate, where the Indo-Australian plate subducts it. This arc has been active in its current position since approximately 10 million years ago in the late Miocene (Smyth et al., 2005; Soeria-Atmadja et al., 1994). The volcanoes in this chain vary in height, with some exceeding 3000 meters, forming the island's backbone with the existence of geothermal manifestation. The dominant composition of today's volcanic products is basaltic andesite (Nicholls et al., 1980), and their eruptive and epiclastic materials cover a substantial portion of the island. Most active volcanoes are located about 100 km above the subducting slab(England et al., 2004) and roughly 300 km north of the subduction margin.

Geothermal manifestations in the study area are one of the products of active volcanoes on the island of Java. The study locations are Tempuran District, Magelang Regency, Central Java Province. This geothermal area called Tempuran Geothermal Field due to the district of the existing geothermal manifestation. The site is located between the active mountain ranges of Sindoro-Sumbing Active Volcano and Merapi Active Volcano. The north of Merapi Volcano lies the currently inactive Mount Merbabu (Figure 1). The study area includes geotourism sites with hot springs, specifically the Ngasinan Hot Springs and Umbul Banyu Roso. Geographically, the location is near the confluence of the Setro and Progo Rivers (Figure 2) and is located approximately 30 km southeast of Sumbing Volcano.

Identification of the Geothermal system of Tempuran Geothermal Field is needed to make a long-term develompment plan of the area. This paper will provide a preliminary information of the Tempuran Geothermal Field using Gravity GGMPlus data (Hirt et al., 2013) and DEM data from DEMNAS (https://tanahair.indonesia.go.id/demnas) for structure deliniation. Those data will be confirmed by mapping of local geology. The use of GGMPlus in Geothermal field exploration has been carried out in several previous studies. Lase used GGPPlus Gravity data to modelling the heat source of Amohola-Sumbersari geothermal, and has been successful to locate the heatsource (Lase et al., 2022). Bahtiar also associated the low Gravity anomaly with some geothermal manifestations in Mount Iyang-Argopuro Geothermal Field (Abi Bahtiar et al., 2021). The topographic data from DEM could also used to deliniate the surface geologic structure (Hooper et al., 2003; Jordán et al., 2005).

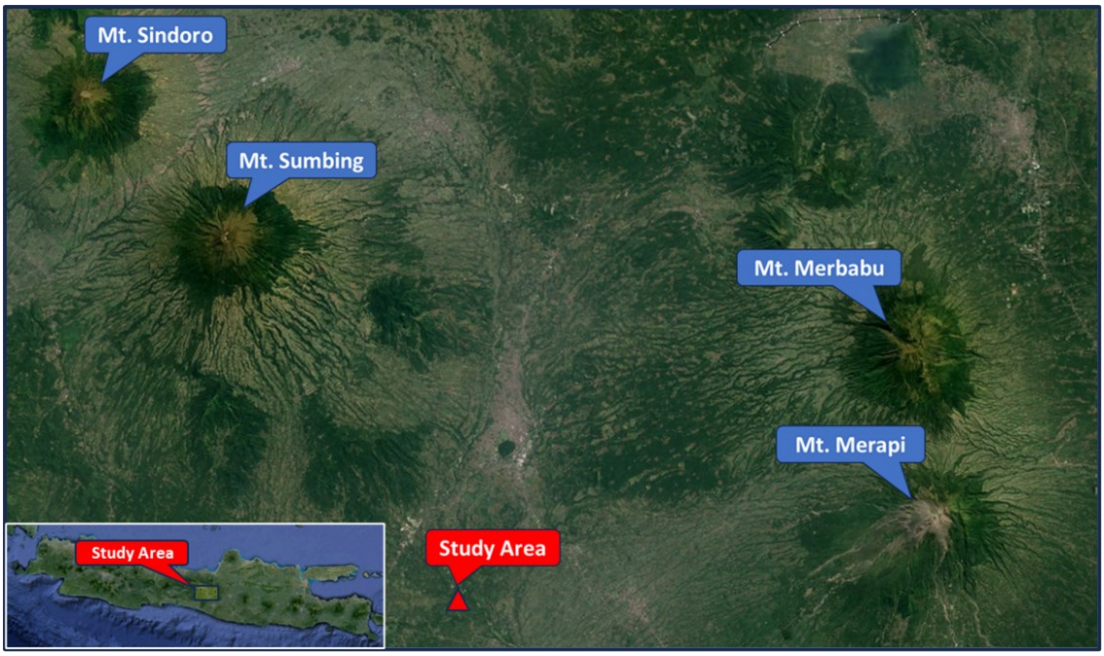

Figure 1: The study area is located between Sindoro-Sumbing Volcano and Merapi Volcano.

Local Geology

Geologically, based on the geological map of the Yogyakarta Sheet (Rahardjo et al., 1995) (shown in Figure 2, the study area is located in the Young Sumbing Deposits (Qsm), which consist of tuffaceous sand, sandy tuff, and andesite breccia. To the east and northeast are Volcanic Breccia deposits (Qb) comprising volcanic breccia, lava flows, tuff, tuffaceous sandstone, and lahar. To the west and northwest are Old Sumbing Deposits (Qsmo) consisting of andesite breccia, agglomerate, and tuff. The study area is located southeast of Mount Sumbing (Figure 1). Based on these geological conditions, it is suspected that the geothermal manifestations in the study area are products of geothermal activity from Sumbing Volcano. This preliminary study aims to uncover the geothermal sources of the Tempuran Geothermal Field based on morphotectonic analysis, aerial photography, and field surveys to validate the morphotectonic analysis results.

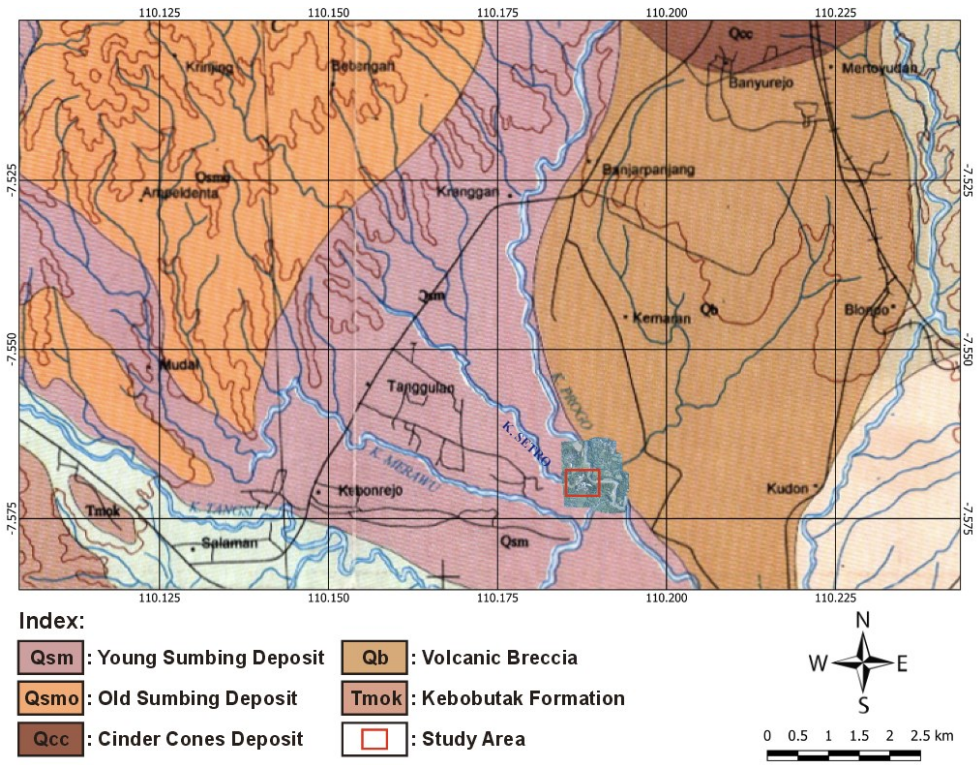

Figure 2: Geological Map of the Study Area (Rahardjo et al., 1995).

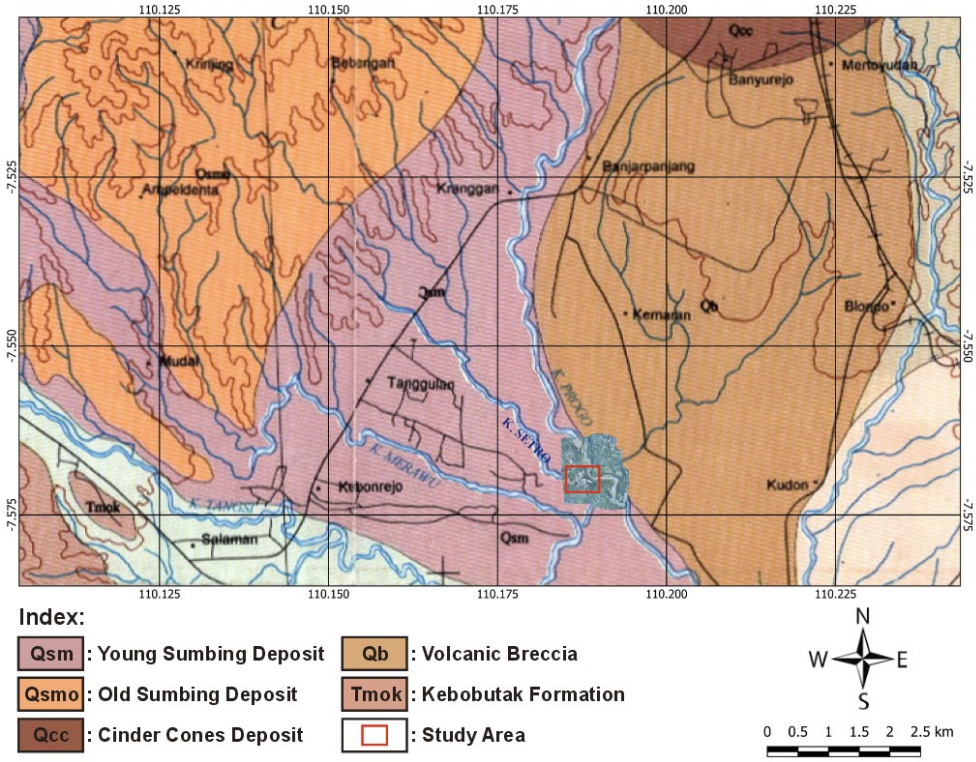

Figure 2: Geological Map of the Study Area (Rahardjo et al., 1995).

2. METHOD

This research is a long-term activity aimed at mapping and identifying geothermal systems in the Tempuran geothermal field in detail. Data yang digunakan adalah data GGMPlus Gravity Data. This data is released by theWestern Australian Centre for Geodesy and Curtin University Perth. This data consist of high resolution high resolution Earth's Gravity data over all continent, including Java and Indonesia. This data obtained through augmentation of satellite (GOCE/GRACE) data, EGM 2008 data, and terrestrial gravity with topography data and delivering detail at ~200 m spatial resolution (Hirt et al., 2013, 2019). The data is collected in research area and processed through standard processing of Gravity data(LaFehr & Nabighian, 2012; Zakaria, 2021). Result of the processing data is Bouguer anomaly and will be analysed. The workflow of gravity data processing can be seen in Figure 3.

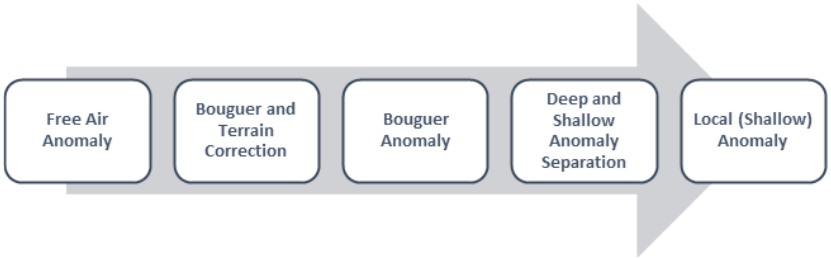

Figure 3: Workflow of GGMPlus Gravity data.

Detailed mapping of the morphotectonic in the study area utilizes Google Earth images, SRTM (Shuttle Radar Topographic Mission) from DEMNAS (Digital Elevation Model Nasional Indonesia), Shp data (https://tanahair.indonesia.go.id/demnas), drone aerial photography, and on-site field surveys. The mapping process identifies diverse lineations, focusing on slope, elevation, shape, and variations of these features. Terrain analyses utilized the DEM to investigate various aspects, including elevation, slope, aspect, topographic profiles, and longitudinal river profiles. Slope and aspect maps were generated from the DEM using Global Mapper and QGis. DEM analysis is crucial for studying elevation-related characteristics in fault zone areas (Duncan et al., 2003; Menges, 1990). The tonal variations in the elevation map provide insights into regional topography and structural features (e.g., Duncan et al., 2003; Hooper et al., 2003; Kassaras et al., 2020; Menges, 1990).

Morphotectonic mapping is divided into two parts, focusing on the Old Sumbing Deposits (Qsmo) and Young Sumbing Deposits (Qsm), due to suspicion that the study area represents a geothermal manifestation originating

from Sumbing Volcano. The morphotectonic mapping was validated using field data consisting of structural manifestations observed at the outcrop scale. Validation was conducted along several rivers near the geothermal manifestations because geological structures are often more visible along riverbanks. Field validation commenced at the first point near the Ngasinan Hot Springs and Umbul Banyu Roso, involving aerial photography, followed by two additional points northwest of Ngasinan Hot Springs and Umbul Banyu Roso based on interpreted lineaments from the morphotectonic map. Furthermore, thorough field observations have been crucial to the study, aiding in verifying, reinforcing, and interpreting the findings derived from the morphotectonic analysis. The workflow analysis can be seen in Figure 4.

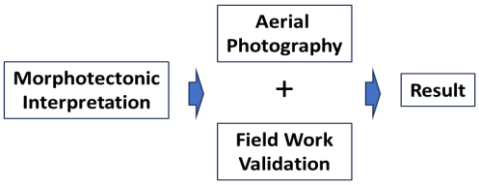

Figure 4: Workflow.

3. RESULT AND DISCUSSION

3.1 Geothermal Manifestation

Tempuran Geothermal Field located in Sumberarum Area, Tempuran District, Magelang Regency, Central Java. The main attraction of this area is the appearance of old hot spring in this area. Nowadays, there are several local residents to exploit this natural phenomenon by drilling around the main hot springs, and using it as public hot spring. This hot spring has been visited by many local residents and became a public bath recreational afterwards (magelangekspres, 2022). As seen in the picture, there are several hot springs appearing: 1. Original Hot Spring, 2. Ngasinan Public Bath, 3. Umbul Roso Public Bath, 4. Lintang Waterpark, 5. Tirta Madu Public Bath, 6. Tirta Sambara Public Bath, 7. Azirza Tirta Public Bath. Tourism development in this area of course requires careful planning so that the existance of hot water and also the temperature of the hot water is maintained. so detailed information about the Tempuran Geothermal System is needed

Figure 5: Location of local public bath appearing in Research area.

3.2 GGMPlus Gravity Data

Figure 6 shows the distribution of local (shallow) gravity anomaly values in research area. Manifestations are in the center of the map and are marked in red. The contour color shows the gravity anomaly value, with variations between -0.223 mgal to 0.148 mgal. Blue values are low anomalies and red are high anomalies.

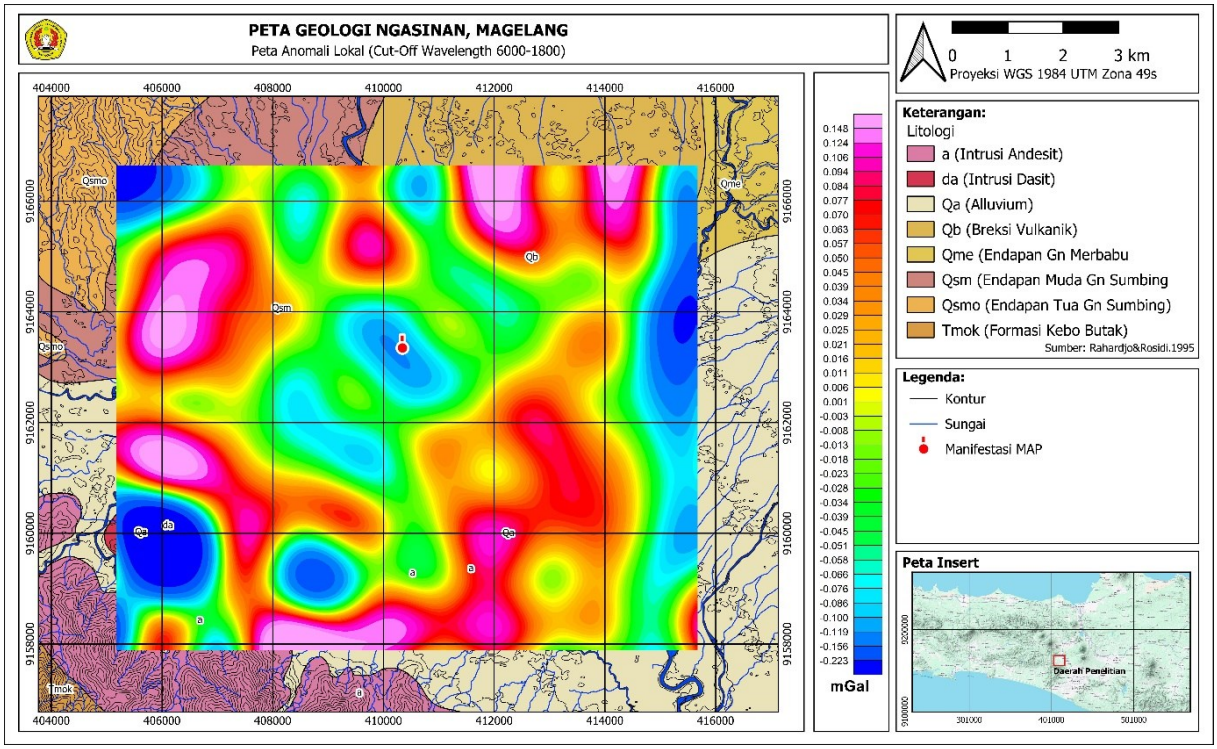

Figure 6: Map of Local Bouguer Anomaly data from GGMPlus Gravity Data on Tempuran Geothermal Field.

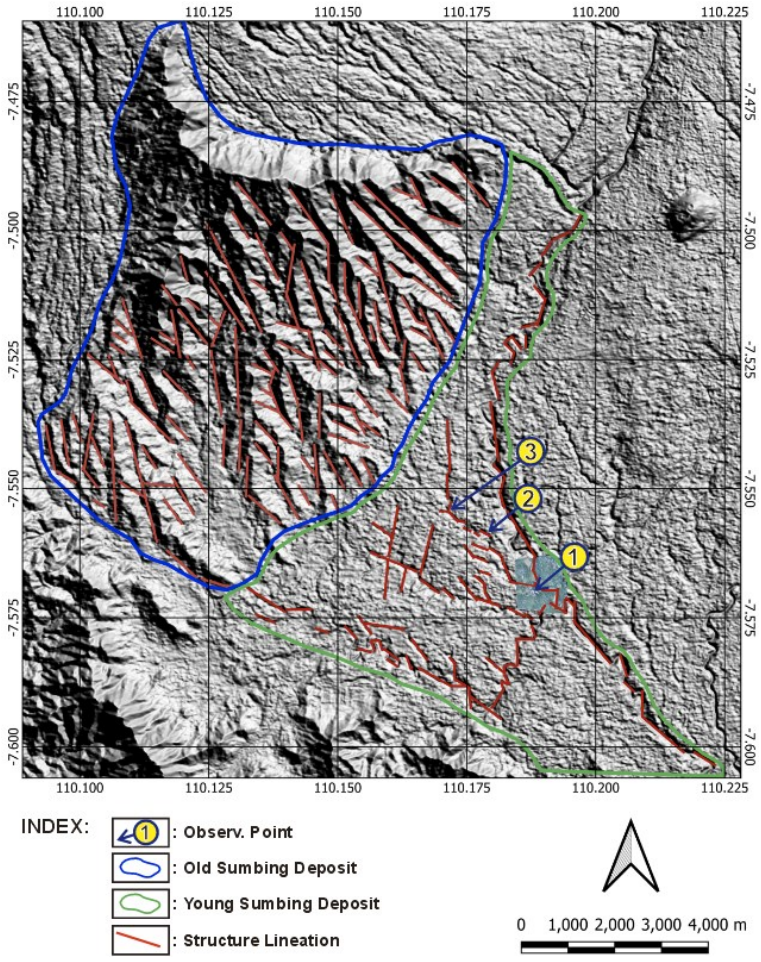

Figure 7: Morphotectonic Map and Observation Point of Study Area.

Rock formations in the research area are dominated by quarter volcanic rocks, products from Sumbing Volcano and Merbabu Volcano. These rocks tend to have a high density so they should provide a high response to gravity anomalies, in the red color. This high anomaly is spread over areas with low anomalies in the central part of the study area. The low anomaly in the middle is interpreted as a change zone or alteration zone caused by the emergence of hydrothermal fluid. Hydrothermal fluid comes out through structures that mix with meteorite water near the surface and change the volcanic rocks into clay rocks. This clay rock is thought to be the cover rock of the geothermal system in the research area.

3.3 Structure Identification and Delineation

Topography can provide valuable insights into the structure of the near-surface crust (Edward & Nicholas, 2002; Pérez-Peña et al., 2009) and deeper lithospheric processes, such as upper mantle dynamics). A relatively easy-to-observe topographic expression is the linearity found on slopes and rivers. In this paper, the author divides the study area into two sections for analysis of general orientation: the Old Sumbing Deposit (Qsmo) and the Young Sumbing Deposit (Qsm), as shown in Figure 7. The results, derived from morphotectonic interpretation data, indicate that the main structural direction of lineaments in both the Old Sumbing Deposit (Qsmo) and the Young Sumbing Deposit (Qsm) is predominantly NW-SE (Figure 8a and b). The author conducted this main direction analysis using rose diagrams.

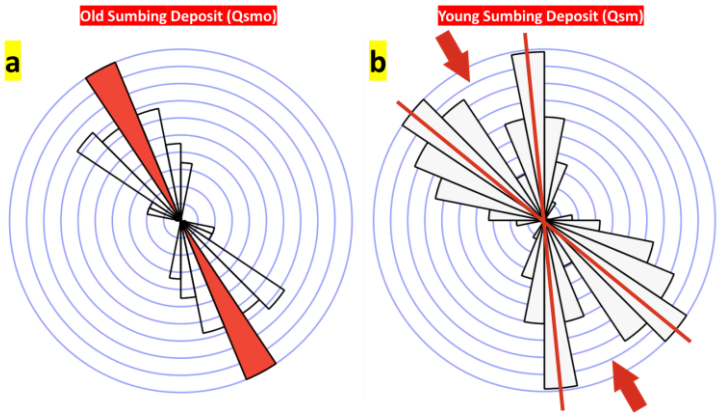

Figure 8: a) Rose Diagram of Old Sumbing Deposit (Qsmo); b) Rose Diagaram of Young Sumbing Deposit (Qsmo).

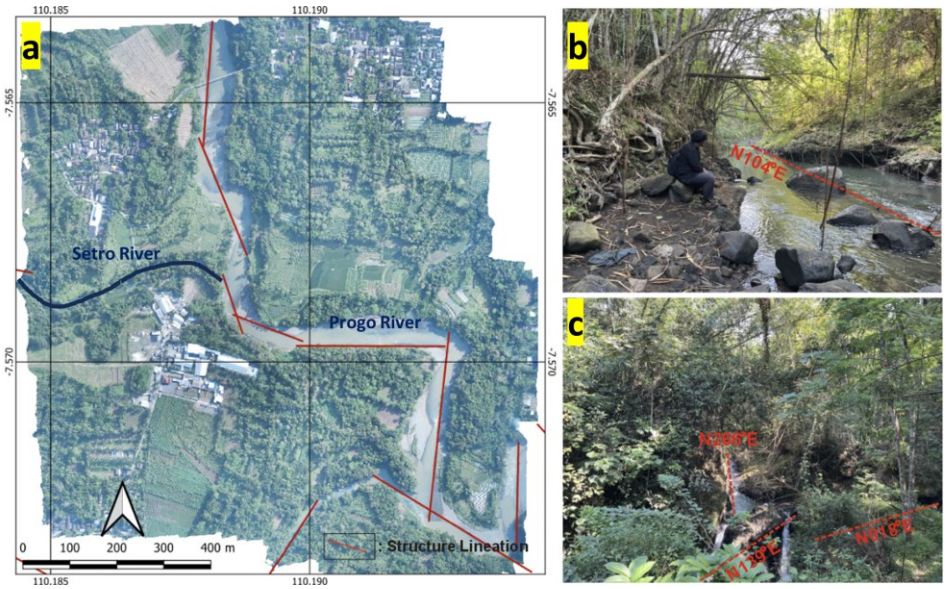

Figure 9: a) Aerial photography (orthophoto) of obvservation Point 1; b) The lineation of obvservation. Point 2; c) The confluence of these three rivers in obvservation point 3.

We analyze The Old Sumbing Deposit (Qsmo) using a rose diagram. The result of the rose diagram shows the main direction of the lineament structures is identified as NW-SE. In Qsmo, it is relatively easy to delineate the lineament structures due to the clear morphological expressions, as the rocks in Qsmo are relatively more resistant, resulting in steep and hilly terrain (Figure 8a).

In contrast, the Young Sumbing Deposit (Qsm) exhibits a flatter morphology due to the influence of younger volcanic deposits, which have not yet consolidated into hard rock. The delineation of lineament structures in Qsm is conducted in river areas, where the features are relatively fresh and easier to observe. The results show that in Qsm, there are two general orientations: approximately N-S and NW-SE. Based on the rose diagram in Figure 8b, the main stress direction is determined to be NNW-SSE.

The validation of lineament delineation was conducted using several methods (Figure 9). In addition to direct field cross-checking, the author also utilized aerial photography (orthophotos) to validate the lineament delineation. Figure 6a shows validation using aerial photography, confirming that the delineation based on the morphological map corresponds to the actual conditions around the Ngasinan Hot Springs and Umbul Banyu Roso. The structure around the Ngasinan Hot Springs and Umbul Banyu Roso is relatively complex, and this area marks the confluence of the Progo River and its tributary, the Setro River.

Field observations were carried out at observation points 2 (Figure 9b) and 3 (Figure 9c). At observation point 2, a river lineament oriented at N104°E was identified. This lineament confirms the validity of the morphotectonic interpretation conducted. At observation point 3, a confluence of three small rivers was found. The orientations of these small rivers are N286°E, N018°E, and N139°E, which are the downstream directions of these rivers. The confluence of these three rivers is likely due to geological structures, as evidenced by the irregular rock formations in this area.

4. CONCLUSION

Gravity data conclude that there are low anomaly around the hot spring geothermal manifestation. This area is corresponding to alteration zone of the Tempuran Geothermal Field System. Morphotectonic analysis indicates that the study area, which includes the Young Sumbing Deposit (Qsm) and the Old Sumbing Deposit (Qsmo) to the northwest, has a predominant lineament orientation of Northwest-Southeast. The author interprets the geothermal source in the study area as originating from Sumbing Volcano, located approximately 30 kilometres to the northwest.

Keywords: Aquifer, Geothermal, Resistivity, Schlumberger

ABSTRACT

The Tempuran area, Magelang Regency is an area that has many hot springs that are close together. Hot springs are a manifestation that characterizes the existence of a geothermal system in a place. These geothermal manifestations are used by the local community to support the economy which has the potential to be further developed by knowing the orientation outflow of the hot fluids that exist below the surface. Based on geological studies, the research area is included in the young Mount Sumbing sedimentary formation which is composed of sedimentary rocks associated with volcanic material. This research uses Resistivity Vertical Electrical Sounding which is spread at several points around the research area to determine the groundwater aquifer that enters the Outflow Zone of the geothermal system in the research area. The acquisition process uses Syscal Jr with a Schlumberger configuration with 7 acquisition points and a stretch of 600 meters each. The results obtained based on the Vertical Electrical Sounding profile show that the top aquifer is at a depth of 100 meters with an average resistivity value ranging from 24 Ωm to 39 Ωm. Subsurface interpretation based on 1D profiles shows the distribution of the aquifer which has an average thickness of 44 meters.

1. INTRODUCTION

Indonesia is part of the Pacific Ring of Fire, which results in the emergence of numerous volcanoes, both active and inactive (Basith et al., 2012). A volcano that has been inactive for a long time is not entirely free from visible volcanic activity. Some long-dormant volcanoes can be utilized as sites for geothermal energy development. Geothermal energy can serve as an alternative to reduce the use of non-renewable energy sources such as fossil fuels.

An area with potential geothermal energy is characterized by surface manifestations. One such area with geothermal manifestations is Tempuran in Magelang Regency. This is indicated by the presence of many hot springs located close to each other. These manifestations appear on the surface due to fractures that allow hot fluids to escape. Geological studies indicate that the study area is part of the Young Sumbing volcanic deposit formation, composed of sedimentary rocks associated with volcanic materials (Rahardjo et al., 1995).

This study aims to identify groundwater aquifers that are part of the outflow zone of the geothermal system using the Vertical Electrical Sounding (VES) resistivity method with a Schlumberger configuration, spread across the study area. The survey involves injecting electrical current into the earth's subsurface to determine the electrical properties, either electrical conductivity or resistivity, of the subsurface medium (Todd, 1980). These electrical properties will reveal the subsurface conditions, including the mineral composition and the porosity of the medium. The distribution of resistivity values will provide information on the distribution of groundwater aquifers in the study area.

2. LITERATURE REVIEW

2.1 Geology of The Research Area

Regionally, the research area consists of 5 rock units, namely volcanic breccia units, Merbabu deposits, Young Sumbing deposits, Old Sumbing deposits, and alluvial deposits (Figure 1). Locally, the research area itself is in the Young Sumbing sedimentary unit (Qsm) which belongs to the medial volcanic facies consisting of tuff breccia, sandy tuff, sandstone and clay lithologies (Nuur, M.F., et, al., 2015). In the mid-Quaternary era, volcanic activity was still ongoing, but the type of eruption became more explosive in the form of large eruptions that ejected pyroclastic material ranging from fine sand to gravel. The pyroclastic material is then carried through the air and falls down under the influence of gravity to reach the area of study and forms the Young Sumbing pyroclastic breccia unit in harmony with the Old Sumbing volcanic breccia and not align with the Kaligesing monomict

breccia. Volcanic activity continued during the Pleistocene but did not continue until the Holocene (Nuur, M.F., et, al., 2015).

2.2 Vertical Electrical Sounding (VES)

The Vertical Electrical Sounding (VES) method is one type of electrical sounding geophysical method. According to Simpen (2015), the geoelectric method is a method that studies the electrical flow properties within the earth and how to detect them from the earth's surface. The physical quantity sought is the specific resistivity of rocks due to the presence of potential fields and currents injected beneath the earth's surface. The measurable depth beneath the surface depends on the electrode spacing. The greater the electrode spacing, the deeper the measured depth. The configuration used in the Vertical Electrical Sounding (VES) geoelectric method is the Schlumberger configuration. This configuration uses four electrodes arranged as Figure 2.

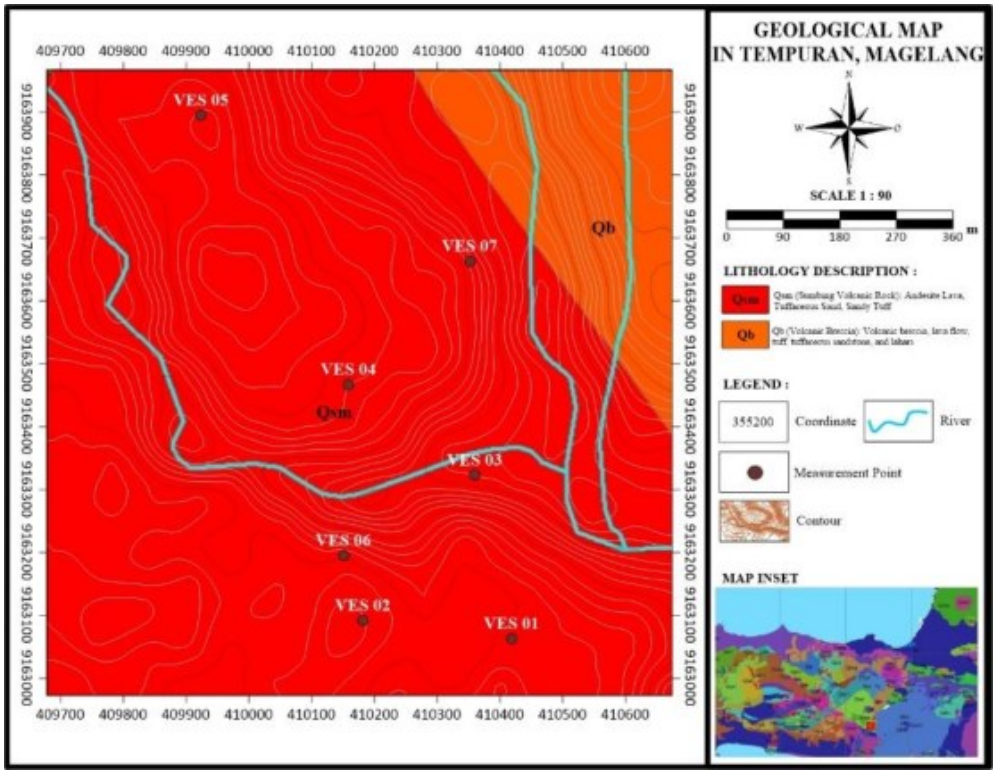

Figure 1: Geological Map of Magelang Regency (modified from Rahardjo, W. et al, 1995).

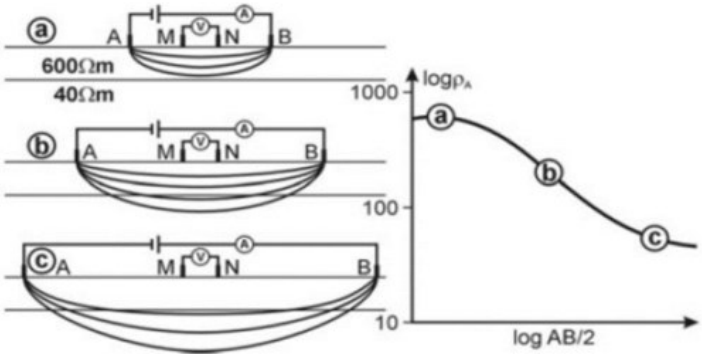

Figure 2: Schlumberger Configuration (Wardana, 2019).

2.3 Types of Aquifer

An aquifer is a subsurface layer capable of storing water due to its high porosity and permeability. Aquifers serve two important functions: as water storage and as water conduits. Each type of aquifer plays a distinct role in the hydrological cycle and water management. Based on lithology, aquifers can be classified into four types (Suharyadi, 1984) :

a. Unconfined aquifer, is an aquifer where the upper boundary is the water table and the lower boundary is confined. This type is also known as a shallow aquifer due to its maximum depth of about 15 meters.

b. Confined aquifer, is an aquifer located between impermeable layers, with pressure greater than atmospheric pressure.
c. Leakage aquifer, is an aquifer where the upper boundary is a semi-permeable layer and the lower boundary is impermeable.
d. Perched aquifer, is an aquifer where the groundwater mass is separated from the main groundwater mass by an impermeable layer and is located in a saturated zone. This type of aquifer is known for having limited water availability.

3. RESEARCH METHODOLOGY

In this hot spring aquifer identification research using the Vertical Electrical Sounding (VES) method, there are several steps in data acquisition and processing as shown in Figure 3a. The first step in conducting this research is to conduct data acquisition using a stretch in accordance with the target to be achieved. The data acquisition will produce primary data in the form of AB/2, MN/2, electric current value (A), and resistivity value (Ω). The data is then processed using Microsoft Excel and arranged in order and coherent so that the processing process is easier. Primary data that has been processed is then further processed by making resistivity profiles and lithology profiles to be given lithology symbols and lithology colors according to Agus Santoso (2013) rock resistivity table. After that, make a discussion of all the results of the lithology profile that has been produced.

Figure 3: Research Methodology, (a) Acquisition Map in The Research Area, (b) Flow Diagram.

4. RESULT AND DISCUSSION

4.1 Subsurface 1D Profiling

4.1.1 Subsurface Profile VES-01

In VES-01 sounding resistivity profile there are 5 layers with 3 kinds of lithology, namely soil with a resistivity range of 13.16 - 73.97 Ωm, sandstone with a resistivity range of 24.50 - 47.22 Ωm, and claystone with a resistivity range of 2.13 - 9.04 Ωm with a maximum depth of 240m. Processing of resistivity values based on inversion in Progress software has an error value of 9%. At this point, the presence of a hot water aquifer at a depth of 160 m can be identified because it can be seen in the lithology profile that the resistivity value of the lowest sandstone is at that depth. So it can be indicated that the VES-01 point is passed by the outflow of the geothermal system which originates from Mount Sumbing.

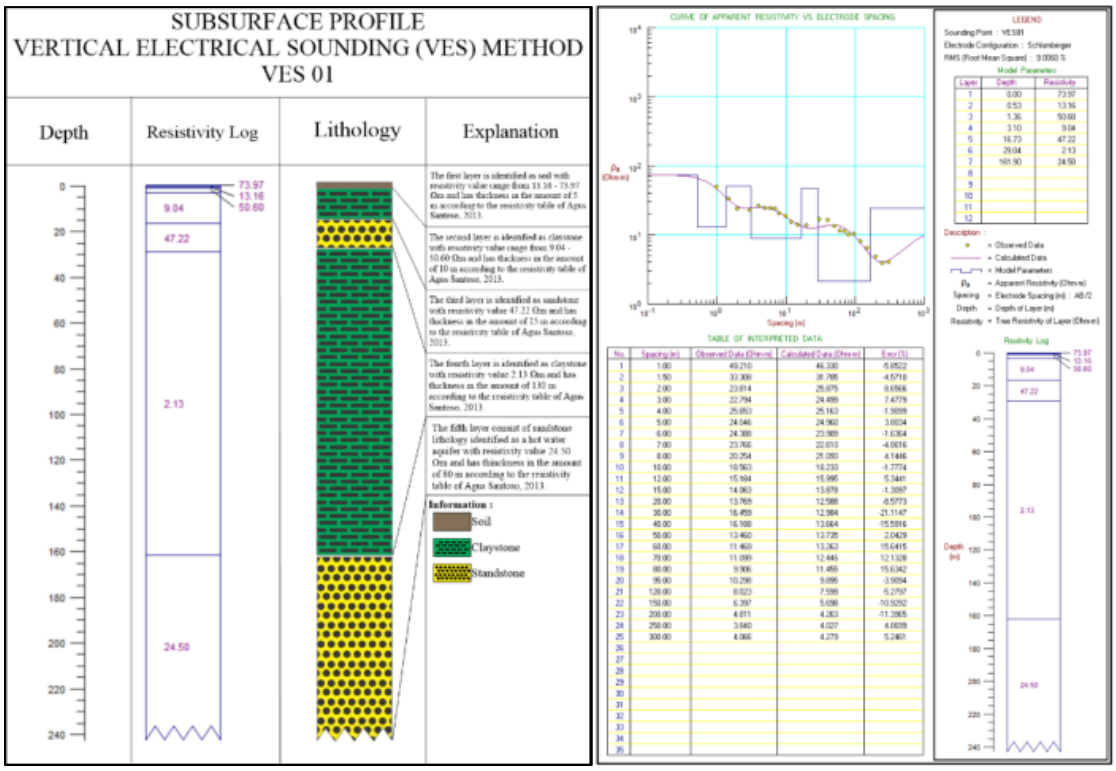

Figure 4: VES-01 Profile.

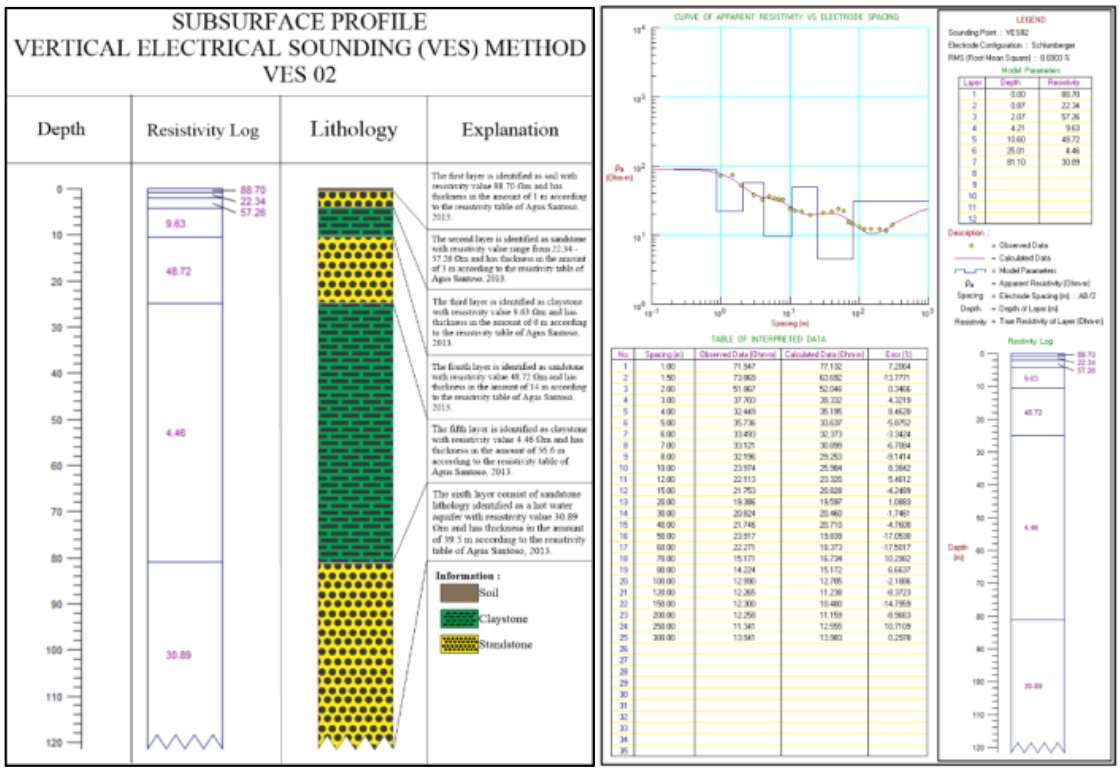

Figure 5: VES-02 Profile.

4.1.2 Subsurface Profile VES-02

In VES-02 sounding resistivity profile there are 6 layers with 3 kinds of lithology, namely soil with a resistivity of 88.70 Ωm, sandstone with a resistivity range of 22.34 - 48.72 Ωm, and claystone with a resistivity range of 4.46 - 9.63 Ωm with a maximum depth of 120m. Processing of resistivity values based on inversion in Progress software has an error value of 8.6903%. At this point, the presence of a hot water aquifer at a depth of 80 m can be identified because it can be seen in the lithology profile that the resistivity value of the lowest sandstone is at

that depth. So it can be indicated that the VES-02 point is passed by the outflow of the geothermal system originating from Mount Sumbing.

4.1.3 Subsurface Profile VES-03

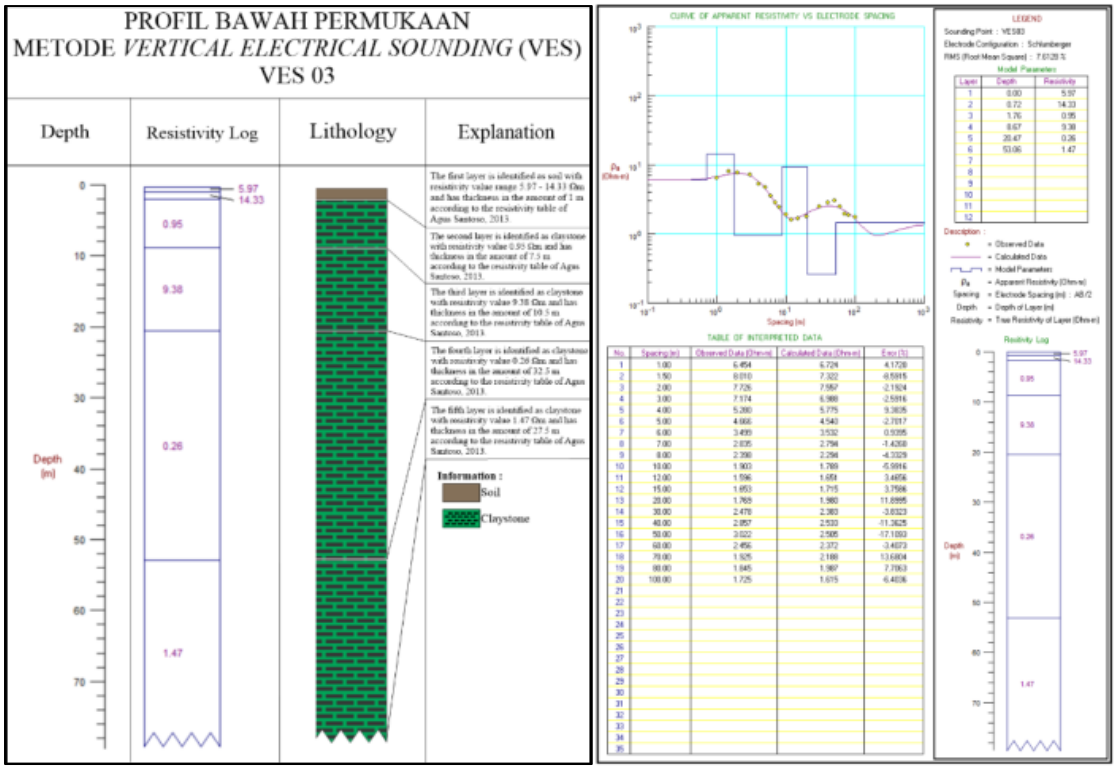

Figure 6: VES-03 Profile.

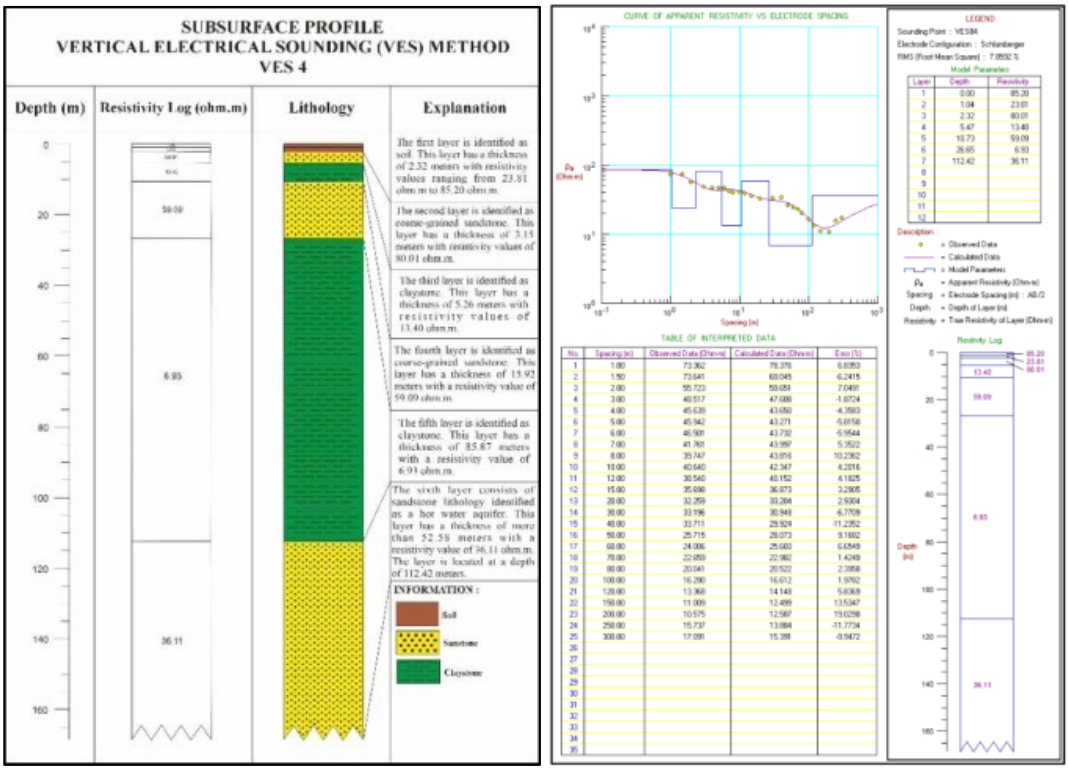

Figure 7: VES-04 Profile.

In VES-03 sounding resistivity profile there are 2 layers with 2 kinds of lithology, namely soil with a resistivity range of 5.97 - 14.33 Ωm, and mudstone with a resistivity range of 0.26 - 9.38 Ωm with a maximum depth of 80m. Processing of resistivity values based on inversion in Progress software has an error value of 7.6128%. At this point, the presence of a hot water aquifer cannot be identified because it can be seen in the lithological profile that the resistivity value of mudstone, which has very low permeability properties due to its very small pores and the cohesive nature of its particles, is usually not ideal as a flow medium for hot water aquifers. Therefore, it can be indicated that the VES-03 point is not passed by the outflow of the geothermal system originating from Mount Sumbing.

4.1.4 Subsurface Profile VES-04

In VES-04 sounding resistivity profile there are 6 layers with 3 types of lithology, namely soil with a resistivity range of 23.81 - 85.20 Ωm, sandstone with a resistivity range of 36.11 - 80.01 Ωm, and claystone with a resistivity range of 6.93 - 13.40 Ωm, with a maximum depth of up to 165 m . Processing resistivity values based on inversion in progress software has an error value of 7.85%. At this point it can be identified that there is a hot water aquifer at a depth of 112.42 m because it can be seen in the profile that the lowest resistivity value of the sandstone is at that depth. So it can be said that at the VES-04 point the Outflow from the Geothermal System which originates from Mount Sumbing passes through.

4.1.5 Subsurface Profile VES-05

In VES-05 sounding resistivity profile there are 6 layers with 3 types of lithology, namely soil with a resistivity range of 18.08 - 39.47 Ωm, sandstone with a resistivity range of 33.38 - 54.72 Ωm, and claystone with a resistivity range of 4.45 - 9.25 Ωm, with a maximum depth of up to 160 m. Processing resistivity values based on inversion in progress software has an error value of 12.94%. At this point it can be identified that there is a hot water aquifer at a depth of 107.41 m because it can be seen in the profile that the resistivity value of the sandstone is the lowest and is not shallow at that depth. So it can be said that at the VES-05 point the Outflow from the Geothermal System which originates from Mount Sumbing passes through.

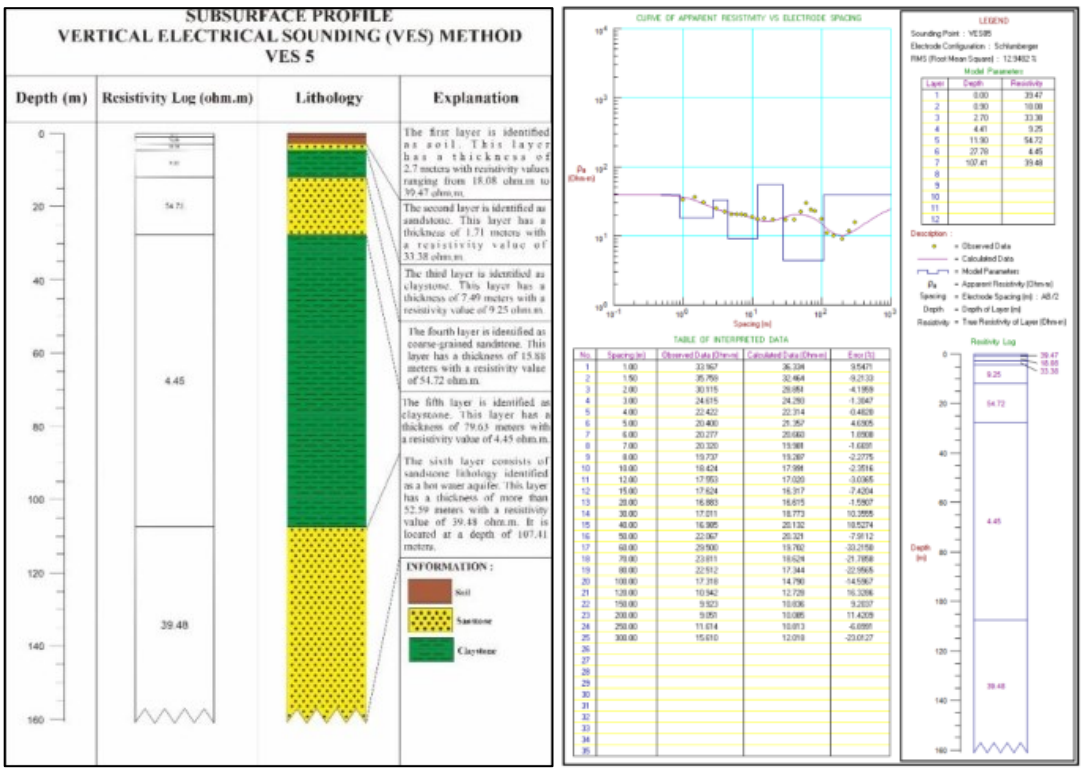

Figure 8: VES-05 Profile.

4.1.6 Subsurface Profile VES-06

In VES-06 sounding resistivity profile there are 6 layers with 3 types of lithology, namely soil with a resistivity range of 41.81 - 49.40 Ωm, sandstone with a resistivity range of 21.83 - 96.66 Ωm, and claystone with a resistivity range of 2.01 - 12.09 Ωm, with a maximum depth of up to 155 m. Processing resistivity values based on inversion in progress software has an error value of 7.59%. At this point it can not be identified that there is a hot water aquifer in this VES Point. So it can be said that at the VES-06 point it is not passed by the Outflow from the Geothermal System.

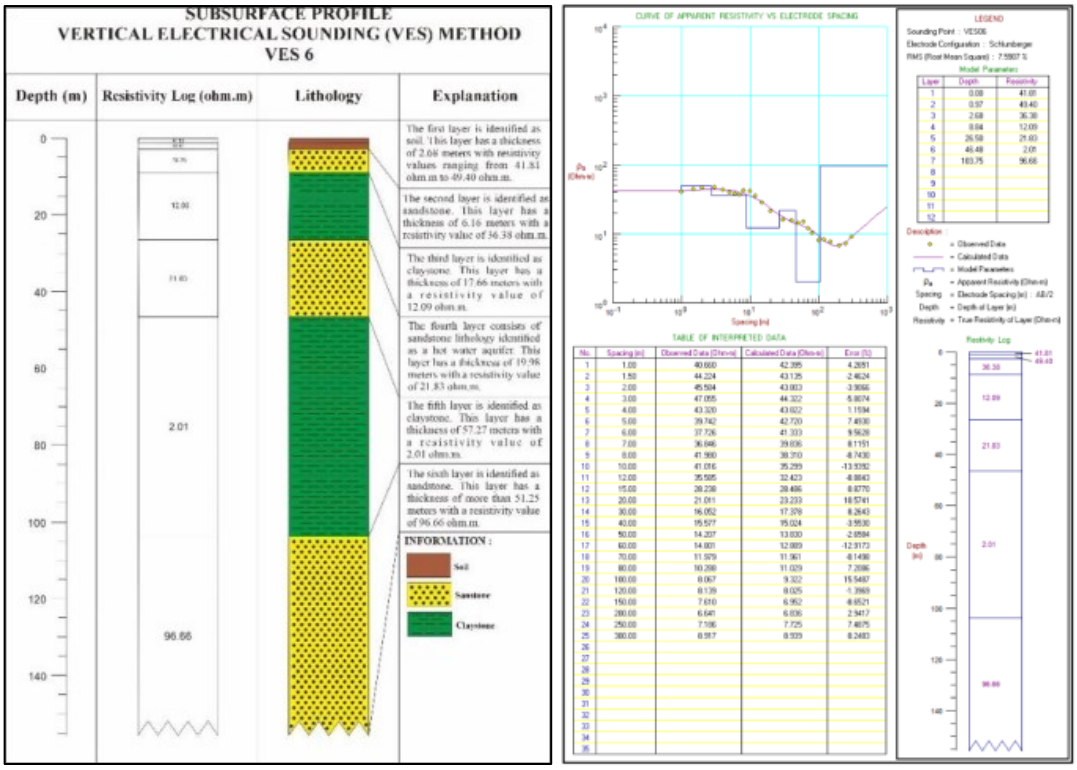

Figure 9: VES-06 Profile.

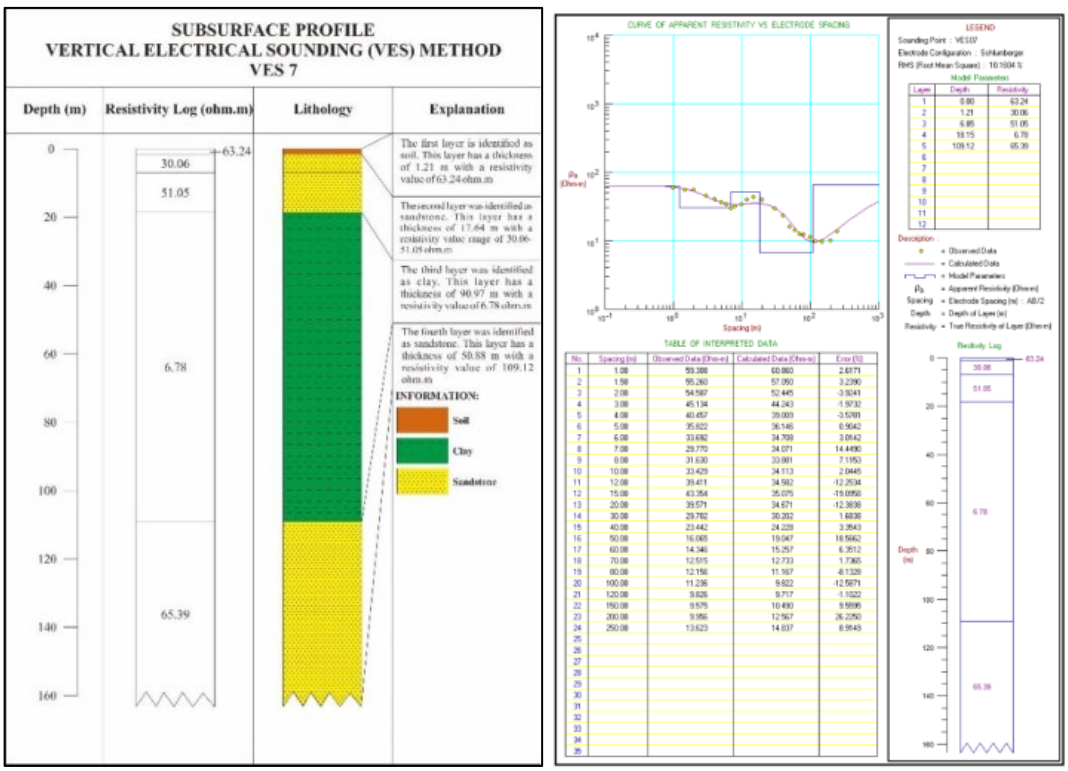

Figure 10: VES-07 Profile.

4.1.7 Subsurface Profile VES-07

In VES-07 resistivity sounding profile, there are 4 layers with 3 types of lithology, namely soil with a resistivity of 63.24 Ωm, sandstone with a resistivity range of 65.39-30.06 Ωm, and claystone with a resistivity of 6.78 Ωm, with a maximum depth of up to 160 m. The resistivity values were processed based on inversion using the Progress software, resulting in an error value of 10.16%. At this point, no hot water aquifer was identified at deeper depths because, as can be seen from the profile, the resistivity value of the sandstone appears high at a depth of 110 m,

indicating that there is no water contained in the pores of the sandstone. Therefore, it can be said that at the VES-07 point, the outflow from the geothermal system sourced from Mount Sumbing does not pass through.

4.2 VES Profile Correlation

Based on the correlation of line 1 and line 2, it can be said that the aquifer is at a depth of >110 meters with lithology in the form of sandstone. From the correlation above, it can be seen that the continuity of the outflow that fills the aquifer zone only passes through the measurement points of VES-01, VES-02, VES-04, and VES-05 with a range between acquisition points is ±500 meters. In line 1 all lithological layers are connected so that there are no missing layers, and in line 1 you can see the continuity of the aquifer zone in the last layer. In line 2 the lithology of the last layer based on data is still the same, namely sandstone, however in VES-07 and VES-06 there is no indication of water content because the resistivity value is quite high. It can be concluded that the outflow from Mount Sumbing is oriented from northwest to southeast.

4.3 Resistivity Map Each Elevation

Figure 12 shows the difference in resistivity values for each elevation difference. The resistivity value of the aquifer has a higher value range between 19 Ωm to 24.6 Ωm. It can be seen from Figure 12 that the elevations of 240 masl and 220 masl have high resistivity values in the western part, but the value gets smaller as the elevation decreases. However, at elevations of 200 masl and 180 masl, the northwest area shows higher resistivity values. The aquifer zone can be identified by its high resistivity value while still looking at its depth. Where this zone begins to appear at an elevation of 200 masl. While the elevation area above it is identified as a sandstone layer that does not contain aquifers.

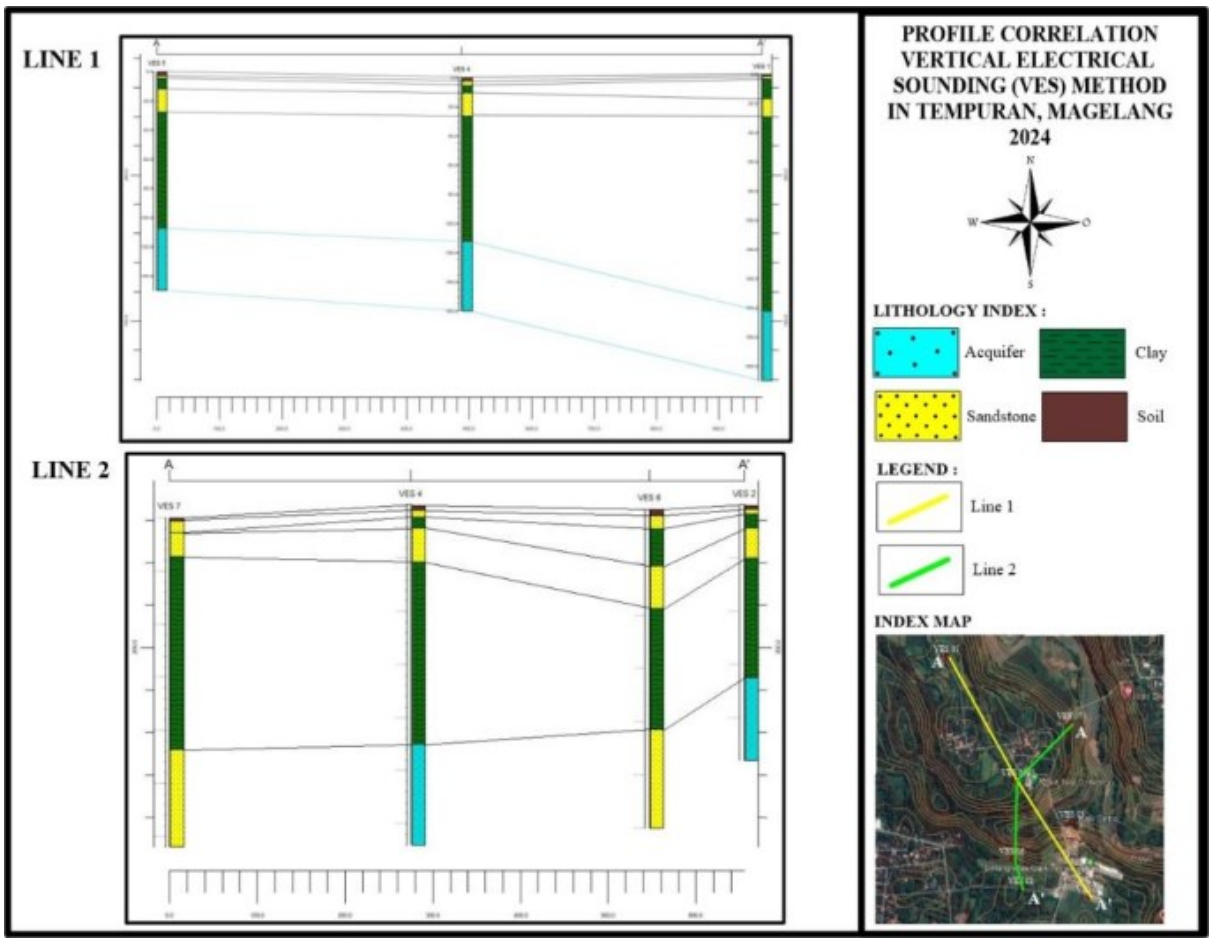

Figure 11: Profile Correlation Line 1 and Line 2.

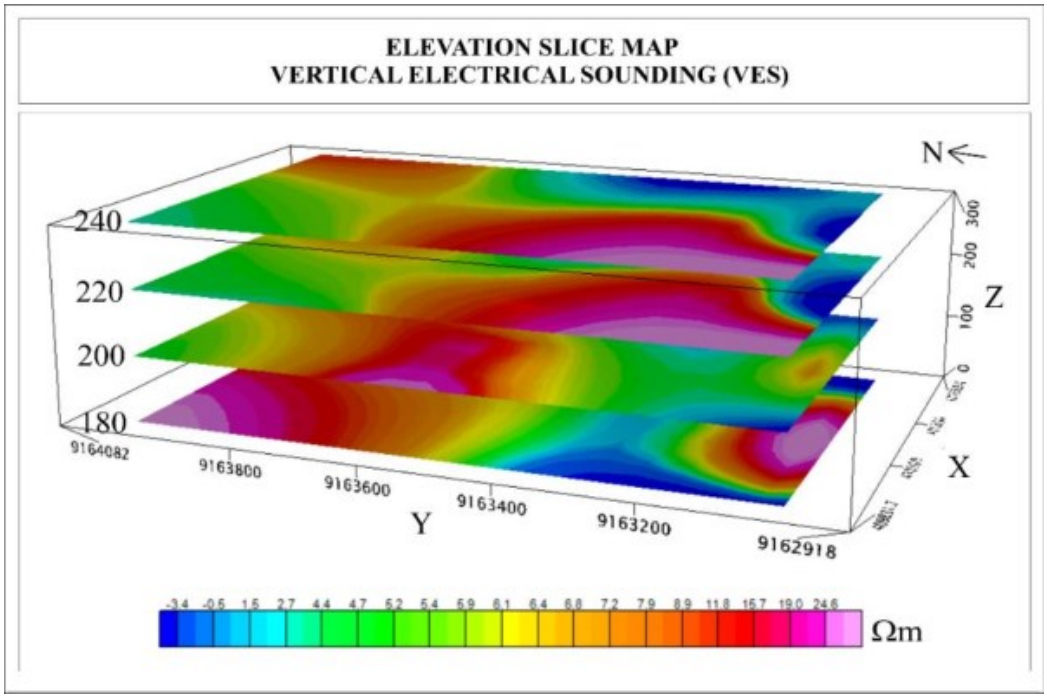

Figure 12: Resistivity Stack Map Elevation.

5. CONCLUSION

Based on the research that has been conducted, it shows that in the study area there is a layer of sandstone that is identified as an aquifer zone at a depth starting from 100 meters with average thickness of 44 meters. The existence of the aquifer zone is identified as arising from the outflow of the Geothermal System sourced from Mount Sumbing is oriented from northwest to southeast.

ABSTRACT

Star Energy Geothermal completed the make-up well drilling campaign in 2020-2021 to maintain steam supply for the existing power plants with a total installed capacity of 227 MWe at the Wayang Windu geothermal field. As a primary objective, based on the steam supply profile, 6 (six) production wells were required to be drilled in this campaign, three wells producing from the steam reservoir and three wells producing from the deep brine reservoir. This combination was necessary to maintain field pressure decline by balancing steam and liquid reservoirs production. Wells prepared in this campaign consist of one re-drill well, four new wells drilled from the existing pad, and one well from the new well pad. Based on historical data, drilling deep into the brine reservoir has been particularly challenging in Wayang Windu field. Several initiatives have been implemented to achieve the objective of this campaign, including lessons learned from previous drilling campaigns as part of continuous improvement. The initiatives in the subsurface area include refining well targeting assessment and detailing potential geological hazard identification, especially in the deep reservoir section. While in the drilling area, several initiatives were made, such as better well planning and improvement in drilling practice. As a result, the drilling campaign was completed with significant success: steam output above the target, successful drilling to the deep brine reservoir, and finishing the campaign with a faster and lower cost than the plan. Moreover, the success of this campaign in drilling deep brine wells has provided more information for the resource team to characterize better the deep brine reservoir for resource assessment to enable future field development and maximize Wayang Windu asset value.

1. INTRODUCTION

Wayang Windu geothermal field (Wayang Windu) is located at Pangalengan district, West Java Province, Indonesia. It lies within the high thermal flow region among other geothermal fields such as Kamojang, Darajat, and Patuha (Figure 1). Wayang Windu is operated by Star Energy Geothermal Wayang Windu Ltd. with a total installed capacity of 227 MW from two power plant units. The field has been running since the first power plant unit generation started in 2000 (110 MW), followed by the second unit in 2009 (117 MW). As part of the field management Star Energy has developed a continuous program to ensure sufficient steam supply to run the power plant at full capacity. The programs include well workovers/interventions and other initiatives such as make-up well drilling. The latter initiative is programmed and scheduled when the well capacity decreases towards minimum steam supply requirement.

From November 2020 to June 2021, Star Energy Geothermal conducted a make-up well drilling program in Wayang Windu. The main objective of this drilling campaign is to maintain the steam supply for the current generation by obtaining steam from both steam and brine reservoirs. The combination of steam and brine wells also aims to achieve optimum production between steam and brine reservoirs and prolong the steam cap reservoir performance.

One of the challenges in this drilling campaign is to drill the well down to the brine reservoir, which has a low historical success rate (less than 50% field-wide). Despite the challenges, this drilling campaign was successfully conducted with the total steam output above the target, completed with faster drilling days, and cheaper well costs. This paper discusses the subsurface and drilling aspect that plays an essential role in the success of this campaign.

2. WAYANG WINDU GEOTHERMAL RESERVOIR IN BRIEF

Wayang Windu is a two-phase liquid reservoir that is transitional from a vapor-dominated reservoir in the northern portion of the field to a more liquid-dominated reservoir in the southern part (Figure 2). Three upflows have been identified at Wayang Windu, lining up from the north to the south called Gambung, Wayang, and Windu upflows. These upflows represent different reservoir regions based on their temperature, pressure, and chemistry. However, the reservoir area is connected laterally and vertically between steam and brine, as confirmed by the tracer injection test across the field (Malik et al., 2020).

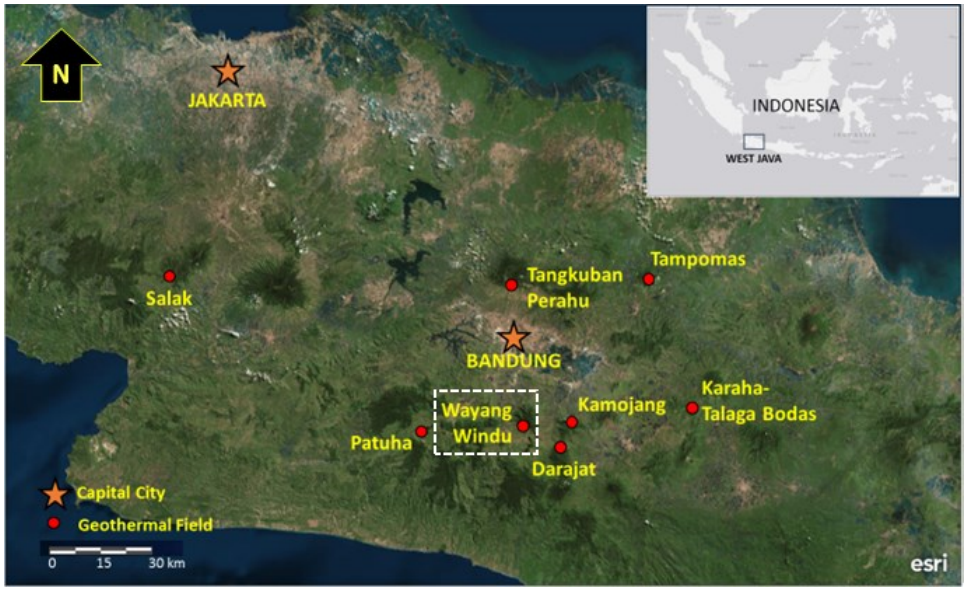

Figure 1: Location of Wayang Windu geothermal field (in the white rectangle) and other nearby high-temperature geothermal field in the West Java province, Indonesia.

The vapor reservoir/steam cap temperature is about 250-260 °C and about 280-290 °C in the liquid/brine reservoir. The steam cap in the northern area is relatively thicker compared to the central and southern parts of the field (Figure 3). The permeability of the steam reservoir in the northern area is also higher than in the other parts of the field, making commercial production in this area more favorable. Currently, about 90% of the steam production is coming from the steam cap in the northern area (MBA, MBB, MBD, MBE, and WWQ wells) and about 10% from the two-phase reservoir in the central area. The southernmost area of the field is currently the locations of the brine and condensate re-injection wells (WWF and WWW wells).

Most of the wells drilled in the northern area penetrated only the steam cap with no direct brine indication, and therefore no clear steam-brine contact can be observed. The steam-brine contact can be observed in the central area as most wells penetrate the brine reservoir. While in the southern part, because the wells are currently re-injection wells, no clear steam-brine contact can be observed (Figure 3, left). Due to the higher production rate of the northern steam cap, the pressure decline is higher in the steam reservoir, although it is still within a tolerable range (about 1 bar/year). On the other hand, the deep-seated liquid reservoir is relatively stable due to lower pressure drawdown (Mulyadi et al., 2023). To maintain pressure decline in the steam cap, one of the initiatives is to optimize the production between steam and brine reservoirs by producing more brine to create more steam from below.

3. WAYANG WINDU MAKE-UP WELL DRILLING 2020-2021

3.1. Well Selection and Targeting

Before the drilling campaign, well trajectory option/catalog that could be drilled in the existing production area (by new wells, sidetrack, re-drill, or deepening the existing wells) were listed and updated based on the latest drilling result. The well catalog was developed considering the subsurface target and surface facility condition (well pad). The list also considers multiple subsurface target options with various depth, azimuth, and inclination. For this campaign, the list is ranked based on the target area (i.e., reservoir temperature), permeability (i.e., potential steam production), potential subsurface risk (i.e., problematic formation issue, scaling, possible cooling/marginal recharge, and interference with the nearby well), potential drilling risk (i.e., well stuck), and surface facility consideration. In addition to the list, a new well pad (MBI) was also constructed for this campaign to extend the northern production area to avoid rapid production and interferences between the existing wells.

This campaign was programmed to provide steam for the full generation of Unit-1 and 2 power plants until 2023. With the current field decline rate and average well production, at least 5-6 wells would be required to meet the steam target of 122 kg/s. From the well catalog, several steam and brine wells at the top rank on the list were selected and assessed to get an optimum option with the highest total steam output while minimizing the drilling costs. Based on the evaluation, six wells (three targeted steam and three targeted brine) were selected for this campaign. The wells consist of one re-drill well from the MBD well pad, four new wells drilled from MBE and WWA well pads, and one from the new MBI well pad (Figure 2).

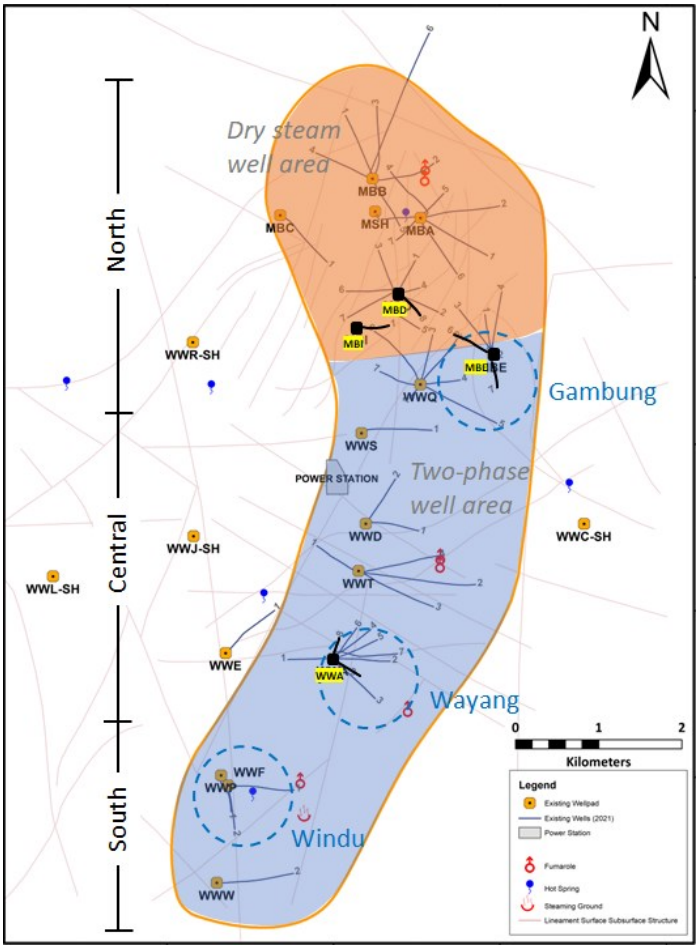

Figure 2: Map of Wayang Windu geothermal field with well courses, two-phase reservoir area, and upflows location (after Malik et al., 2020).

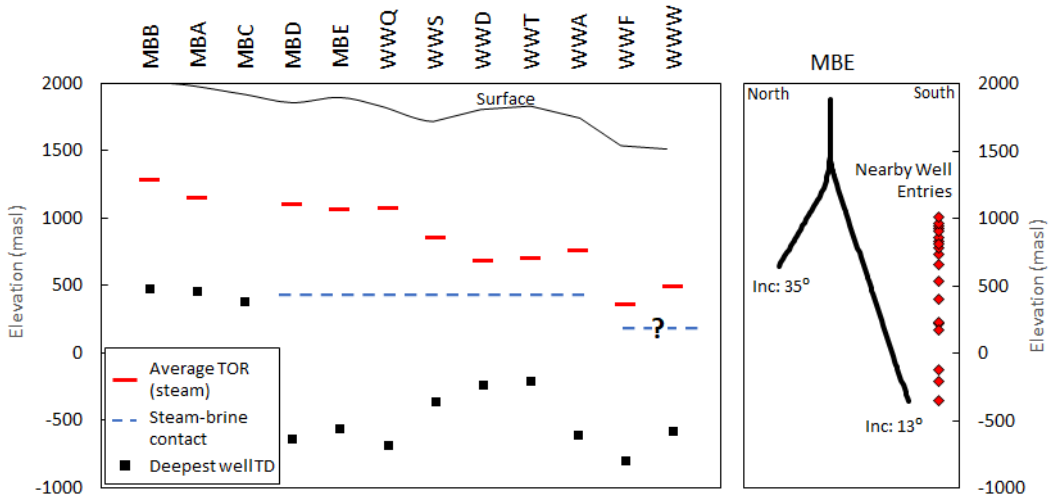

Figure 3: Left: a simplified N-S section of Wayang Windu geothermal field with average top of reservoir steam (TOR), steam-brine contact and deepest well TD at each well pad. Right: example of well trajectory in 2020-2021 drilling campaign for steam (left) and brine well target (right). See Figure 2 for well pad location.

Well trajectory of each well candidate was designed to penetrate either steam reservoir only or a steam and brine reservoir. The well targeting considers the optimum direction related to the strike of the open fractures and the depth of the productive zone based on the nearby wells. To minimize a potential higher risk of doing directional drilling in the reservoir section, a 2-D J-shaped well design was selected for all wells. The well design is

considered optimum as the target of productive zone can be achieved while maintaining the allowable distance with the nearby wells to avoid production interference. Figure 3 (right) shows the example of well trajectories prepared from the MBE well pad. One of the MBD well targets the steam reservoir with a 35º inclination to the northeast, while the other well targets the brine reservoir with a 13º inclination to the south. The average total depth for the steam well is 1,370 meters and for brine well is 2,100 meters measured depth (mMD).

The well targeting of the selected wells relied heavily on the nearby wells' information. It includes the location of the permeability target at both steam and brine reservoirs (well entries) and potential subsurface risk. In this campaign, a new and improved approach to calculate the steam output and the location of the well entries was applied carefully, especially for the well at the new well pad and the brine well, which have limited data.

In Wayang Windu, drilling the brine reservoir, especially in the central and northern areas, is challenging. In addition to the limited subsurface information in the deep brine reservoir, the drilling risk is historically high (less than 50% of the drilling success rate). One of the subsurface risks encountered when drilling the brine well is the limited information on the formation-related drilling difficulties like tuffaceous siltstone (TS). The TS is a reactive smectite-rich formation that could swell when exposed to the drilling fluid within ~48 hours and can lead to a stuck pipe (Putra et al., 2021). The TS is a common formation in volcanic regimes like in Wayang Windu that was originated from the volcanic ash which reacted with water to form clays and iron oxides. The thickness of this formation can vary, and its distribution can be identified based on the offset wells. Figure 4 shows the distribution of TS layers at WWA well pad based on the latest study conducted before this drilling campaign. At least nine layers of TS were observed in most wells at the WWA well pad. The TS occurs above and within the reservoir section and can lead to the stuck pipe under certain conditions.

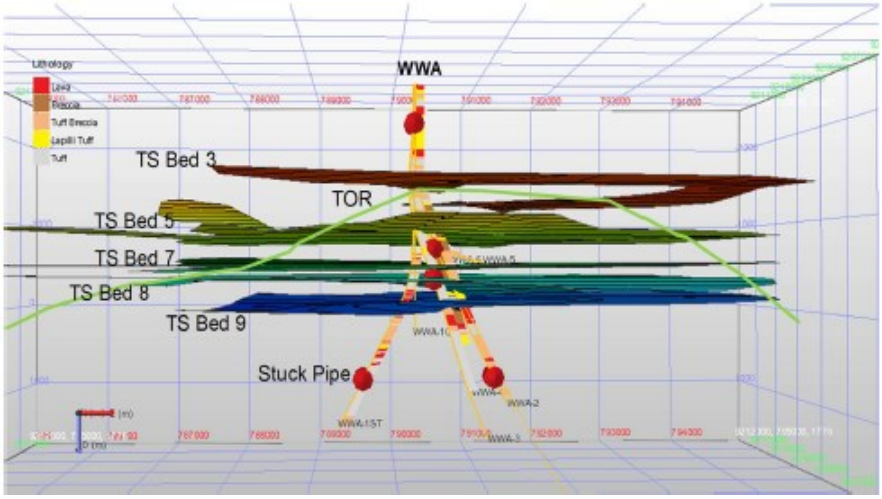

Figure 4: Distribution tuffaceous siltstone at WWA wellpad as part of the detail study (Star Energy, 2020).

3.2. Well Planning and Well Drilling

The drilling in Wayang Windu has improved over time, as reflected by the faster drilling, fewer stuck pipe events, and lower drilling cost (Putra et al., 2021). However, there is still some room for improvement that can be done to get better results, especially in the well planning and drilling practice.

An example of well planning is that an improved understanding of the behavior of the problematic formation, such as TS leads to a better selection of the drilling fluid. A better understanding of identifying clay mineral content using XRD analysis helps to design suitable drilling fluid based on formation needs. A behavior study of a similar formation in Salak (Ganefianto, 1994) shows that only a few drilling problems encountered above the reservoir are related to TS. In addition, using KCl as clay inhibitor below top of reservoir section was ineffective in inhibiting the swelling (Ganefianto, 1994). A thorough study was conducted to identify the stuck pipe mechanism that occurred in the reservoir section. The study concluded that drilling without clay inhibitors such as KCl is suitable to be used in Wayang Windu. It is because the presence of high Cl^- in drilling fluid coming from KCl is counter-effective since it can initiate the propagation of high illite-chlorite clay structure. In Wayang Windu, the drilling fluid without KCl has successfully mitigated the problematic formation in the reservoir section.

The predictive offset well monitoring and real-time drilling monitoring are implemented in this campaign as it effectively improves the drilling operation. The system's effectiveness has been identified since the previous drilling campaign (Putra et al., 2021); therefore, it is maintained as one of the best practices for this drilling campaign. Real-time drilling monitoring displays the data collected from the sensors at the rig site and then

transmitted lively and can be monitored by the field and office team 24 hours daily. One example of utilizing this system is predicting the well's entries/possible feed zones to enhance the rate of penetration (ROP) and cutting management to ensure well cleaning during the drilling (Figure 5). With this approach, in this drilling campaign, the ROP is improved from 120 m/day to 358 m/day in the reservoir section.

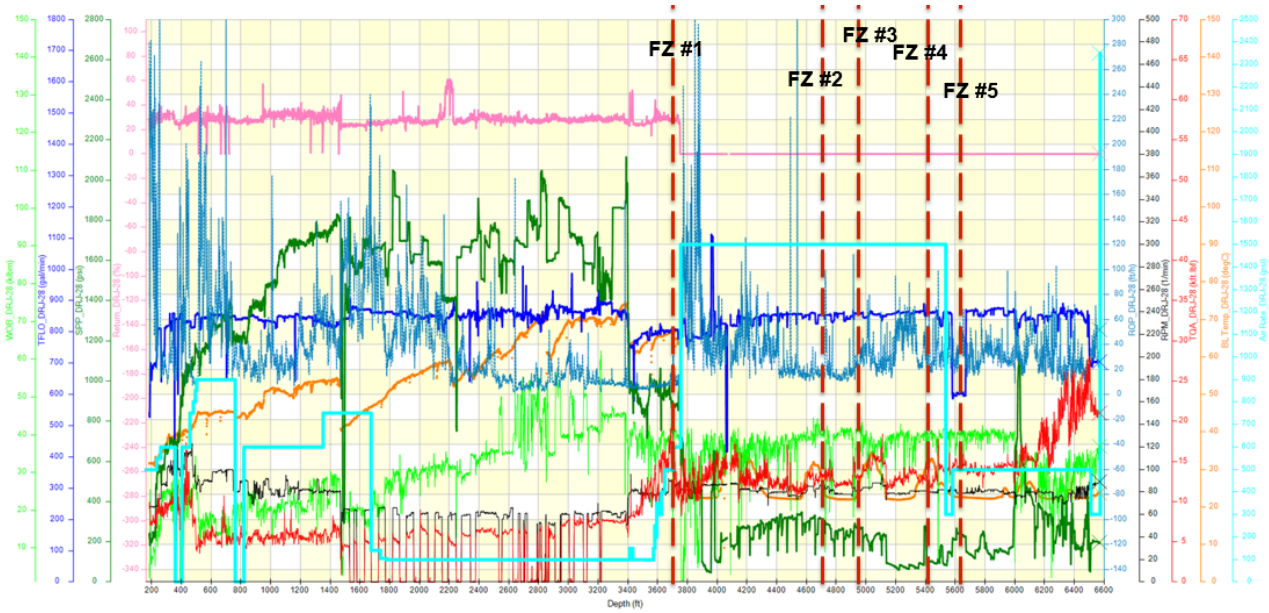

Figure 5: Example of the real-time drilling monitoring to predict entries/feedzone (FZ) to assist when to accelerate or when we have to hit the break.

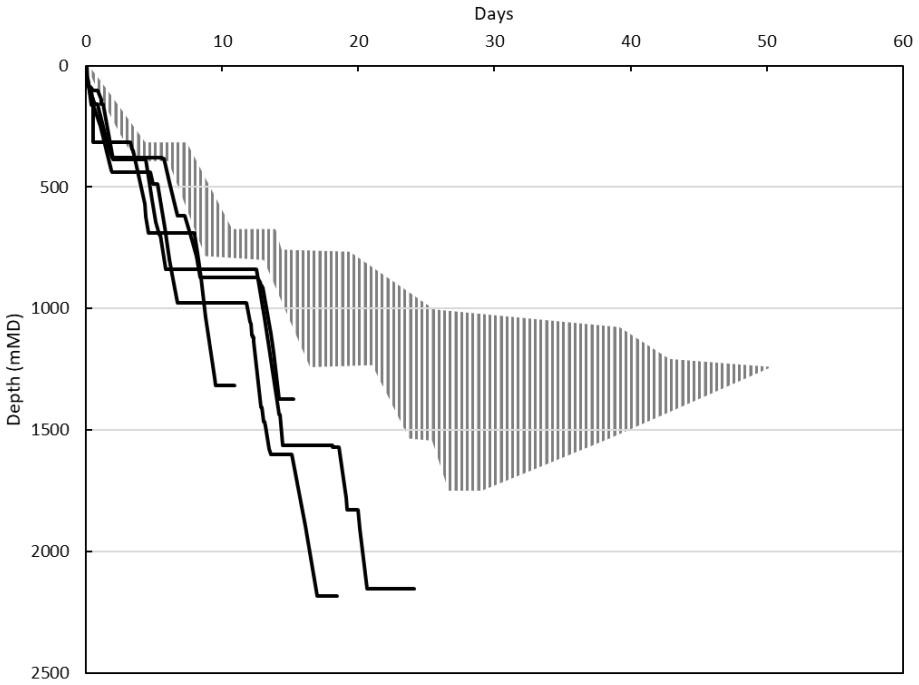

Figure 6: Time (days) vs. depth (meter measured depth) comparison of the MUW 2020-2021 (black lines) with the last drilling campaigns in Wayang Windu (shaded area).

3.3. Drilling Results

Six wells were drilled in this campaign, starting with the re-drill well in the MBD well pad, then two wells in the MBE well pad (one steam well and one brine well), two wells in the WWA well pad (two brine wells) and completed in the MBI new well pad (steam well). This sequence represents the drilling started from the well with the lowest drilling risk to the higher drilling risk, allowing the drilling to be improved over time. The total steam gained in this campaign is 131 kg/s (9 kg/s above the target), where four wells delivered the steam above the

expected target, and the other two were near and below the target. The actual location of the feed zones in the steam reservoir generally fits with the planned depth. In contrast, for the brine wells, the actual depth of the feed zones is offset for several targets, showing that the limited data in the brine well leads to high uncertainty. However, all the expected major feed zones from steam and brine reservoirs are obtained.

The total drilling days in this campaign is142 days (63 days faster than the plan), with most of the wells successfully drilled to the planned TD. Compared to the last drilling campaign, this campaign has improved significantly in terms of drilling days for each well and successfully drilled to the deep brine wells with an average well TD of 2,100 mMD (Figure 6). Moreover, the new well at MBI was successfully drilled to the planned TD at 1,308 mMD in 11 days, breaking the whole-time drilling record for the steam well in Wayang Windu. The average well cost in this campaign also decreased significantly to less than USD 3 million per well. The main contribution to the efficiency came from the faster drilling time and the elimination of the KCl in the drilling fluid.

The make-up well drilling in 2020-2021 is not only successfully providing steam supply for the current generation but also providing vital information for the future development of the Wayang Windu field. The successful drilling of the brine reservoir in MBE and WWA well pad has provided confidence in drilling in the brine wells, especially in the northern area. It is also found that commercial productivity appears in the brine reservoir and can sustain as indicated since the well started producing.

4. CONCLUSION

The 2020-2021 make-up well drilling in Wayang Windu was completed successfully, providing steam supply to the existing power generation. This success was the result of continuous improvement in the drilling campaign. The total steam production in this campaign is above the planned target, with faster drilling days. In addition, the success of this campaign in drilling deep brine wells has provided vital information for the resource team to characterize better the deep brine reservoir for resource assessment to enable future field development and maximize Wayang Windu asset value.

ACKNOWLEDGEMENT

The authors would like to thank the Asset Management team of PT Star Energy Geothermal and the management for their support and permission to publish this paper. Special acknowledgement to Rifqa A Wicaksono as the Project Manager of Wayang Windu 2020-2021 Make-up Well Drilling Campaign.

ABSTRACT

Paleosol, or ancient soil formed in the past and buried under more recent deposits, is commonly observed in volcanic environments, which often host geothermal systems worldwide. The presence of paleosol has been reported in several geothermal fields in Indonesia, such as Salak, Wayang Windu, and Sarulla. Paleosols developed in volcanic environments mainly consist of weathered volcanic materials, such as volcanic ash, cinder, and pumice. Soils derived from volcanic products are classified as Andosols. In Wayang Windu area, paleosol is well-known as Tuffaceous Siltstone (TS) material, predominantly composed of weathered tuff with a silt grain size. Physically, paleosol at Wayang Windu appears reddish-brown-grey and primarily consists of fine-grained tuff. The mineralogy of the paleosol mainly comprises smectite and/or mixed layers with illite or chlorite. Generally, it can be classified as either sticky or non-sticky (brittle).

Paleosol at Wayang Windu has been a significant concern due to its suspected correlation with stuck pipe incidents during drilling. There is a strong conjecture that the characteristic of the paleosol, which tends to swell upon contact with drilling fluid and has poor mechanical strength, is responsible for many stuck pipe incidents. Therefore, modeling the distribution of paleosol at Wayang Windu has critical implications.

The updated static model of Wayang Windu in 2023 was constructed based on formation distribution, enabling the modeling of paleosol distribution at the formation scale. Single well paleosol distribution analysis has revealed that paleosol deposition at Wayang Windu occurs in three types: continuous thin layers, single thin layers, and single thick layers. The distribution of paleosol within and beyond individual wellpads has been synthesized by incorporating each single well analysis with data from other wells within the same formation using 2D and 3D correlation and modeling techniques. The 2D correlation method has successfully differentiated at least three paleosol layers within each formation at Wayang Windu. Combining the results of 2D correlation with the 3D structural and static models makes it possible to interpret paleosol distribution beyond the existing wells. This distribution provides valuable information for identifying potential subsurface hazards related to paleosol distribution (stuck pipe incidents) during well planning activities.

1. INTRODUCTION

The Wayang Windu Field is geographically located in the Pangalengan district, about 40 km South of Bandung, the capital city of West Java Province, and about 150 km southeast of Jakarta, the capital city of Indonesia. Wayang Windu is a two-phase geothermal field with an electricity generating capacity of 230.5 MW. This field is surrounded by several high-terrain geothermal systems such as the Darajat, Kamojang, Patuha, and Karaha-Talaga Bodas fields (Figure 1).

The volcanological setting shows that Wayang Windu lies on the southern slopes of a large andesitic stratovolcano called Mt. Malabar, along with a series of smaller volcanoes trending southward, including Mt. Wayang and Mt. Windu. This setting permits paleosol development across the Wayang Windu field. Paleosol in Wayang Windu, mostly known as the Tuffaceous Siltstone (TS) layer, consists of fine-grained tuff with a reddish-brown and grey color, high smectite content (either as smectite layer or mixed layer smectite) and is categorized into two types: sticky and non-sticky (brittle) material.

The impact of paleosol on drilling activity has been under special investigation since the beginning of Wayang Windu development. The initial exploration stage, undertaken by PERTAMINA, drilled the discovery well of the Wayang Windu field in 1991. The first paleosol study was conducted internally in 1997 with Kingston Morrison, which aimed to establish the cause of the instability of the paleosol, suspected to be a problematic formation causing drilling problems at Wayang Windu (Kingston Morrison, 1997). In 2019, an update on the paleosol (tuffaceous siltstone) study was conducted as part of drilling lookback to better understand the impact of the paleosol (TS) to the drilling problem in order to increase the probability of success (POS) to drill deep brine

reservoir in WW (Earth Science AM WW, 2019), The objective of the study was to update the paleosol characterization based on physical appearance, mineral composition, distribution, and its correlation with the drilling problems (i.e. stuck pipe incident). Paleosol distribution was initiated based on bed correlation referring to the 1997 paleosol study under pad basis. The assessment in Wayang Windu in 2019 concluded that 20% of the stuck pipe incidents in central Wayang Windu correlated with paleosol existence, while in the north Wayang Windu area, 30% of the stuck pipe incidents were related to paleosol. Hence, modeling the distribution of paleosol at Wayang Windu has critical implications for the success of the next make-up well drilling campaign.

Figure 1: The location map shows the geographical location of Wayang Windu and its relative position to the surrounding geothermal fields.

In 2023, Wayang Windu updated the static model by incorporating the petrophysical group and paleosol layer to define formation distribution. The use of the paleosol layer as a marker is based on the recommendation of the 1997 paleosol study, which concluded that at least five beds of paleosol have extensive occurrence and distribution in the north of Wayang Windu. Thus, it is useful to use the paleosol as a marker horizon. The update of the static model identified eleven formations spread across the Wayang Windu area (Purnomo et al., 2023). The established 2D and 3D distribution of the formations improved the understanding of their spatial distribution in Wayang Windu. Therefore, this paper discusses the utilization of formation distribution by incorporating detailed paleosol categorization to define the paleosol distribution in Wayang Windu. By having detailed distribution in 2D and 3D, a more accurate paleosol distribution model can be acquired, aiding in identifying the paleosol zone during drilling and defining mitigation strategies when encountering this zone.

2. PALEOSOL CHARACTERIZATION

Two major descriptions of paleosol are accepted today, related to two branches of geoscience: soil science and geology. In soil science, paleosol refers to a soil layer that formed a long time ago and has a different chemical and physical composition compared to the recent soil layer, which is controlled by present-day climate or vegetation. In geology, particularly paleontology, paleosol refers to ancient soil that is preserved due to being buried by other sediments or volcanic deposits. These sediments might consist of alluvium or loess, while volcanic deposits can include lava from lava flows or pyroclastic material such as volcanic ash deposits. Paleosol formed in volcanic environments is categorized as Andosols (or Andisols in some publications; this paper will use Andosols). The common concept of Andosols is that they are paleosols derived from loose volcanic ejecta such as volcanic ash, cinders, and pumice. Another source of the materials forming Andosols might be other explosively erupted, fragmental volcanic material (tephra) and volcaniclastic or reworked volcanic materials (McDaniel et al., 2012).

Paleosol in Wayang Windu, known as the Tuffaceous Siltstone (TS) layer, can be distinguished into four categories based on physical appearance (megascopic) identified at the drilling site as follows: a) Reddish brown sticky clay, b) Grey sticky clay, c) Reddish brown non-sticky/brittle, and d) Grey non-sticky/brittle as seen in the Figure 2 (Earth Science AM WW, 2019). To further understanding its composition, the TS is also defined based on laboratory analysis results of samples using petrography, XRD, and SEM-EDAX. In the case of blind drilling and no cutting return from the wellbore, potential TS presence can still be identified by involving borehole image (BHI) analysis. A combination of physical and laboratory characterization of TS shows characteristics of reddish-brown and grey, very fine-grained tuff with high smectite content (Ca-smectite with more than 80% smectite in the form of interlayered Illite-Smectite). The origin of TS in Wayang Windu is concluded to be derived from

volcanic ash (unconsolidated, easily reworked and filled the lake) that reacted with water to form clays and iron oxides. Relating to the geothermal system in Wayang Windu, the TS is not in equilibrium with the Wayang Windu hydrothermal system (mineralogy composition indicates a temperature of less than 170°C, while the measured temperature is almost 200°C).

The distribution of paleosol in Wayang Windu is mostly observed interlayered with other pyroclastic rocks, and minorly with volcanogenic sandstone or conglomerates. The paleosol study in 1997 suggested that paleosol is divided into 13 layers (from 17 wells), with the depths of the top and thicknesses of TS beds based on the continuous core data obtained from four slim holes. Five beds have extensive occurrences, with bed 8 (450-330 masl) being the most widespread, extending to the NE and the most useful as a marker horizon. The study also concluded that variation in elevation could be due to variation in paleo topography at the time of deposition combined with the subsequent structural modification. The study in 2019 examined Methylene Blue (MeB), XRD and physical appearance under microscope to analyze the characteristic of paleosols, where indicating that the majority of the sticky paleosol was encountered above the reservoir section, while in the reservoir, most paleosols are not sticky and brittle. The additional data from the 2019 study are more distributed to the north and infield, and generally, the number of TS encountered in the reservoir section is greater than above the reservoir, where it is absent toward MBB pads (Figure 3).

The relationship between paleosol existence and drilling problems in Wayang Windu is mostly due to the reaction of the paleosol with the drilling fluid. On a mineralogical scale, the Ca-smectite which abundant in paleosol, will swell when in contact with water, causing swelling in paleosol. This causes the rock to have very poor mechanical strength. A study in 1997 observed that swelling is also affected by temperature and salinity, being strongest at low temperatures (<100°C) and low salinity. When in contact with Na/Ca rich solution, Na will exchange with Ca to form Na-smectite and increase the volume. The initial grace period before paleosol collapses into the hole is around 48 hours. When sudden massive losses of circulation are encountered, severe collapse of paleosol can occur due to the reduction of confinement pressure. In such instances, extensive reaming and tripping have rarely improved the hole condition sufficiently. The study in 2019 also concluded that, in correlation to drilling problems, paleosol at Wayang Windu can easily swell when in contact with water/drilling fluid and has very poor mechanical strength (easily sloughing as a respond to the reduction of hydrostatic pressure due to total loss circulation). The study also observed that the majority of drilling problems associated with paleosol occurred in the reservoir hole section.

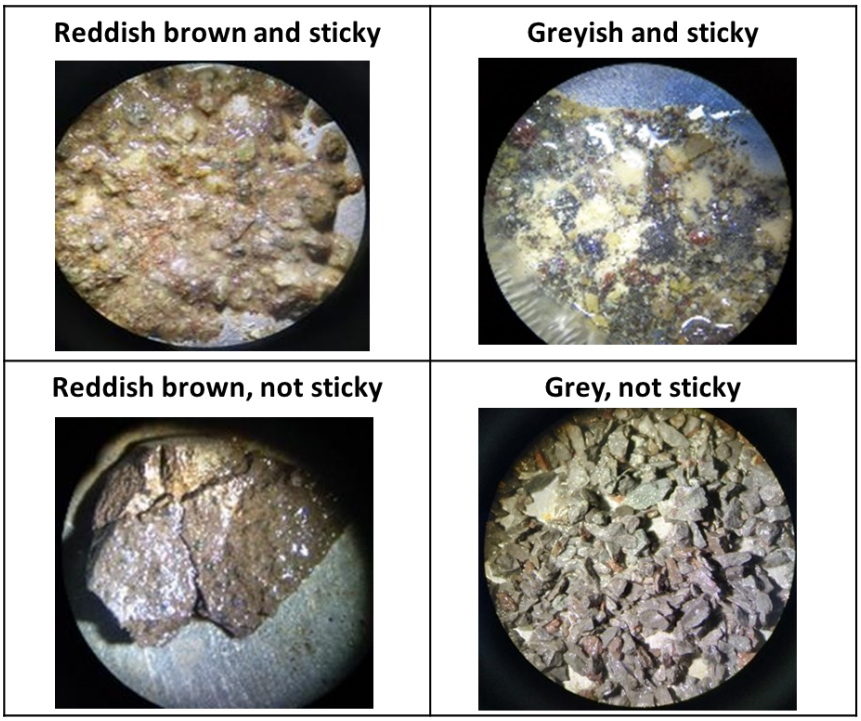

Figure 2: The megascopic view of paleosol in Wayang Windu based on early drilling observations. There are four groups based on the color and physical characteristics of the paleosol (sticky or not sticky).

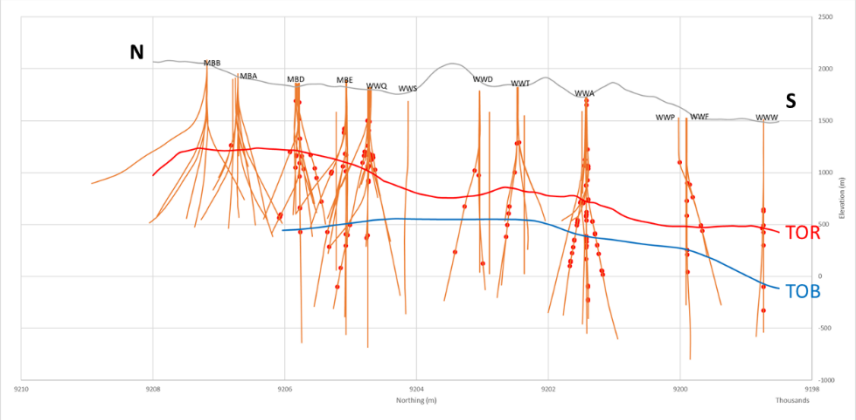

Figure 3: The location of paleosol in Wayang Windu's well (red dot in the well trajectory). It shows that the paleosol is mostly observed in the reservoir section (below TOR) and is getting absent toward the MBB pad in the north.

3. PALEOSOL DISTRIBUTION BASED ON STATIC MODEL

Several initiatives have been conducted at Wayang Windu as part of updating the static model. One major initiative correlated with paleosol distribution is formation profiling. Formation profiling in Wayang Windu is based on grouping PGs in the well by composition (in %), where the differences between each formation are based on distinct differences in PG composition (in %), compared to the above or below PG groups (Purnomo et al., 2023). Some formation profiles have markers that are easy to distinguish (e.g., conglomerate and basaltic andesite lava in Pangalengan formation, dacite lava in Gambung-B formation and Young Wayang formation); however, some formation profiles do not. Hence, formation profiling includes paleosol analysis to help define petrophysical group distribution (Boogie and McKenzie, 1986 and Purnomo et al., 2003).

The basis of the paleosol analysis in helping define the formation profiling is that the paleosol layer present between formation profiles acts as a formation depositional break marker (paleosol develops when the volcanic depositional process is stopped and taken over by the weathering-erosion process). According to the origin of the paleosol, two processes might produce paleosol represented by illitization types. The two major types of illitization in paleosol are pedogenic and diagenetic processes. Pedogenic illitization is associated with the formation of soil on the earth's surface, while diagenetic illitization is associated with compaction after deposition, involving factors such as water-rock reaction and microbial activity. Therefore, the paleosol containing illite from pedogenic illitization represents paleosol as a depositional break marker (soil formed during a volcanic depositional break on the earth's surface) (Purnomo et al., 2023).

Three TS samples have undergone special analysis to define the correlation of their illitization process with the type of depositional process they represent. The TS samples were collected from clear sections that represent boundaries of formation deposition. TS-1 was taken from the boundary between the Gambung-A and Puncak Besar formations, where there is no age deposition gap. TS-2 and TS-3 were collected from formation boundaries that have age deposition gaps, specifically between Young Wayang and Old Wayang formations, and Young Wayang and Pangalengan formations, respectively. According to the diagenetic and pedogenic characteristics explained by Purnomo et al. (2023), TS-1 does not exhibit pedogenic characteristics compared to TS-2 and TS-3. This conclusion aligns with the depositional relations of TS-1, TS-2, and TS-3, where TS-1 indicates diagenetic processes, while TS-2 and TS-3 show pedogenic characteristics. This analysis provides evidence that the formation profiling in Wayang Windu is valid, as demonstrated by the characteristics of the paleosol (TS) layers in Wayang Windu. Moreover, the paleosol layers in Wayang Windu show significant evidence of being markers that define formation depositional breaks.

The positive correlation between the type of paleosol layer and the distribution of formations in Wayang Windu allows for further analysis by combining paleosol and formation distribution data. To gain a good understanding of the paleosol layer deposition in the wells, single well analysis is conducted to categorize the type of paleosol in each well in Wayang Windu. This categorization is based on the location of the paleosol layer relative to the unique distribution of several petrophysical groups (PG). The single well analysis identified the pattern of paleosol distribution in each well, which can be divided into three groups: continuous thin paleosol layers, single thin paleosol layers, and single thick paleosol layers (Figure 4). The continuous thin paleosol layers are well observed when the paleosol exists within the thick PG distribution. The single thin and thick paleosol layers might exist within a single PG or between two different PGs.

To map the distribution of paleosol beyond individual wells, 2D and 3D correlations are conducted. The 2D correlation is developed prior to the 3D correlation to refine the category of each paleosol in each well by observing the consistency of the relationship between specific groups of paleosol deposition patterns and unique PG distributions across the wells. The correlation is conducted within the same formation, where the paleosol layers within the same formation are likely deposited during the same age and represent a continuous deposition regime. This effort helps detail the depositional sequence of several groups of paleosol layers, with the 2D correlation successfully defining up to three paleosol layers for each formation in Wayang Windu. Some discontinuities in deposition are observed, which, based on paleosol studies from 1997, might represent a combination of variations in paleo topography at the time of deposition and subsequent structural modifications. These discontinuities will be useful for the 3D correlation to determine whether they are controlled by paleo topography or structural geology. Additionally, the 2D correlation allows for the possibility of subdividing formations based on unique PG distributions and existing paleosol groups, enhancing the understanding of depositional sequences in Wayang Windu.

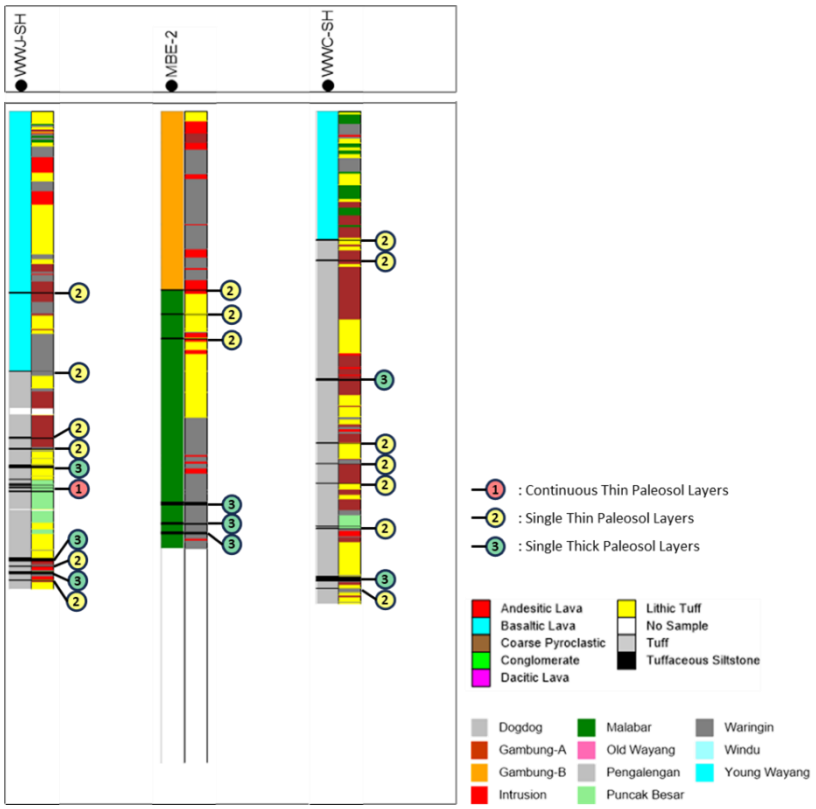

Figure 4: Example of the application of paleosol single well analysis to determine the group of paleosol layers within the well. The continuous thin paleosol layers group is usually clearly observed in the thick PG deposition, while the single thin and thick paleosol layers might be observed in a single PG or exist between different PGs.

An example of 2D correlation constructed in the North of Wayang Windu, from wellpad WWR to MBE (West to East), is applied in the Puncak Besar Formation (Figure 5). This correlation suggests that the Puncak Besar Formation might be divided into three sub-formations: Puncak Besar-1 (PB1), Puncak Besar-2 (PB2), and Puncak Besar-3 (PB3). The determination of the sub-formations refers to a combination of paleosol layers and unique PGs, as not all the complete sequences of paleosol layers are observed in the wells. This is due to geologic factors such as structure and depositional heterogeneity or data availability issues like lost zones.

In the Puncak Besar Formation, four groups of paleosol layers are observed, namely paleosol D, D.1, D.2, and D.3. The determination of the paleosol follows the single well analysis. For example, paleosol D is a single thick paleosol layer found in thick lithic tuff at the shallow elevation of the Puncak Besar Formation. Another example is paleosol D.1, observed in the middle of thick coarse pyroclastic with a lava layer in between. This paleosol layer is observed at the middle elevation of the Puncak Besar Formation. The relation of each paleosol layer is also concluded from the single well analysis, showing that paleosol D is the shallowest one, deposited above D.1 in WWQ-2 and D.3 in MBC-1ST2. Paleosol D.1 is found above D.2 in MBI-1, and D-3 is observed below D.2 in MBE-3. An additional paleosol layer, D.a, is observed above D as indicated in MBB-1 and MBE-3 (?).

By adding the unique PG, the sub-formation PB1 is deduced from the existence of thick lithic tuff upwards in the shallow part of the Puncak Besar Formation, which is associated with paleosol D. There is a possibility of paleosol D.a being observed above paleosol D. The distribution of PB1 is observed between MBC-1ST2 and MBB-1 (eastward) and is discontinued in the middle of the correlation line. PB1 is observed again in the eastern part from WWQ-2, thickening towards MBE-4. PB2 is in the middle of the Puncak Besar Formation, dominated by coarse pyroclastic-lava and related to paleosol D.1 and D.2. PB2 is observed continuously from West to East, with the western part (WWR-SH) exposed near the surface. PB2 has a unique relationship with paleosol layers, as the paleosol layer is not observed from the west (WWR-SH) to the center of the correlation line (MBD-6). However, PB2 in MBI-1, WWQ-2, and MBE-3 is clearly associated with paleosol D.1 and D.2. This discontinuity is interesting, as it occurs within the same sub-formation, creating an area of Puncak Besar Formation free of paleosol layers between MBB-1 and MBI-1. PB3 is observed at the deeper part of the Puncak Besar Formation, at the bottom of MBC-1ST2 and MBE-3 (?), associated with thick lithic tuff and paleosol D.3.

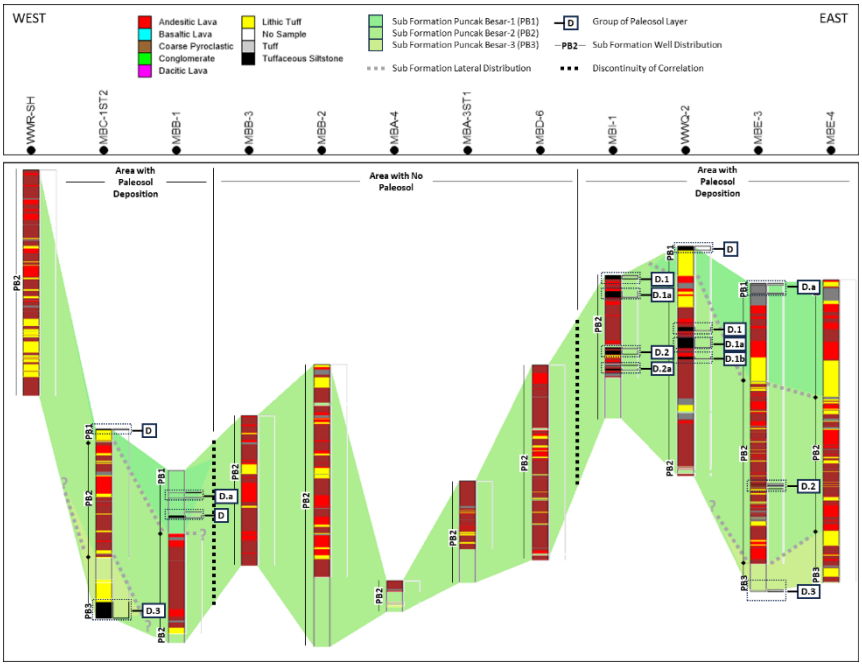

Figure 5: The application of 2D correlation of paleosol layers in the North of Wayang Windu. The correlation suggests two discontinuities: the first is the PB1 discontinuity in the west to the center of the correlation line. The second is the paleosol discontinuity in PB2, which creates an area with no paleosol in Puncak Besar Formation in wellpads MBB-MBA-MBD.

Following the construction of the 2D correlation, the 3D correlation is developed. The 3D correlation considers either paleo topography or structural impact on the paleosol deposition to explain the discontinuities observed in the 2D correlation. Additionally, the trajectory plot showing the actual direction of trajectory might add supplemental insight regarding the distribution of paleosol layers in a well and their relationship with paleo topography and structural setting. The information gathered in the 2D correlation has been plotted into the faulted 3D static model, which already incorporates a 3D structure model and shows its structural impact on the development of formations in Wayang Windu (Figure 6). By observing the correlation between the area of paleosol layer distribution from the 2D correlation and the structure, it can be concluded that area ① and ② is divided by the Kawah Burung fault, while area ② and ③ are divided by the Cibitung fault.

Focusing on area ①, it is concluded that paleosol layers D and D.a represent the boundary between the Puncak Besar Formation and the Gambung-A Formation. A gap between paleosol layers, from D to D.3, is observed in well MBC-1ST2. This well intersects the Kawah Burung fault at a deeper depth and has a relatively low inclination, with the fault showing upward movement at the bottom of the well. As a result, paleosol layer D.1 and D.2 are missing, and paleosol D.3 is found at nearly the same elevation. Following this logic, in area ②, paleosol layers D.2, D.1, and D might be present above paleosol D.3. This issue will be further discussed in the explanation of area ②.

Area ② is an interesting part for discussion due to the absence of paleosol in this area. Only paleosol D.3 is observed in area ②. Paleosol D.3 might be related to the boundary of the Puncak Besar Formation and the Malabar Formation underneath it. Relating to the nature of the Kawah Burung Fault, paleosol D.3 might have been uplifted to the recent depth. According to the same logic, another paleosol layer should be observed above paleosol D.3 in

wells drilled in area ②, but in fact, none are found. An interpretation to explain the absence of paleosol layers is related to the deposition of the Gambung-A Formation above the Puncak Besar Formation in this area. The paleosol layers D.2, D.1, and D might have existed in the shallowest part of this area, but as this area acts as the deposition basin of the Gambung-A Formation, those paleosol layers were destroyed when the paleo topography of the Gambung-A Formation was formed, leaving only paleosol layer D.3 undisturbed.

Area ③ is also a very interesting topic. In this area, a complete sequence of paleosol layers is observed (from paleosol D.a to D.3). Paleosol D and D.a are related to the boundary of the Puncak Besar Formation and the Gambung B formation. Paleosol D.1 is also observed as the boundary of the Puncak Besar Formation and the Gambung-A Formation, instead of D and D.a. This might be result of the same process that caused the absence of the paleosol layer in area ②. The striking fact is the incomparable depth of paleosol D and D.a in this area compared to area ①. According to the geometry of the Puncak Besar Formation deposition and assuming that the paleosol in the Puncak Besar Formation is continuously deposited, an uplifting process pushed up the Puncak Besar Formation in this area, creating a significant gap in paleosol depth between area ① and this area. The existence of the Malabar Horst Structure, a regional structural object, might explain this condition, as the development process of this structure corresponds to the observed paleosol distribution in this area.

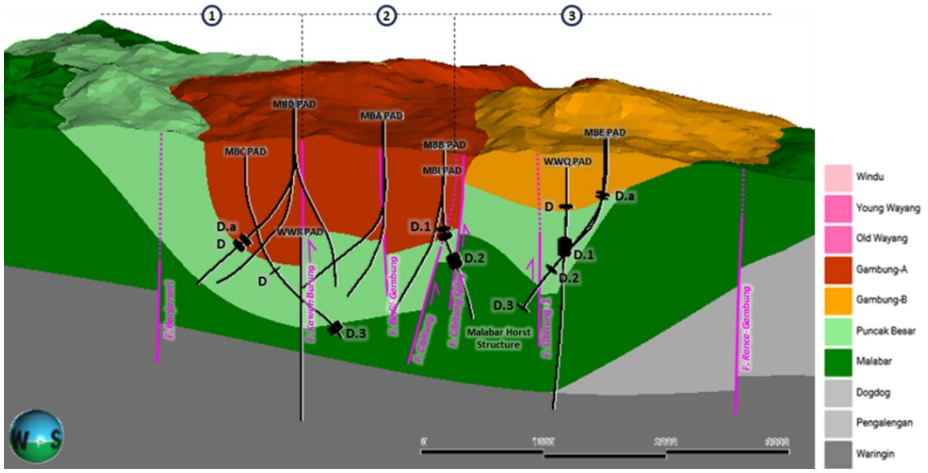

Figure 6: The application of 3D correlation of paleosol layers in the North of Wayang Windu extends the understanding of paleosol distribution from the 2D correlation. The 3D correlation might explain the first discontinuity of PB1 in area ①, where it is bounded by uplifted area ② driven by the Kawah Burung Fault. The paleosol discontinuity in PB2, which creates an area with no paleosol in area ②, can also be explained. It is related to the fact that area ② is the main part of the depositional basin of the Gambung-A Formation. Hence, the paleosol layer in the shallow part of this area is destroyed when the paleo geography of the basin is formed. Related to the distribution of paleosol layers in area ③, the Malabar Horst Structure might explain how this structure uplifted the Puncak Besar Formation in area ③. This structure creates a wide gap in depth between the same paleosol layers in area ③ and area ①.

Regarding the paleosol layer distribution for drilling purposes, the 3D correlation will be useful to expect potential paleosol distribution in the Puncak Besar Formation. It can be concluded that wells that will be drilled in area ① intersect the deep part with potentially two paleosol layers (D and D.a). Another paleosol layer might be observed below paleosol D, as this area is undisturbed, though no well data supports this assumption. Wells in area ② will not intersect paleosol layers in the Puncak Besar Formation but might intersect layer D.3 at depth, close to the Malabar Formation. Wells in area ③ might intersect a complex of paleosol layers (D.a to D.3) at shallow depths. Therefore, wells that will be drilled in this area should be aware of the abundant paleosol layers in the Puncak Besar Formation. As this interpretation is specific to the Puncak Besar Formation, it should be taken into account when considering the paleosol layers in the formations above and below the Puncak Besar Formation and incorporating the results to have a comprehensive well assessment of paleosol existence along the well.

5. CONCLUSION

Paleosol distribution in Wayang Windu has been characterized since 1997 and updated recently in 2019. Physically, paleosol can be categorized into sticky and non-sticky (brittle) types. It is concluded that the paleosol in Wayang Windu originates from volcanic ash, which is unconsolidated and easily reworked, then filled the lake and reacted with water to form clays and iron oxides. In relation to the geothermal system in Wayang Windu, the paleosol is not in equilibrium with the hydrothermal system, as the mineralogical composition indicates temperatures of less than 170°C, while the measured temperature is almost 200°C. The paleosol distribution is

mostly within the reservoir and is dominated by non-sticky (brittle) paleosol. Several paleosol layers have extensive occurrence and distribution, making them useful as marker horizons. However, variations in elevation for each paleosol layer are observed and interpreted as a result of paleo topography variations at the time of deposition and subsequent structural modifications. The relation between paleosol existence and drilling problems in Wayang Windu is primarily due to the reaction of paleosol with the fluids used in drilling activities. Paleosol in Wayang Windu can easily swell upon contact with water or drilling fluid and has very poor mechanical strength, making it prone to sloughing when hydrostatic pressure is reduced due to total loss circulation, leading to stuck pipe incidents.

Paleosol has been incorporated into the development of the static model in Wayang Windu to help define formations based on unique petrophysical group distributions. Following this concept, detailed analysis of paleosol layers aims to define sub-formations and map their distribution within specific formations. Single well analysis categorized the paleosol layers into three groups: continuous thin paleosol layers, single thin paleosol layers, and single thick paleosol layers. Continuous thin paleosol layers are well observed when paleosol exists within thick petrophysical group distributions. Single thin and thick paleosol layers might exist within a single petrophysical group or between two different petrophysical groups.

Following single well analysis, 2D correlation was conducted for each formation by incorporating the paleosol layer with unique petrophysical groups to define sub-formations. The 2D correlation generally identified up to three paleosol layers for each formation in Wayang Windu. Discontinuities in the paleosol layer observed in 2D correlation were then incorporated and further evaluated using faulted 3D formation distribution. In the example of paleosol layer correlation in the Puncak Besar Formation, single well analysis identified four groups of paleosol layers. The 2D correlation identified three sub-formations within the Puncak Besar Formation and observed two discontinuities. The 3D correlation explained the contributions of two faults (Kawah Burung and Cibitung) and the Malabar Horst Structure, which are responsible for these discontinuities. Paleo topography is also responsible for the discontinuity observed in the middle of the Puncak Besar Formation, creating a zone with no paleosol distribution. The formation of a depositional basin in this area might have destroyed the paleosol layers that would have been found there, based on the 2D-3D correlation.

Keywords: Geology, springs, physical characteristics, fault

ABSTRACT

Mount Pandan is one of the geothermal prospecting areas in Indonesia. This is shown by the appearance of several warm springs, such as Banyu Kuning, Jari Hot Spring, and others in the north of Mount Pandan Area. However, there has been no study about control for the appearance of Mount Pandan Area, and there are still very few studies about detailed geology in Mount Pandan Area. The purpose of the study is to determine the geological conditions and understand the control for the appearance of springs in the north Mount Pandan Area. Understanding geological conditions is based on field mapping, which includes geological mapping, geological structure, and volcanostratigraphy analysis. Meanwhile, the control for the appearance of springs is based on the physical characteristics of the springs and geological condition.

The study area can be divided into 5 Crown of and 13 Hummock of based on the volcanostratigraphy analysis and 40 informal lithological units based on the geological mapping. The main geological structure is a left slip fault with a trending NNW-SSE (tear fault). This causes the formation of normal left slip faults trending NE-SW, reverse right slip faults trending NW-SE, and small folds trending ENE-WSW.

Spring mapping shows there is 7 hot springs. Springs can be divided into 3 groups, fault spring in Wackestone Unit aquifer with high TDS value and neutral pH, fault spring with dome unit aquifer with lower TDS value than Wackestone Unit aquifer and neutral pH, and depression spring in Wackestone Unit aquifer with low TDS value and acid pH. The water flow is controlled by faults and lithology orientation. The faults also control the secondary permeability to increase heat flow as heat source of the hot springs. Radiogenic heat production and gradient geothermal also make the springs have higher temperatures.

1. INTRODUCTION

Mount Pandan is a stratovolcano on Java Island, in the middle of Kendeng Basin and north of the Quaternary volcano on Java Island (Figure 1). Mount Pandan is one of the geothermal prospecting in Indonesia. The geothermal activity is shown by appearance of several hot spring such as Banyu Kuning, Jari Hot Spring, and others in the north of Mount Pandan Area. However, there has been no study about control for the appearance of hot spring in Mount Pandan Area, and there are still very few studies about detailed geology in Mount Pandan Area. To understand the control for the appearance of hot springs, understanding geological condition is necessary. Purpose of this study is determining the geological conditions and understand the control for the appearance of springs in the north Mount Pandan Area. Understanding geological conditions is based on field mapping, which includes geological mapping, geological structure, and volcanostratigraphy analysis. Meanwhile, the control for the appearance of springs is based on the physical characteristics of the springs and geological condition.

There are many classifications of springs based on the spring's temperatures. This paper will use hot springs classification based on Zhou et al. (2023). There are two types of hot springs: low to moderate temperature hot springs (equal to and greater than 25 ◦C to below the local boiling point), and high temperature hot springs (equal to and greater than the local boiling point). There are appearances of low to moderate temperature hot springs in the northern area of Mount Pandan. Hot springs are one of the important geothermal features on the Earth's surface. A hot spring results from special geological and tectonic factors, and specific geothermal and hydrogeological conditions. Hot springs occurring at different places with different tectonic backgrounds exhibit a wide variety of hydrothermal activities and geochemical constituents due to the differences in the circulation depth of groundwaters, the nature of the heat source, the size of tectonic structures, the distance and elevation difference between the recharge area and the spring orifice and the permeability of the geothermal reservoir (Huang, 1993 in Zhou et al.,2023). There are 5 questions raised when we study the origin of hot springs (Zhou et al., 2023): (1) what are the factors controlling the occurrence of a hot spring? (2) what causes the emergence of a hot spring at a certain location? (3) what determines the temperature, flow rate, and geochemical constituents? (4) why are hot springs frequently encountered in some places, but are sparse in other regions? (5) why do the

temperatures and flow rates of hot springs occurring in different places vary so widely? This paper is trying to answer that questions in the northern area of Mount Pandan area based on geological conditions and physical characteristics of the springs.

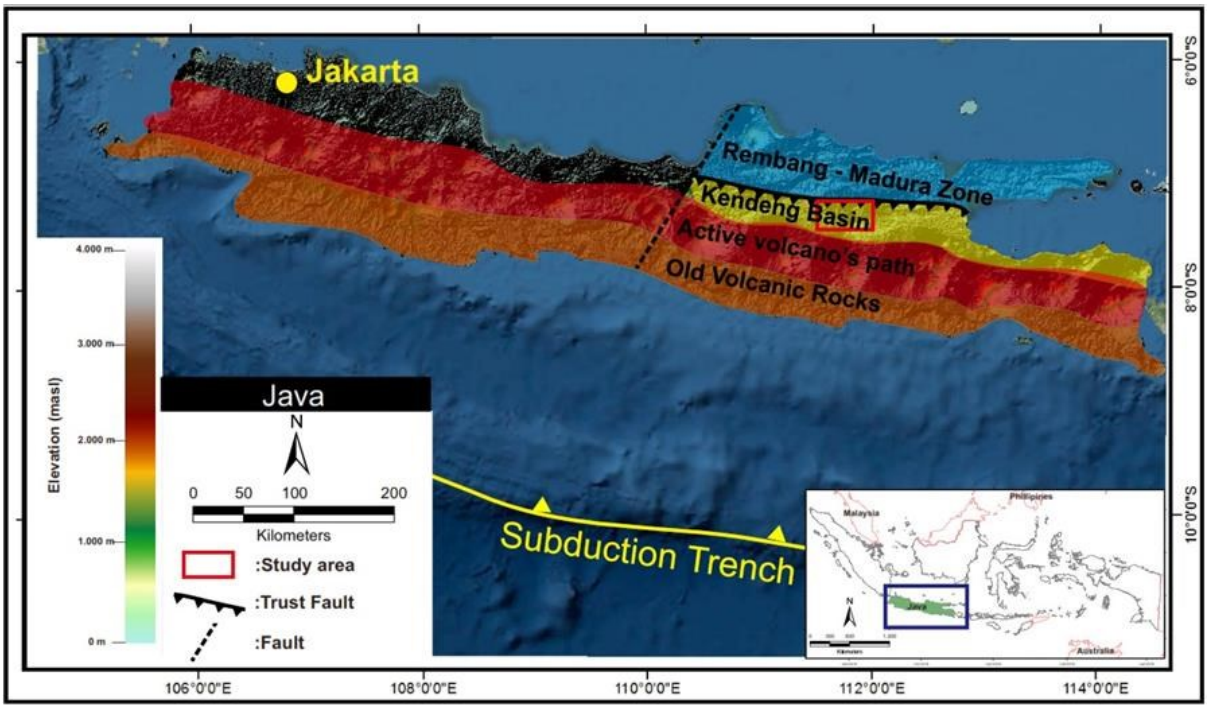

Figure 1: Location of the study area (Jati et al., 2021).

2. DATA AND METHODS

The data of this study consists of primary and secondary data. The primary data is based on geological mapping and laboratory analysis. Lithology, geological structure, and physical characteristics of springs are geological mapping data. Based on geological mapping, there are 160 observation stations, 120 shear fractures data, and 7 physical characteristics of springs data. Laboratory analysis is needed to make sure the megascopic description with petrography analysis. This study used 23 thin section data. The physical characteristics of springs consist of air temperature, spring temperature, Total Dissolved Solids (TDS), and pH. There are also secondary data, such as 100 shear fractures data from Jati et al. (2021) and Bojonegoro Geological Map from Pringgoprawiro and Sukido (1992).

The research began by conducting a literature study regarding the geology and hydrology of the study area. Continue with making the volcanostratigraphy interpretation based on contour and topography. The collecting data stage is carried out by conducting geological and spring mapping. Then the data analyzed to make a geological map of the study areas. The geological condition knowledge and physical characteristics of springs will help in understanding control for the appearance of hot springs. Conceptual models are carried out to understand control for the appearance of hot springs.

3. GEOLOGY OF THE STUDY AREA

3.1 Geology and Stratigraphy

Geological understanding and stratigraphy of the study area used the volcanostratigraphy concept based on Indonesian Stratigraphy Codes by Martodjojo and Djuhaeni (1996). Analysis and overview of geological conditions is based on Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992). Then, the volcanostratigraphic map is interpreted to indicate the cores in the form of conical and circular features, and to indicate the expulsion from the core. Volcanostratigraphic analysis is done on a scale of 1:100.000 and :50.000 to identify stratigraphy units. Naming the core with no specific name yet is based on geographical and cardinal directions if it is in the same geographical location.

Volcanostratigraphic map 1:100.000 (Figure 2) shows there are 5 Crown in the study area, such as Crown of Jari, Crown of Senganten, Crown of Pandan, Crown of Buntung, and Crown of Tritik. Crown of Jari and Crown of Senganten show an isolated hills. Crown of Pandan shows isolated hills and flowing texture from Mount Pandan in contour analysis. Crown of Tritik and Crown of Buntung show isolated hills. Volcanostratigraphic map

1:50.000 (Figure 3) shows there are 23 Hummock in the study area, consisting of 9 Hummock part of Crown of Pandan, 3 Hummock part of Crown of Senganten, and 11 Hummock part of Crown of Jari.

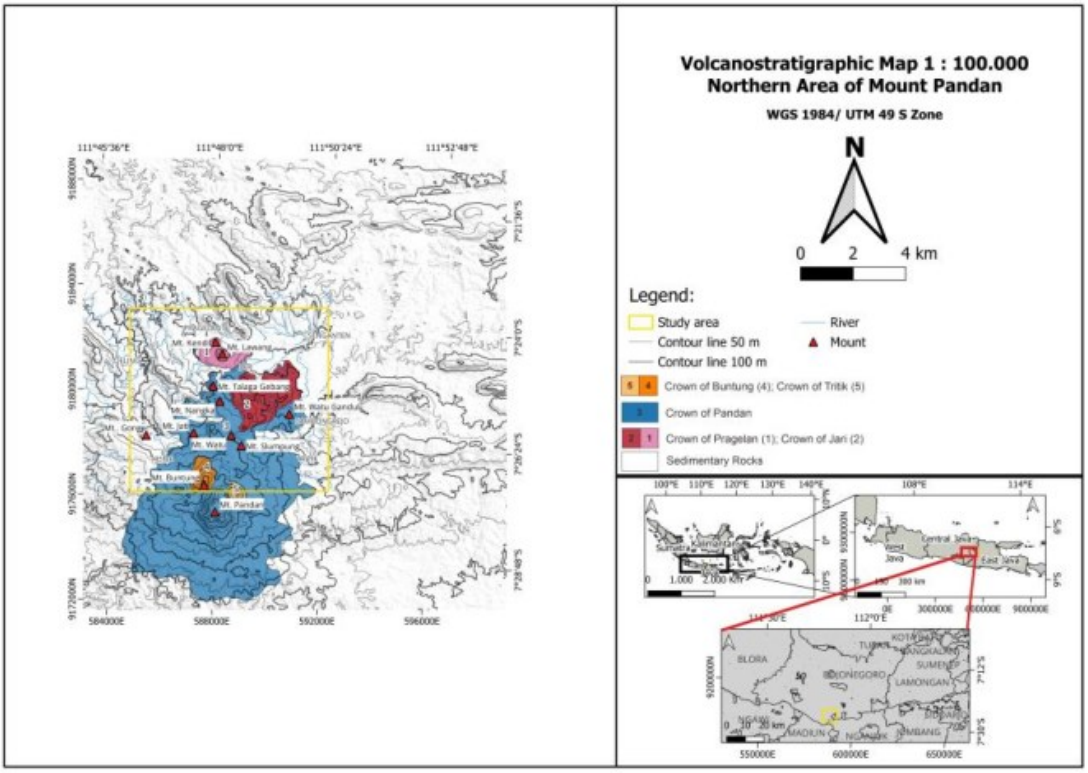

Figure 2: Volcanostratigraphic map 1:100.000.

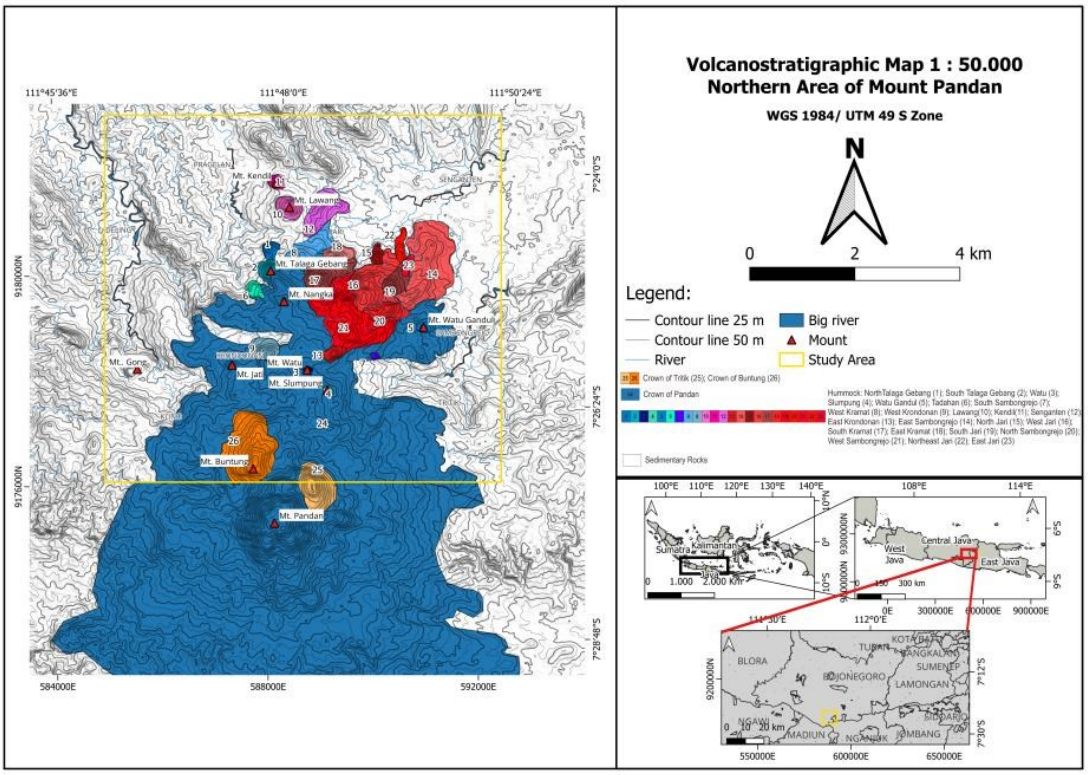

Figure 3: Volcanostratigraphic map 1:50.000.

Based on topographic analysis, shows that the topography of the Crown of Senganten and Crown of Jari is rougher than Crown of Pandan, Crown of Tritik, and Crown of Buntung. In Crown of Pandan, several hills show a deflection pattern texture from the flowing texture. This shows the hills are older than the Pandan deposits.

Meanwhile, the flow texture deposits from Crown of Pandan are relatively younger than Crown of Jari due to the deflection of the flow texture. The Crown of Buntung and Crown of Tritik were identified as younger Crown than Crown of Pandan based on the presence of lava flow texture buried by other flow in the west of Crown of Buntung deposits.

A geological map was made based on descriptive similarities of rocks and a volcanostratigraphic map (Figure 4). the stratigraphy of 39 informal lithological units in the study area is shown in Table 1. The core geometry was identified based on residual magnetic anomaly based on Maubana et al. (2019). There is a low magnetic anomaly in the Crown of Jari. This indicates the small size of the core geometry due to intrusion rock will have a high magnetic anomaly. There are many circular features in the study area with dome morphology. The dome units in the study area are defined as monogenetic volcano. Monogenetic volcano commonly consists of large numbers of volcanic clusters and/or alignments that include hundreds of structures (Condit and Connor, 1996; Connor, 1987, 1990; Con-nor et al., 1992, 2000; Connor and Conway, 2000; Conway et al.,1998; Valentine et al., 2006; in Németh, 2010).

3.1.1 Wackestone Unit

Wackestone Unit is the oldest unit in the study area. This unit consists of light grey calcareous claystone (Figure 5 (a)) with many fractures in the station. Based on petrography analysis, this unit consists of wackestone (Dunham, 1962) with many microfossils like Foraminifera Globigerina, other foraminifera, and coral. The Wackestone Unit is equal to the Kalibeng Formation in the Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in the Upper Miocene-Lower Pliocene.

3.1.2 Breccia-1 Unit

Breccia-1 (Figure 5 (b)) Unit is a younger unit than Wackestone Unit. Breccia-1 Unit consists of brown breccia lithology with andesite fragments with fine sand matrix. Breccia-1 Unit is equal to Atasangin member of Kalibeng Formation in Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in the Upper Miocene.

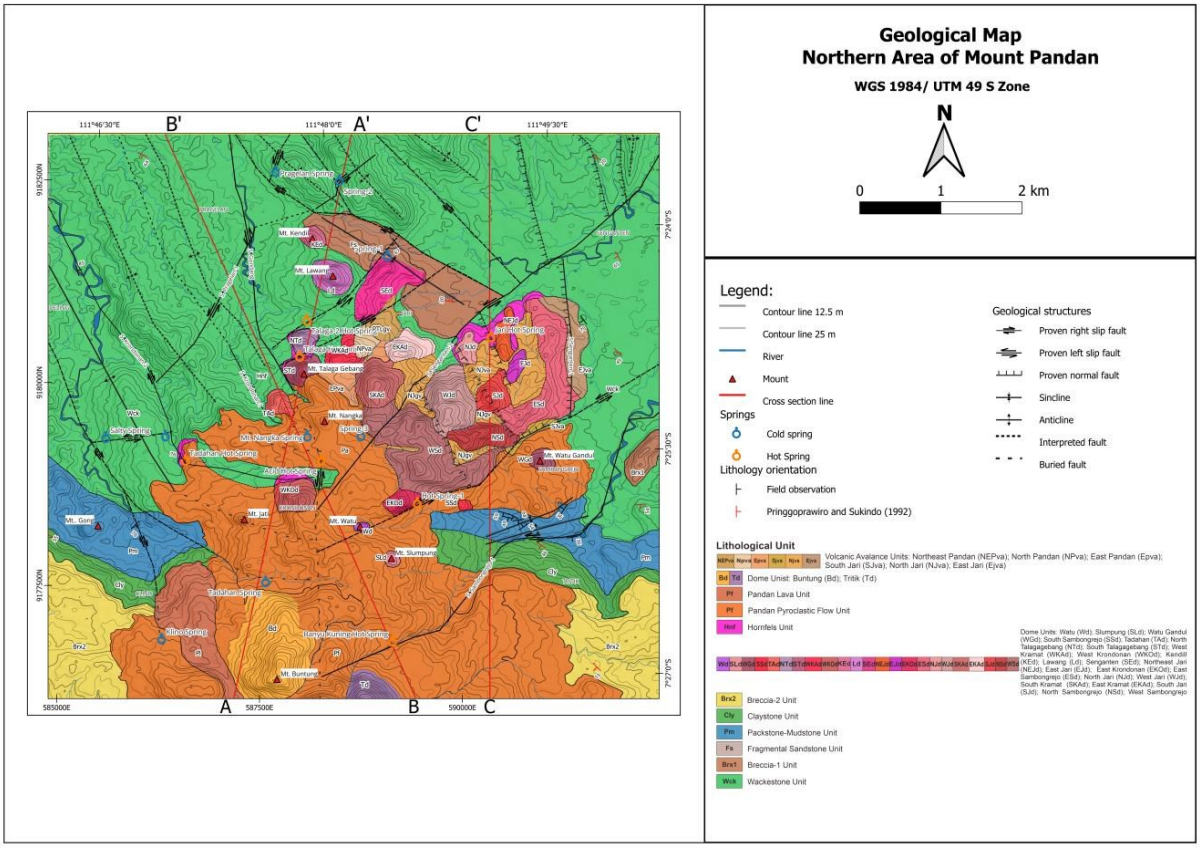

Figure 4: Geological Map of the study area.

	Late Miocene	Kalibeng Formation				Breccia-1 Unit (Brx1)			
						Wackestone Unit (Wck)			

3.1.3 Packstone-Mudstone Unit

Packstone-Mudstone Unit (Figure 6 (a)) is a younger unit than Breccia-1 Unit. This unit consists of interbedded light grey calcarenite with dark grey calcareous claystone. Based on petrography analysis, this unit consists of packstone (Dunham, 1962) and mudstone (Dunham, 1962). There are ENE-WSW syncline and anticline structures in this unit. Packstone-Mudstone Unit is equal to Klitik Formation in the Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in Lower Pliocene-Middle Pliocene.

3.1.4 Claystone Unit

Claystone Unit (Figure 6 (b)) is a younger unit than the Packstone-Mudstone Unit. This unit consists of black claystone with Brachiopoda, pelecyopoda macrofossil fragments, and Packstone-Mudstone Unit lithic fragments. This unit is equal to the Sonde Formation in the Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in the Middle Pliocene.

3.1.5 Breccia-2 Unit

Breccia-2 Unit (Figure 6 (c)) is a younger unit than Breccia-2 Unit. This unit breccia with andesite and basalt fragments and fine sand matrix. Based on petrography analysis shows clastic texture with lithic and minerals as fragments and mud as matrix in the unit. This unit is equal to the Pucangan Formation in the Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in the Upper Pliocene-Pleistocene.

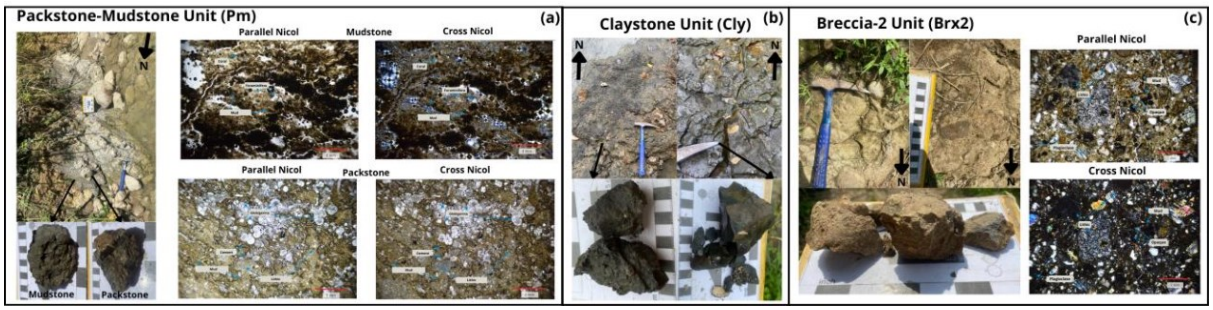

Figure 6: Packstone-Mudstone (a), Claystone b), and Breccia-2 Unit characteristic.

3.1.6 Crown of Senganten

Crown of Senganten (Figure 7) is in the north of the study area which was formed at the same age as the Crown of Jari. Crown of Senganten consists of three Hummock, such as Hummock of Lawang, Hummock of Kendil, and Hummock of Senganten. Crown of Senganten consists of 3 informal lithological units, such as Lawang Dome Unit (Ld), Kendil Dome Unit (KEd), and Senganten Dome Unit (SEd). The lithology of Ld, KEd, and SEd is hornblende andesite (Williams et al., 1998). Lithology identification of Lawang Lava Unit was based on Thoha et al., (2014). The dome Units in the study area are defined as monogenetic volcanoes. Crown of Senganten is equal to the Intrusion Rock Unit in the Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in the Pleistocene.

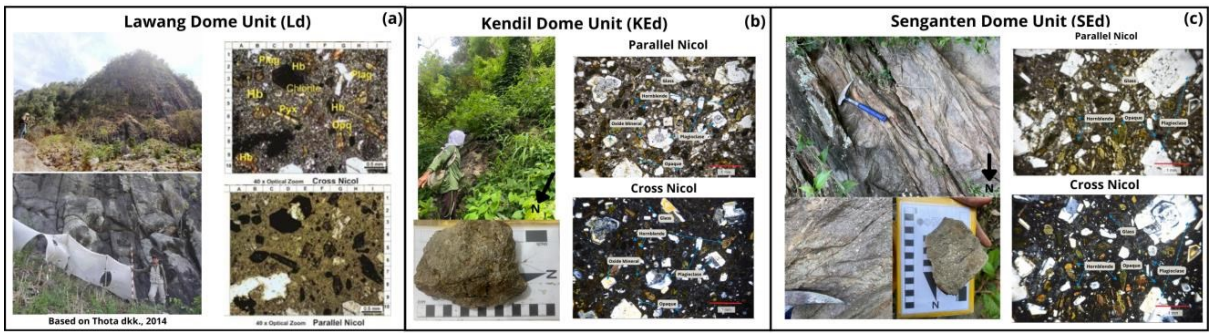

Figure 7: Crown of Senganten Unit characteristic.

3.1.7 Crown of Jari

The Crown of Jari (Figure 8) is in the east of the study area which was formed at the same age as the Crown of Senganten. Crown of Jari consists of eleven hummock with 13 informal lithological units, such as East Jari Dome Unit (EJd), Northeast Jari Dome Unit (NEJd), East Krondonan Dome Unit (EKOd), East Sambongrejo Dome Unit (ESd), North Jari Dome Unit (NJd), West Jari Dome Unit (WJd), South Jari Dome Unit (SJd), West Sambongrejo Dome Unit (WSd), South Kramat Dome Unit (SKAd), East Kramat Dome Unit (EKAd), South Jari Volcanic Avalanche (SJva), East Jari Volcanic Avalanche (EJva), North Jari Volcanic avalanche (NJva). The dome Units in the study area are defined as monogenetic volcanoes. The lithology of dome units is hornblende andesite (Williams et al., 1998). SJva and NJva were identified as volcanic avalanches from dome units in Crown of Jari. Besides that, Ejva was identified as volcanic avalanche from East Sambongrejo Dome Unit (ESd). Dome units are equal to Intrusion Rock Unit and volcanic avalanche units in Crown of Jari are equal to the Pandan Breccia Unit in the Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in the Pleistocene.

3.1.8 Crown of Pandan

The Crown of Pandan (Figure 9) is in the south-north of the study area and relatively younger than the Crown of Senganten and Crown of Jari. Crown of Pandan consists of nine Hummock with 14 informal lithological units, such as Watu Dome Unit (Wd), Slumpung Dome Unit (SLd), Watu Gandul Dome Unit (WGd), South Sambongrejo Dome Unit (SSd), Tadahan Dome Unit (TAd), North Talagagebang Dome Unit (UTd), South Talagagebang Dome Unit (SJd), West Kramat Dome Unit (WKAd), West Krondonan Dome Unit (WKOd), Pandan Flow Unit (Pf), Pandan Lava Unit (Pl), North Pandan Volcanic Avalanche (NPva), Northeast Pandan Volcanic Avalanche (NEPva), and East Pandan Volcanic Avalanche (EPva). The dome Units in the study area are defined as monogenetic volcanoes. The lithology of Dome and lava units is hornblende andesite (Williams et al., 1998), except the SLd Unit consists of pyroxene andesite (Williams et al., 1998). Pandan Flow Unit consists of pyroclastic breccia with andesite fragments. The size of the fragments shows finer to the north of the study area or further away from Mount Pandan Core. NPva and EPva were identified as volcanic avalanches from lava units and pyroclastic breccia units in Crown of Pandan. Besides that, NEPva was identified as a volcanic avalanche West Kramat Dome Unit (WKd). Dome units is equal to the Intrusion Rock Unit; besides that, volcanic avalanche units, Pandan Flow Unit, and Pandan Lava Unit in Crown of Pandan are equal to the Pandan Breccia Unit in the Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in the Pleistocene.

3.1.9 Crown of Buntung and Crown of Tritik

Crown of Buntung and Tritik is in the Southwest and Southeast of the study. The Crown of Buntung and Tritik was formed after Crown of Pandan. The interpretation of the age is based on the contour pattern changed in the East of Pandan Lava Unit. The Crown of Buntung consists of Buntung Dome Unit (Bd). The Crown of Tritik consists of Tritik Dome Unit (Td). Bd and Td are interpreted younger Pandan Breccia Unit in the Bojonegoro Geological Map by Pringgoprawiro and Sukindo (1992) in the Pleistocene.

3.1.10 Hornfels Unit

Hornfels Unit is in around of some lava units. The Hornfels unit was formed because of contact metamorphism which was changed by the Wackestone Unit.

3.2 Geological Structure

The Geological structure section consists of kinematic analysis based on field data and previous study data, and identification order of the fault and the fault implication to the geological condition of the study area.

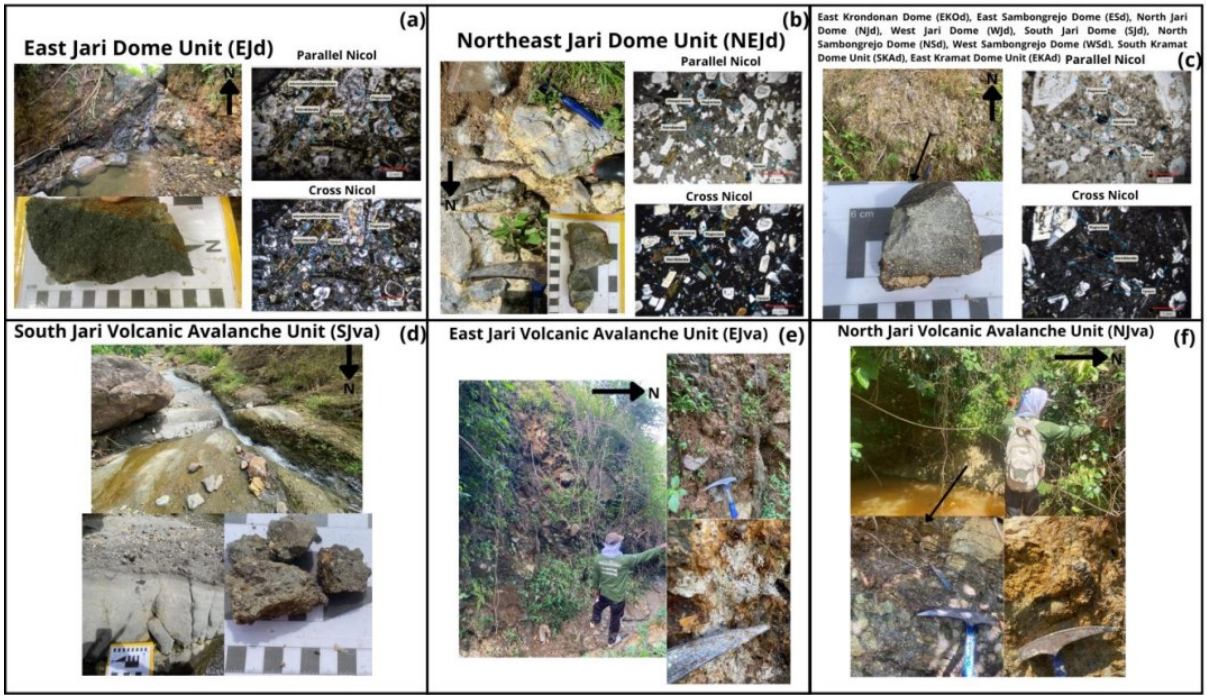

Figure 8: Crown of Jari Unit characteristic.

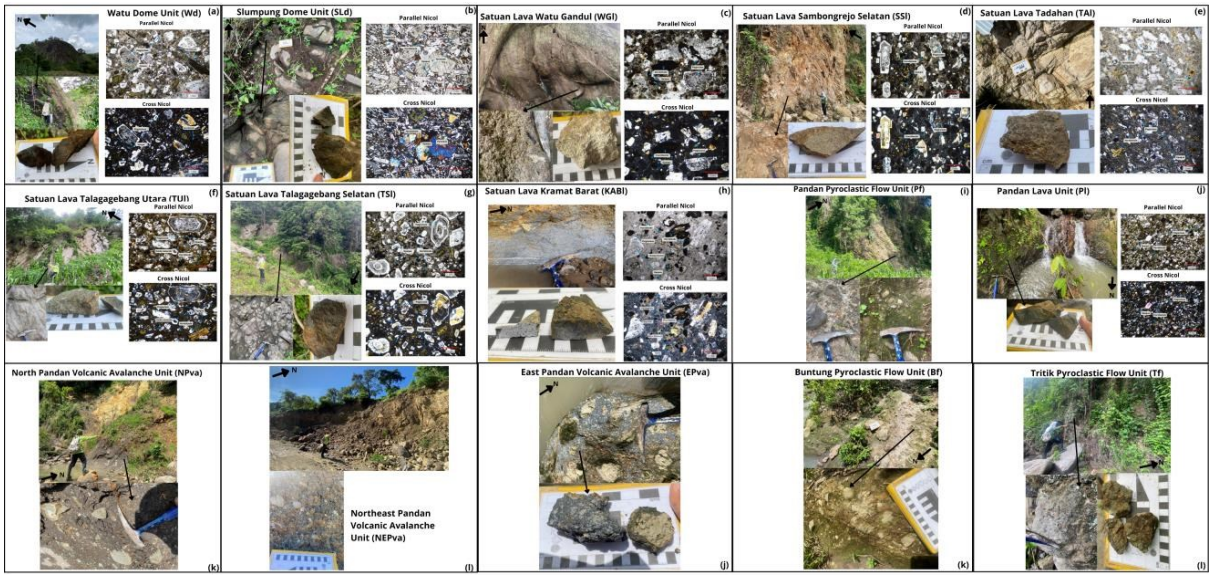

Figure 9: Crown of Pandan characteristic.

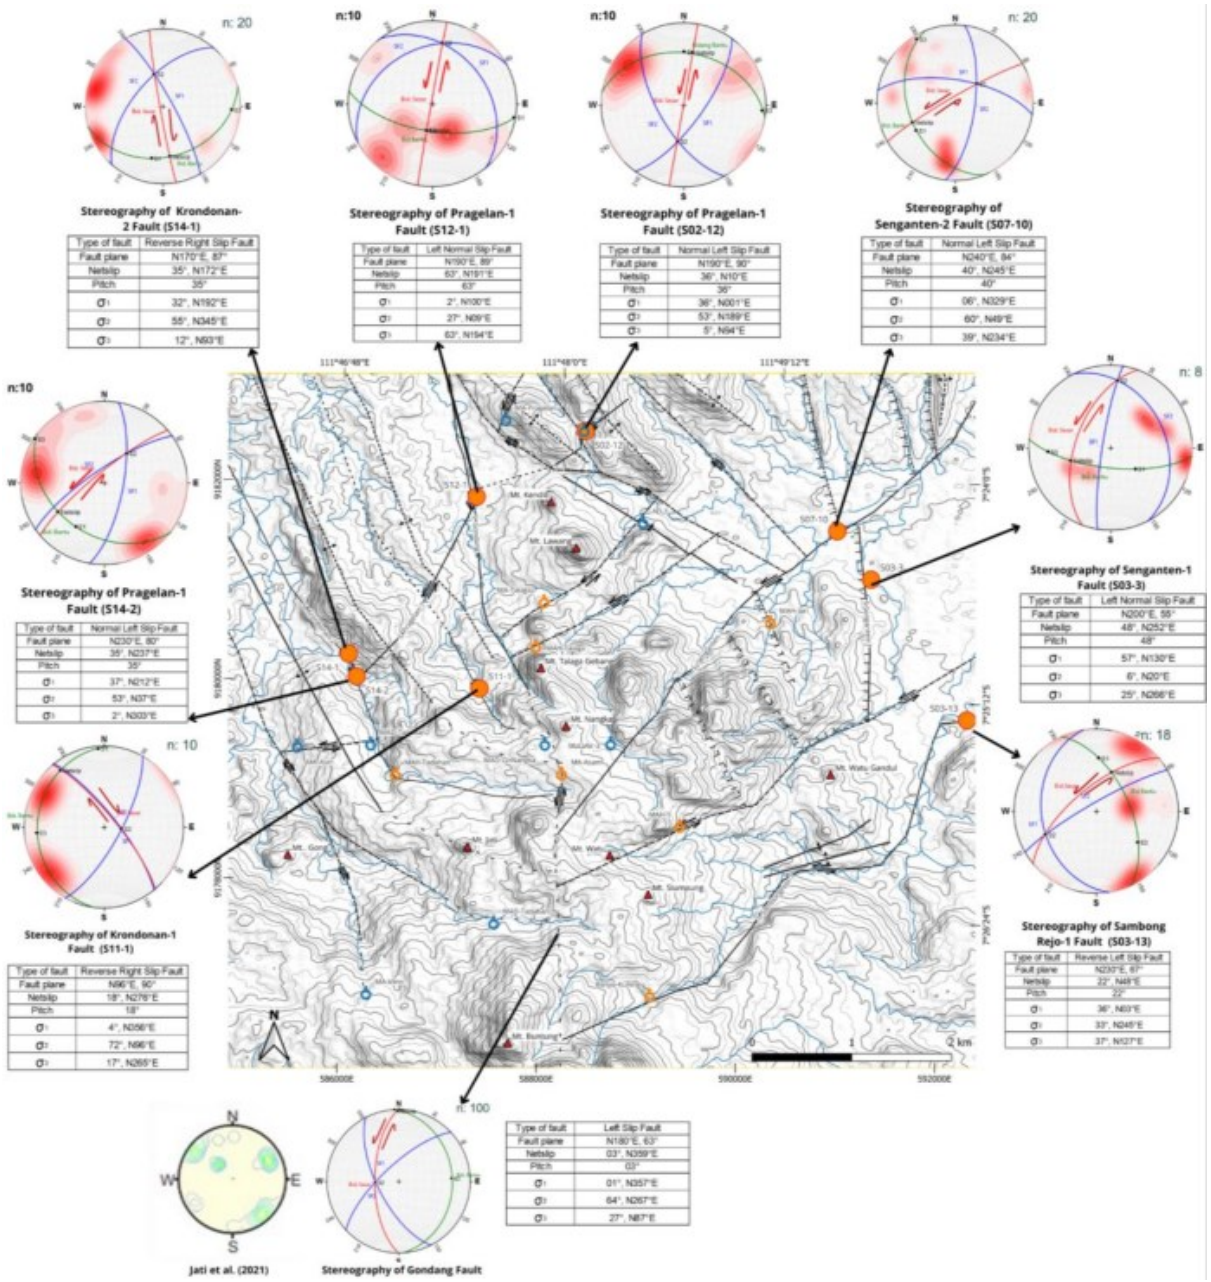

Figure 10: Mount Pandan fractures and locations.

3.3.1 kinematic Fault Analysis

Kinematic analysis is based on shear fracture data and lineament. The trend of lineament is interpreted as a strike of the fault plane. Identification of the stress and relative movement of the fault plane used stereonet software and classification from Rickard (1972). 6 faults were identified based on the field mapping data and 1 fault was identified based on the previous study from Jati et al. (2021). Reanalysis of the fault was done because there was a mistake in determining the movement of the fault. The spatial distribution of the fault analysis is shown in Figure 10.

- Pragelan-1 fault is a Normal Left Slip Fault, N190ºE/90ºNW (Rickard, 1972).
- Sambongrejo-1fault is a Reverse Left Slip Fault, N230ºE/90ºNW (Rickard, 1972).
- Senganten-1 fault is a Left Normal Slip Fault, N200ºE/55ºNW (Rickard, 1972).
- Senganten-2 fault is a Reverse Right Slip Fault, N96ºE/90ºSW (Rickard, 1972).
- Krondonan-1 fault is a Reverse Right Slip Fault, N96ºE/90º SW (Rickard, 1972).
- Krondonan-2 fault is a Reverse Right Slip Fault, N170ºE/87º SW (Rickard, 1972).
- Gondang fault is a Left Slip Fault, N180ºE/63º SW (Rickard, 1972).

3.3.2 Order of The Fault and The Implications

Based on the Cinematic analysis, there are several faults in the study area. In the geological map, Gondang fault has a trend NNW-SSE in the study area. There is a different position of Packstone-Mudstone Unit and Claystone Unit in the east and west of the study area. The east area is a relative left movement than the west area. The movement is caused by the Gondang Fault movement. If the fault is seen in the smaller scale map, the Gondang Fault has a continuity to the north from the study area. The Strike of the Gondang Fault is relatively perpendicular to the strike of Kendeng Anticlinorium (W-E trend). Based on previous pure shear or simple shear models, nothing has been explained yet about strike slip fault parallel to the dominant stress (Sigma1). Gondang Fault is identified as a tear fault that is formed when the folding process. A tear fault is a strike-slip fault that runs across the strike of a contractional or extensional belt and accommodates differential displacement between two segments of the belt. Like transfer faults, tear faults are usually confined to hanging walls of detached systems (Burg, 2020). Tear fault is normally found in the folding areas, such as the Andong Fault Area in Gyeongsang Basin, South Korea (Choi et al., 2002), the Zaghouan Thrust Belt, Tunisia (Aridhi et al., 2011), and others.

Gondang Fault was identified as a cause form other faults in the study area. This identification is validated with the model by Riedel (1929). North-South Left Slip Fault will make left slip fault with trend NE-SW (Pragelan-1 Fault, Sambongrejo-1 Fault, and Senganten-2 Fault) is identified as R Shear, right slip fault with trend NW-SE (Krondonan-1 Fault and Krondonan-2 Fault) is identified as R' Shear, and fold with trend ENE-WSW in the Southeast of the study area. NW-SE Right slip fault causes movement of the fold trend in the study area. Gondang fault is also identified as a permeable zone to form Mount Pandan, other cores, and the continuity trend of springs.

Senganten-1 Fault is a normal fault with trend N-S. The movement of the Senganten-2 Fault and the interpreted left slip fault in the south of the Senganten-2 Fault caused Senganten-1 Fault and other normal faults (identified as a normal fault zone). This normal fault zone is identified as a permeable zone that controls the form of cores in Crown of Jari with every Hummock having a relative trend N-S and Jari Warm Spring.

Table 2: Physical Characteristic of Springs.

Springs Name	X (m)	Y (m)	TDS (ppm)	pH	Water Temperature (°C)	Air Temperature (°C)	Elevation (mdpl)	Spring Classification		
								Temperature	TDS	pH
Talaga 2	588082.1	9180758	16200	6.52	31	32.8	283.65	Warm spring	Salt water	Neutral

Jari	590353.6	9180551	7800	6.3	43.9	33.6	200.54	Warm spring	Brackish water	Neutral
Tadahan	586586.4	9179028	1070	6.81	31.1	30.7	327.29	Warm spring	Brackish water	Neutral

4. CONTROL FOR THE APPEARANCE OF HOT SPRINGS

4.1 Characteristic of Springs

Understanding the Characteristic of Springs is based on the physical parameter of springs. Physical parameters used in this research consist of springs and air temperature, total dissolved solid (TDS), and pH (Table 2). The value of each parameter will show the process of the water flow in the subsurface until it reaches the surface. The springs condition and distribution are shown in figure 11.

4.1.1 Temperature

The value of water temperature in the study area has an interval from 31-43.9°C and the average air temperature in the study area is 30.7°C. Those springs are classified as low-medium hot springs (Zhou et al., 2023). Acid Spring and Talaga-2 Spring have relatively higher temperatures than average air temperatures in the study area. Although Acid Spring and Talaga-2 Spring have lower temperatures than the air temperature when collecting data. So, Acid Spring and Talaga-2 Spring were classified into warm spring in this study. Higher temperatures can indicate water comes from deeper aquifers/reservoirs (USGS, 1955). The study area shows Jari Warm Springs as the warmest spring which is the location of in the normal fault zone. So, the geological structure conditions also control the temperature. The temperature value is colder in more simple geological conditions.

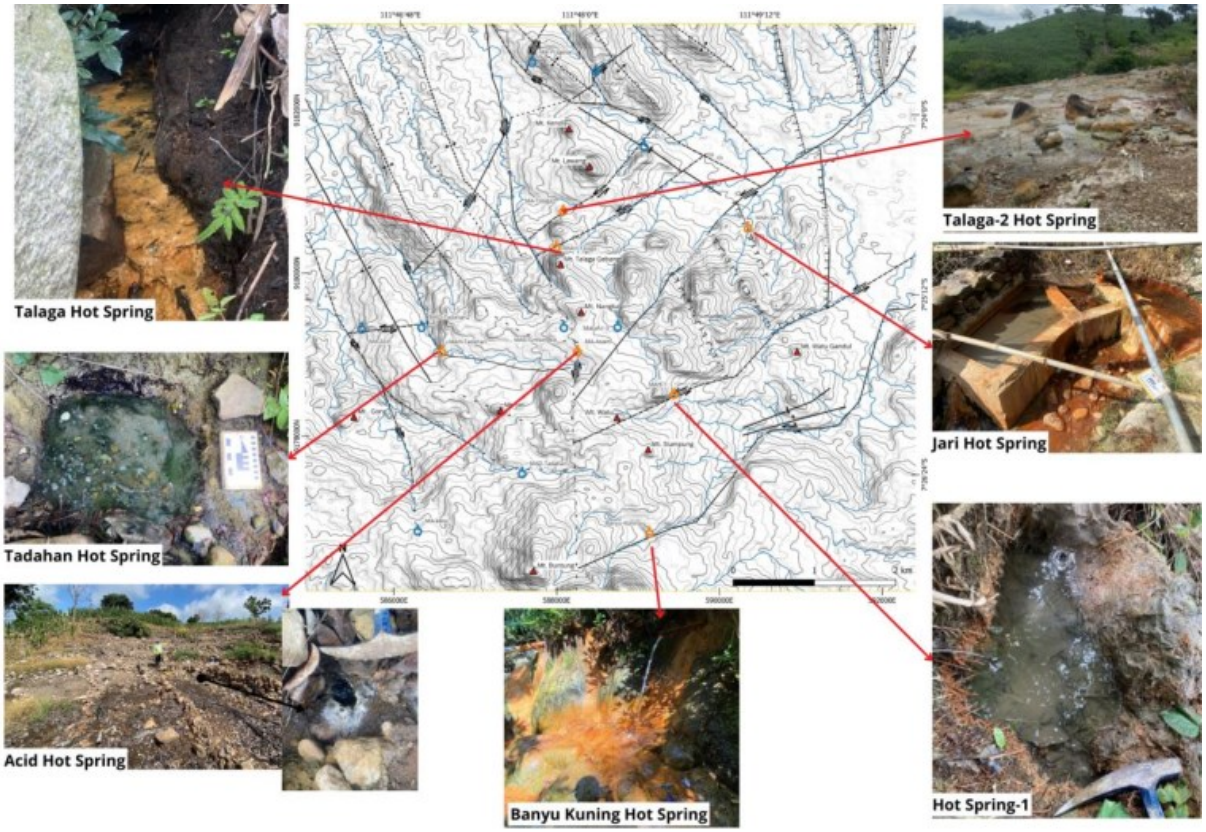

Figure 11: Springs condition and distribution.

4.1.2 Total Dissolved Solid (TDS)

Total dissolved solid shows the amount value of dissolved solids in the water. TDS Value can be classified into fresh water (0-1,000 mg/L); brackish water (1,000-10,000 mg/L); salt water (10,000-100,000 mg/L); brine water (>100,000 mg/L) (Freeze and Cherry, 1979). The TDS value in the study area has intervals from 350-16200 ppm. So, there are 2 freshwater springs, 4 brackish water springs, and 1 saltwater spring. TDS value is also affected by the time of water circulation/ depth of the aquifer and the lithology of the aquifer or reservoir. The aquifer of the springs is identified by the lithology around the spring and the physical characteristics of the spring. In the study area, spring with a wackestone aquifer has a higher TDS value than another aquifer. Based on that value, a spring with a carbonate aquifer will have high TDS value. That is also equal to Cartwright et al. (2017), spring in a marl aquifer (based on Pringgoprawiro and Sukindo (1992), Wackestone Unit equal to marl lithology in Kalibeng Formation) have high TDS value. Acid Spring has the lowest TDS value and low debit with pyroclastic breccia aquifer. Talaga Hot Spring is classified as a freshwater spring with a lava aquifer. But there is a spring with the same lithology but has diverse TDS, this is also affected by the depth of the fault and temperature of the springs. Springs with deeper faults and higher temperatures will have deeper aquifers and higher TDS values in the study area.

4.1.3 pH

pH can indicate dissolved substances in spring. pH is influenced by fluid salinity, temperature, and buffer minerals (Nicholson, 1993). Springs can be classified into 6 types based on pH value, such as very acid spring (pH<2), acid spring (2≤pH<4), light acid spring (4≤pH<6), neutral spring (6≤pH<7.5), light alkali spring (7.5≤pH<9), and alkali spring (9≤pH) (Subtavewung et al., 2005). The pH value in the study area has an interval from 3.95-6.81 with 5.66-6.1 rainwater pH. So, there is 1 acid spring and 6 neutral springs. Acid Spring shows a lower pH value than rainwater. This indicates that another influence makes the water acid. Based on field observations, there a sulfur deposits and vegetation anomalies around Acid Spring. This indicates acid properties come from water with high sulfur content.

Sulfur deposits can come from volcanic origin (inorganic), Bacterial sulfate reductions (organic), thermal decomposition of organic sulfur bearing compound (organic), and thermochemical sulfate reduction (organic) (Ma et al., 2019). This indicates the form of sulfur deposit not just from young vulcanism origin. In the study area, magmatism has an age of 1.8-0.8 million years ago, Pleistocene (Pringgoprawiro and Sukindo, 1992), or classified as inactive or extinct magmatism related to volcanism (McCoy-West et al., 2011 in Moeck, 2014).

Thermochemical sulfate reduction (TSR) became the most influential source of H2S in the sedimentary basin. TSR is made by hydrocarbon and sulfate minerals interaction at >100ºC (Ma et al., 2019). This is because there is a petroleum system in the Kerek Formation (the older formation than Kalibeng Formation or Wackestone Unit) based on Setyowiyoto et al. (2007); and Putra and Praptisih (2017). Wackestone unit can be a source rock in petroleum systems (Setyowiyoto et al., 2007). So, the TSR can be the process of making a sulfur deposit with cubic opaque minerals in petrography analysis of the Wackestone Unit. Thermal decomposition is interpreted as another source of sulfur deposits. Thermal decomposition normally takes place during the heating periods of organic matter and following petroleum formation (Ma et al., 2019). This is shown by the vulcanism in the Pleistocene heated Wackestone Unit and Kerek Formation.

4.2 Factors affecting the formation of springs

Strata and rocks, tectonic structures, geothermal geology, and hydrogeological conditions all have an important impact on the formation of hot springs (Zhou et al.,2023).

4.2.1 Aquifer and Hydrogeological conditions on the formation of hot springs

An Aquifer rock or sediment in a formation, group of formations, or part of a formation that is saturated with water and permeable enough to convey economical amounts of water to wells and springs (Fetter, 2014). The overlay of the aquifer or reservoir is controlled by lithology and geological structure in the study area (Irawan and Puradimaja, 2013). The permeability of lithology in the study area is classified into low and moderate permeability based on Vojtek and Vojtekova (2019) classification. Wackestone, andesite, and claystone have low permeability. Pyroclastic breccia, volcanic avalanche, fragmental sandstone, and packstone-mudstone have moderate permeability. However, at the observation station, there are many fractures in the Wackestone Unit. Fractures will increase the permeability of the rocks. It looks like there are many springs in Wackestone Unit and several resident's groundwater wells.

Recharge area in hydrogeological system is controlled by slope, lithology, and geological structure (Rajaveni et al., 2017). So, the area recharge area potential in study area is in high elevation with flat slope of Pandan Flow Unit and fault zones. Groundwater flows from high to low elevations. The subsurface flow conditions in the study area are interpreted based on the groundwater level of resident's groundwater wells. The water flows from south to north of the study area in the wackestone aquifer. However, the flow will always depend on the orientation of the aquifers.

4.2.2 Impact of structures on the formation of hot springs

The occurrence of a hot spring can be affected by a single fault (regional or local, including normal, or reverse or strike-slip faults) and multiple fault sets including parallel faults, intersecting faults and major faults with descendent faults, and even three-level faults of different scales. A regional fault is usually large and deep, with multiple periods of activity in its evolution. It often plays an important role in heat convection and transmitting groundwaters and is favorable for the formation of hot springs. Sometimes several hot springs exist along a major fault (Zhou et al., 2023). In the study area, the major fault is the Gondang Fault. Gondang Fault controls the appearance of the springs, heat convection for the springs, and transmitting groundwaters.

Identification of structural control on the appearance of hot springs is based on field observations, geological conditions, and fault continuity around the hot springs. Springs can be divided based on the control for appearance of the springs into contact spring, depression spring, fracture spring, fault spring, sinkhole spring, and fracture zone spring (Fetter, 2014). Fault springs generally have high water discharge. However, in the field observations, it is difficult to measure water discharge because in general the springs have more than one discharge point, which means measuring discharge at one point will not be representative. So, in this study interpretation of springs type is based on field observations in the form of qualitative output, lineament interpretation, and physical characteristics of the springs.

There are 2 types of springs in the study area, such as depression spring and fault spring. A spring is formed when the water table reaches a land surface because of a change in topography (Fetter, 2014). Acid Hot Spring is a depression spring in the study area. This spring is characterized in the field by relatively small debit water flow, low TDS value, and moderately steep-steep slope. A spring is created by the movement of two rock units on a fault (Fetter, 2014). Fault springs in the study area consist of Jari Warm Spring, Tadahan Warm Spring, Talaga Warm Spring, Banyu Kuning Warm Spring, and Talaga-2 Warm Spring. These springs are characterized in the field by relatively high debit water flow (there are several discharge spots and several pools), high TDS value, and the continuity of the fault.

4.2.3 Impact of conditions of geothermal geology on the formation of hot springs

Higher hot spring temperatures indicate the water comes from deeper aquifers/reservoirs (USGS, 1995). The heat can come from volcanic or nonvolcanic. The Volcanic heat source of the hot springs also depends on the age of

the magmatism. There are 3 terms of magmatism based on McCoy-West et al. (2011) in Moeck (2014), with active magmatism related to volcanism 0-500 years old, recent magmatism related to volcanism 500–50,000 years old, and inactive or extinct magmatism related to volcanism 450,000 years old. The nonvolcanic heat source can come from the geothermal gradient (Wang et al., 1993; Liu et al., 2015; in Zhou, 2023) and the cooling of the Earth's core and the radioactive heat generation in the upper 20 to 40 km of the Earth's crust. Radioactive heat generation is a product of crustal rocks containing high concentrations of naturally occurring radioactive elements: thorium, potassium, and/or uranium (SMU,2023). Faults will have an important role in this heat source because the fluid will circulate deep within the crust and transport heat to near the surface along permeable faults (Moeck, 2014).

In the study area, the last vulcanism was 1.8-0.8 million years ago (Mount Pandan activities) or included in inactive or extinct magmatism related to volcanism classification. For that reason, volcanic activities will not be the heat source in the study area. Hot springs in the study area were in the continuity of the faults. So, the faults have an important role in the study area because the fault didn't only control the appearance of the springs but also the appearance of the vulcanism. If faults extend to zones above the magma or magma chambers, heat may be easily transported to shallow zones through the faults. Groundwater that circulates deeply through fault zones and is heated indirectly from magma or a magma chamber, may be used as a high temperature hot spring (Moeck, 2014). In the study area, the existence of the gondang fault which is deep enough to create volcanism can be secondary permeability to increase heat flow. Besides that, radiogenic activities also make higher temperatures. In the study area, the Kerek Formation (consisting of alternation sandstone, claystone, tuff, marl, and limestone) will show higher heat production than the Wackestone Unit or Kalibeng Formation (consist of Marl) (Norden & Förster, 2006). So, the heat source in the study area can be dependent on the heat flow, geothermal gradient, and radiogenic heat production. The higher temperature spring can indicate deeper reservoirs or deeper faults or in the fault zone so will have higher heat flow. So, deeper reservoirs (gradient geothermal) and fault zones (secondary permeability to increase heat flow) will have higher temperatures reservoirs in the study area. It can be seen in the Jari Warm Spring, the warmest spring in the study area.

5. CONCEPTUAL MODEL

5.1 A-A' Section

A-A' section shows the conceptual model of Talaga-2 Hot Spring and Talaga Hot Spring (Figure 12). The water flow is controlled by fault and the orientation of the lithology. Talaga-2 Hot Spring has a deeper fault and reservoir based on TDS value. The water flows from south to north of the study area. The fault is interpreted as the permeable zone to be a path for fluid recharge in the reservoir. Krondonan-1 Fault and high topography with a relatively flat slope West of Mount Slumpung are interpreted as the recharge area for Talaga and Talaga-2 Hot Spring. Then the water flows and is heated during the flow process by heat flow. Water flows and passes through faults, then the water comes out as Talaga-2 Hot Spring and Talaga Hot Spring.

5.2 B-B' Section

B-B' section shows the conceptual model of Acid Hot Spring and Banyu Kuning Hot Spring (Figure 13). The water flow is controlled by fault and the orientation of the lithology. Water flows from south to north of the study area in the Pandan Breccia Unit. The recharge area was also controlled by the Senganten-2 Fault. Then, the water flows deeper and follows the lithology orientation. The water flows in the Wackestone Unit and flows to the south of the study area. Water flows and passes through faults, then the water comes out in Banyu Kuning Hot Spring. For Acid Hot Spring, the recharge area is controlled by the Krondonan-2 Fault. Water flows deeper in the Wackestone Unit and is heated during the flow process by heat flow. Because the fault is buried by the Pandan Breccia Unit, the output of the Acid Hot Spring is relatively small and is heavily influenced by the flow of more local springs.

5.3 C-C' Section

C-C' section shows the conceptual model of Jari Hot Spring (Figure 14). The water flow is controlled by fault and the orientation of the lithology. The recharge area was also controlled by the NE-SW fault in the north of Watu Gandul. The water flows through the Wackestone Unit from south to north of the study area. The water then flows through the normal fault zone and is heated during the flow process by heat flow. Water flows and passes through faults, then the water comes out as Jari Hot Spring.

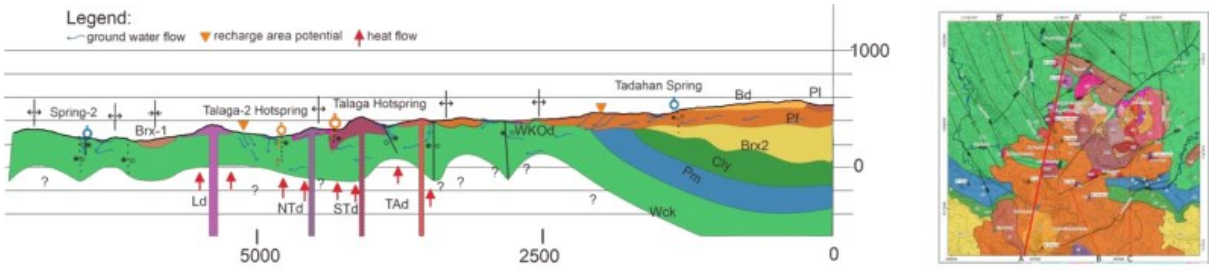

Figure 12: Conceptual model of A-A' section.

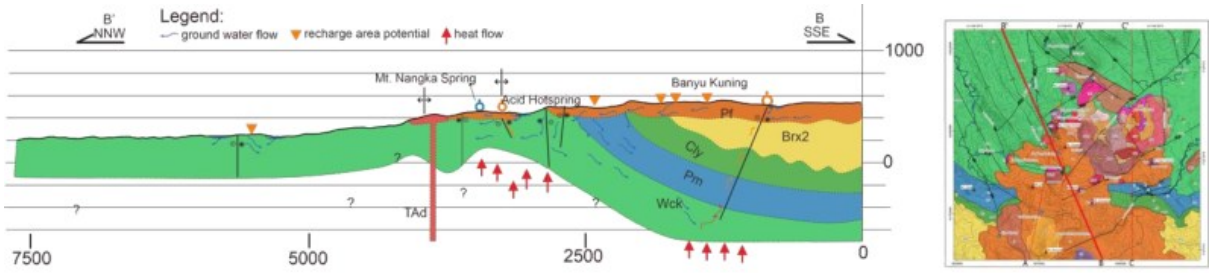

Figure 13: Conceptual model of B-B' section.

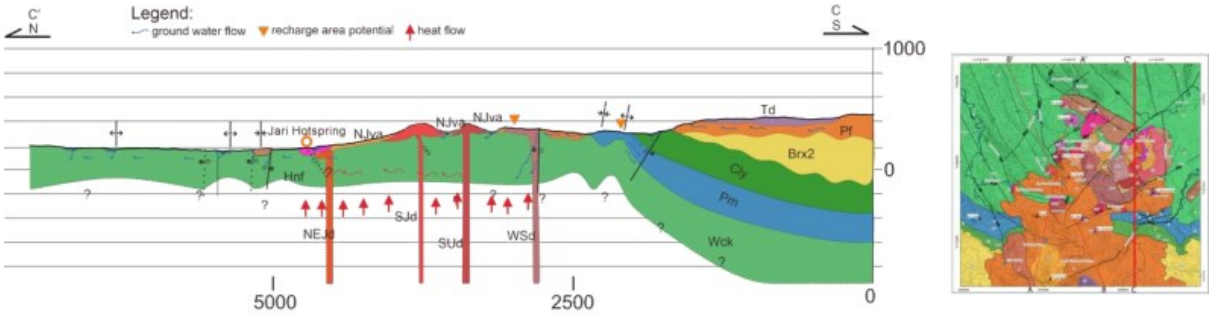

Figure 14: Conceptual model of C-C' section.

6. CONCLUSION

There are 39 informal lithological units in the study area with 5 Crown and 23 Hummock based on vulcanostratigraphy analysis. Left Slip Fault or Gondang Fault (NNW-SSE) is the main fault in the study area. Gondang Fault causes NE-SW Normal Left Slip Fault and Left Normal Slip Fault, NW-SE Right Slip Fault, ENE-WSW Folding, and Normal fault zone in the east of the study area.

There are 7 hot springs in the study area. The springs can be classified into 3 groups, such as fault springs in the Wackestone Unit aquifer with high TDS value and neutral pH, fault springs in the lava dome unit aquifer with lower TDS value than Wackestone Unit aquifer and neutral pH, and depression springs in the Wackestone Unit aquifer with low TDS value and acid pH. Water flows from the south to the north of the study area. Water flow is controlled by faults and lithology orientation. Faults have a dominant influence on the control for appearance of hot springs in the study area. The faults also control the secondary permeability to increase heat flow as the heat source of the hot springs. Radiogenic heat production and gradient geothermal also make the springs have higher temperatures. The fault zone can make better permeability, so we have Jari Hot Spring as the warmest spring in the study area.

ABSTRACT

Understanding the fluid flow in the reservoir is critical for geothermal utilization. Imbalanced fluid mass during extraction and reinjection caused a decline in the generation of electricity due to a decrease in the quantity of fluid in the reservoir. Time-lapse microgravity monitoring can offer a comprehensive view of fluid movement in the reservoir by observing mass changes over a specific period of time. 3D inversion time-lapse microgravity monitoring can determine the location and depth of mass changes that occur in the reservoir. Annual Microgravity monitoring from 2015-2023 in the Lahendong geothermal field reveals that the majority of the injection fluid flows back into the reservoir through the LHD-51 injection well. Additionally, natural recharge fluid is observed entering the reservoir from an elevation of -500 masl in the southwest area, which has been confirmed by Pressure-Temperature measurement data in the LHD-53 well that show a reversal temperature. Further investigation is required to determine the impact of the natural recharge fluid inflow from the southern region of the Lahendong reservoir.

1. INTRODUCTION

Lahendong geothermal field located about 30 kilometers South of Manado city, the capital of North Sulawasi Province, Indonesia (Figure 1). 80 MW of electricity has been produced from geothermal energy, with UNIT-1, UNIT-2, UNIT-3, and UNIT-4 each generating 20 MW. (Atmojo et al., 2015; Azka et al., 2015; Brehme et al., 2016; Firmansyah et al., 2021; O'sullivan et al., 2023; Permana et al., 2015; Prasetyo et al., 2016; Sambodho et al., 2021; Sumantoro et al., 2015; Yani, 2022; Zahid et al., 2021). In 2001, UNIT-1 initiated operations, followed by UNIT-2 in 2007, UNIT-3 in 2009, and UNIT-4 in 2011. (Koestono et al., 2010; Prabowo et al., 2015; Prasetyo et al., 2016; PT. BURSA EFEK INDONESIA, 2023; Sambodho et al., 2021).

The annual average difference between the fluid extracted and reinjected into the reservoir is estimated to be 3-5 MTon per year since UNIT-4 has been operational(Haq et al., 2019; PT. Pertamina Geothermal Energy, 2024). The result indicates the reservoir experiences a fluid imbalance annually due to geothermal exploitation on the surface, as the fluid extracted exceeds the fluid injected back into the reservoir.

The process of fluid extraction and injection in the reservoir at various well locations suggests that fluid movement will occur within the reservoir. This exploitation process results in the movement of not only the production and injection fluids, but also natural recharge. Recharge is one of the four primary components of a geothermal system, as per Hochstein and Browne (2000). Figure 2 shows conceptual model geothermal system.

Naturally, the reservoir's pressure will fluctuate as a result of mass loss, resulting in the fluid's move from a higher to a lower pressure, as illustrated in Figure 3. In the blue box, there is a loss of mass (ΔM) as a result of fluid extraction during periods 0 to 1 (Figure 3a). Assuming that the fluid extraction conditions stay constant from period 0 to period 2, the mass loss that occurs goes through a shift in location, driving the fluid mass closer to the center (Figure 3b). The mass loss moves further to the left from period 2 to period 3, as illustrated in Figure 3c. This illustrates the fluid's progression from the left to the production well on the right, where it is ultimately extracted. And Figure 3d shows the total mass loss from period 0 to period 3, which demonstrates the fluid mass loss resulting from extraction from production wells during that period.

Naturally, the fluid in the reservoir undergoes movement as a result of the exploitation process, as the geothermal power plant in Lahendong continues to operate. Of course, it is crucial to determine how the geothermal fluid circulates within the reservoir. Barbier (2002) and Rybach (2003) found that sustainability can be achieved in Lahendong by ensuring that the amount extracted is equivalent to or less than the amount replaced. This is because it is associated with geothermal development. In the case of Lahendong, it is evident that the quantity of

fluid extracted exceeded the quantity of fluid returned. However, a natural recharge component is anticipated to compensate for the fluid that was lost as a result of the exploitation.

Consequently, it is crucial to identify how the fluid is transported within the reservoir, whether through extraction, injection back into the reservoir, or natural recharge, which replaces the fluid that is lost in the reservoir. Therefore, it is anticipated that it will be able to offer information on the balance of fluid movement within the reservoir, thereby ensuring the sustainability of geothermal energy utilization for a longer period.

2. MATERIAL AND METHOD

Gravity is a geophysical method that has been widely used by researchers to help identify geological structures beneath the surface (Gunadi Putra et al., 2021; Nainggolan et al., 2015; Natasia et al., 2016; Natul & Heliani, 2022; Pertiwi et al., 2023; Rosid et al., 2022, 2023; Sastranegara et al., 2015). However, regarding monitoring changes in mass, modification of this method is required. Differences in gravity values at the same location at different times can help explain differences in mass values that occur between these periods (Agung et al., 2023; Rosid et al., 2021). In the last four decades, time-lapse microgravity monitoring has been widely used in geothermal fields. The identification of fluid movement and mass redistribution in geothermal reservoirs is very important for the sustainability and development of geothermal fields. The studies carried out have explained many causes that might result in changes in gravity in operating geothermal fields (Agung, 2022; Agung et al., 2018; Allis & Hunt, 1986; Apuada & Olivar, 2005; Banos et al., 2020; Haq et al., 2019, 2023; Hunt, 2005; Menzies, 2011; Nishijima et al., 2005; Nordquist et al., 2004; Omollo, 2018; Omollo & Nishijima, 2024; Portier et al., 2021, 2022; Wardhani, 2023).

Gravity changes in micro scale ($\Delta \boldsymbol{g}$) measured on the surface are obtained from the results of gravity measurement readings at different periods between $\boldsymbol{g_{period1}}$ and $\boldsymbol{g_{period2}}$ (Nishijima et al., 2015). The difference between the gravity readings in the two periods describes the mass changes that occurred between those periods.

$$\Delta g = \left(g_{period2} - g_{period1}\right) \tag{1}$$

Hammer (1945) explained that Gauss theorem could be used to calculate mass from residual gravity anomaly data (LaFehr, 1965). The value of gravity in a certain area on the surface of the earth can be quantitatively determined by the value of the total mass beneath it by using the following equation:

$$M = \frac{1}{2\pi G} \iint_{S} \Delta g \, dS \tag{2}$$

where M is the total mass, G is the universal gravitational constant, S is the surface area covering the mass anomaly of interest, and Δg is the relative gravitational acceleration value. In time-lapse microgravity monitoring activities, the Δg value is the difference in gravity readings between two measurement periods.

By knowing the mass change value for each annual period, it is possible to estimate the movement of geothermal fluids that occur in the reservoir. Changes in the total loss or addition of mass resulting from calculations using Gauss theorem can provide an overview of fluid mass transfer from one location to another. This mass change is known from the results of annual time-lapse microgravity monitoring.

The time-lapse microgravity data in Lahendong used is for the period 2015, 2016, 2017, 2018, 2019, 2020, 2021, 2022, up to 2023. Around 118 Benchmark (BM) gravity is routinely monitored every year (Figure 4), and the distance between BM points is ± 200 m. Because UNIT-4 has been operating since 2011, monitoring data that has been carried out routinely since 2015 is assumed to have no significant changes in mass withdrawal; only in June 2017 was there a change in the injection scenario from the LHD-7 well to the LHD-51 well. Apart from that, all Lahendong microgravity time-lapse data has been corrected for the effects of changes in elevation and changes in shallow groundwater levels during each measurement period. So it is assumed that the detected change in gravity is the effect of mass changes that occur only in the reservoir due to exploitation.

The flow rate data for each well is cumulated according to the period the time-lapse microgravity monitoring was carried out. The analysis was carried out during the monitoring period every year and cumulatively for eight years from the beginning of 2015-2023. This was done in the hope of providing an overview of the movement of geothermal fluid changes that occurred in the reservoir during the monitoring period. The results of forward modeling using Gauss Theorm based on flow rate data for each well in Lahendong, show that the gravity changes that occur in Lahendong are estimated to reach -26 µGal (Figure 5), based on a study conducted by Agung et al. (2023), the optimum period for obtaining an overview of fluid mass movements in a reservoir using Scintrex CG-5 or CG-6 is a change in gravity of more than ±25 µGal. Therefore, the monitoring period carried out every year is optimal and is also carried out in the same season.

For each monitoring period, the total mass change is calculated from the results of microgravity monitoring, and a 3-D time-lapse microgravity inversion is carried out to obtain an estimate of the location and depth of the Lahendong reservoir fluid mass change. A detailed schematic flow chart for investigating the characteristics of reservoir fluid movement in Lahendong is shown in Figure 5.

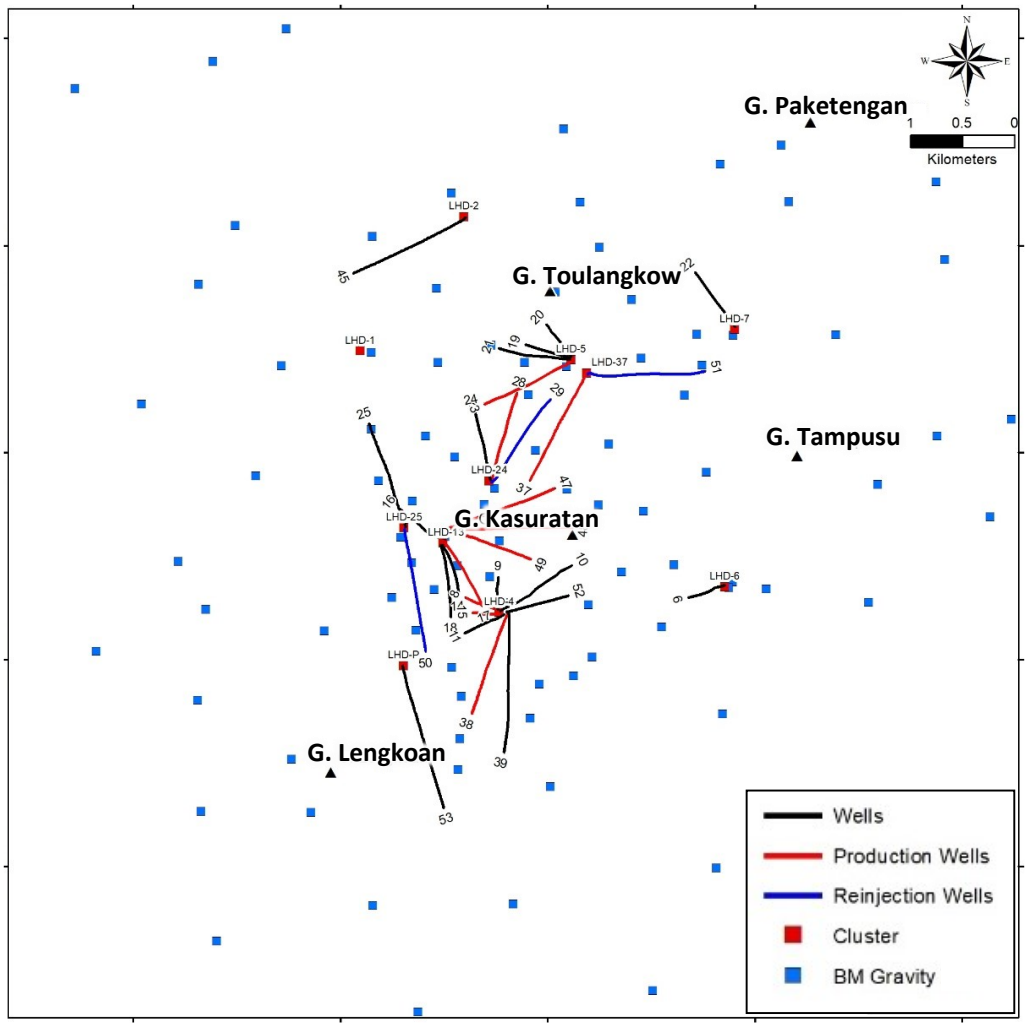

Figure 4: Benchmark microgravity monitoring Lahendong geothermal field.

3-D time-lapse microgravity inversion in Kamojang using the VOXI Modeling Tool in a Geosoft Oasis Montaj cloud and clustered computing module platform (Geosoft, 2024). The Geosoft platform uses the Catercian Cut Cell (CCC) method and an iterative re-weighting inversion algorithm developed by Ingram et al. (2003), and then simplified by Ellis and MacLeod (2013) in order to describe the geometry of the geological surface more efficiently, accurately, and simply than the previous Voxel model results. The iterative re-weighting least squares (IRLS) algorithm approach, which was originally developed by Lawson (1961), is applied to solve optimization problems that may occur iteratively using weighted least squares calculations. Regularization with the misfit function in this iterative inversion is applied to obtain a more stable solution between the observed values and the calculations. Conversely, the extent to which the predicted response matches the observed is influenced by reduced chi-squared misfit (Taylor & Thompson, 1982).

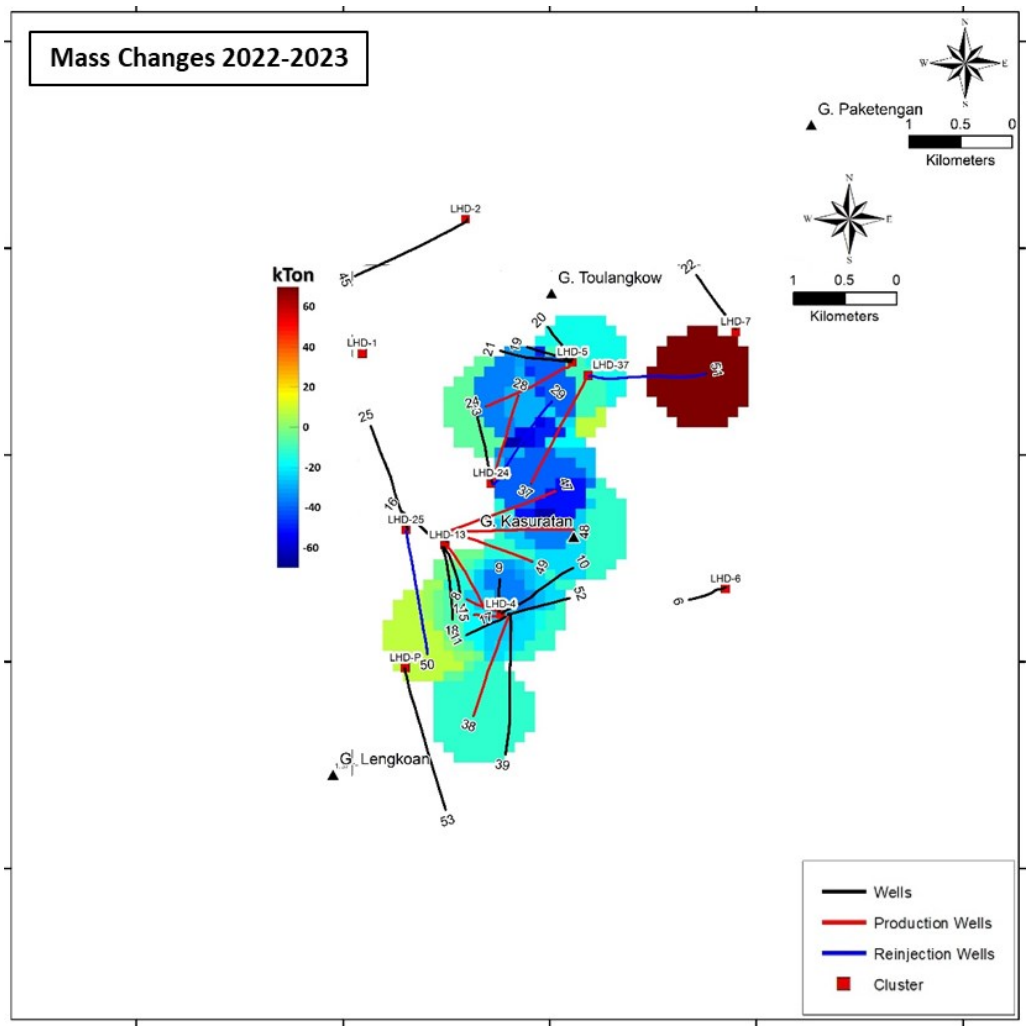

Figure 5: Changes in the mass of production and injection wells in the Lahendong geothermal field over 12 months.

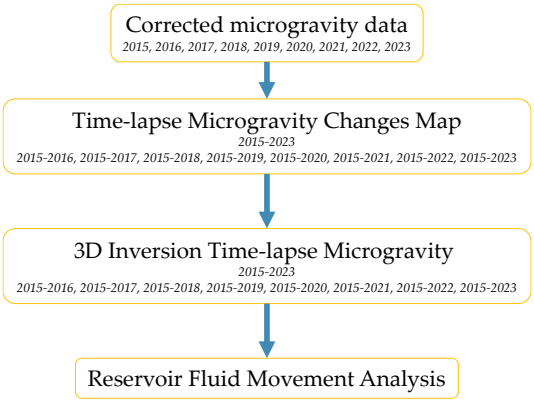

Figure 6: Flow chart investigation of reservoir fluid movement at Lahendong Geothermal Field.

In the 3-D inversion process, the microgravity time-lapse results are only modeled in the reservoir area. Gravity changes that occur near the surface due to the effects of changes in elevation and changes in groundwater levels have been corrected (Allis et al., 2000; Allis & Hunt, 1986). Apart from that, the mass changes that occurred in the Lahendong subsurface over a period of up to eight years are assumed to be only due to changes in fluid mass that occurred in the reservoir. In this very short monitoring period, the rock mass and lithology are considered to have not changed. So the 3-D time-lapse microgravity inversion carried out in Lahendong was only carried out from the top of the reservoir to a depth of around -2000 masl.

From the results of the analysis of gravity change maps during various monitoring periods, and the results of density changes from the results of 3-D inversion modeling, it is hoped that they will be able to describe the distribution of mass changes that occur in the Lahendong reservoir. So it can provide an overview of the fluid movements and dynamics that occur in the reservoir. In this way, it is hoped that we will be able to create a development strategy in the future that will maintain the sustainability of the use of geothermal energy in Lahendong.

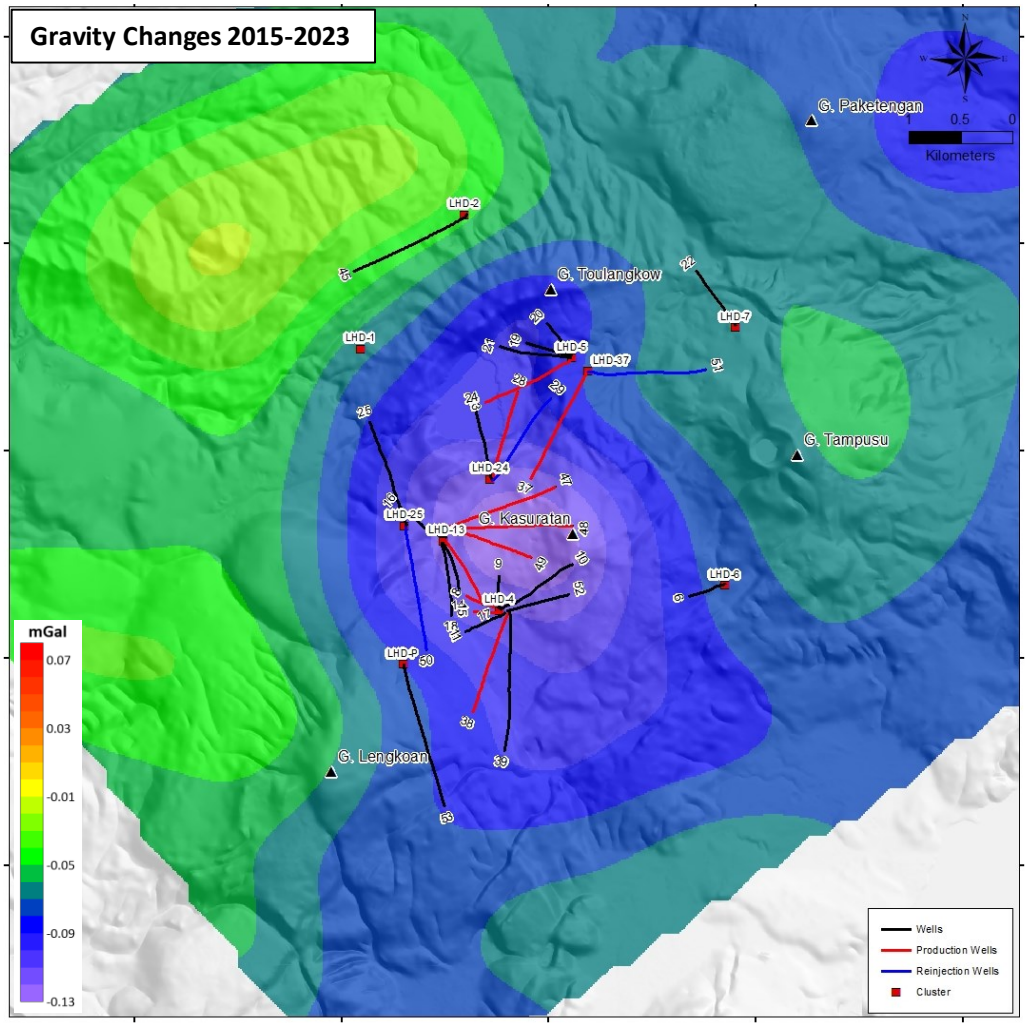

Figure 7: Map of microgravity changes between the 2015–2023 period.

3. RESULT

Figure 7 shows the results of time-lapse microgravity monitoring from 2015–2023, depicting a large decrease in gravity in the zone area near the production wells in Lahendong, which illustrates the occurrence of mass loss in that area. However, interestingly, there is an area in the southern part of the production zone that also experiences a decrease in gravity, meaning that this southern area is also affected by mass extraction in the Lahendong reservoir.

This is also illustrated by the results of annual cumulative gravity monitoring shown in Figure 8, the occurrence of mass loss in the southern area, and the results of time-lapse microgravity monitoring in several periods, including 2015–2016, 2018–2019, and 2021–2022. The loss of mass far from this reservoir also indicates fluid movement from the south towards the Lahendong reservoir.

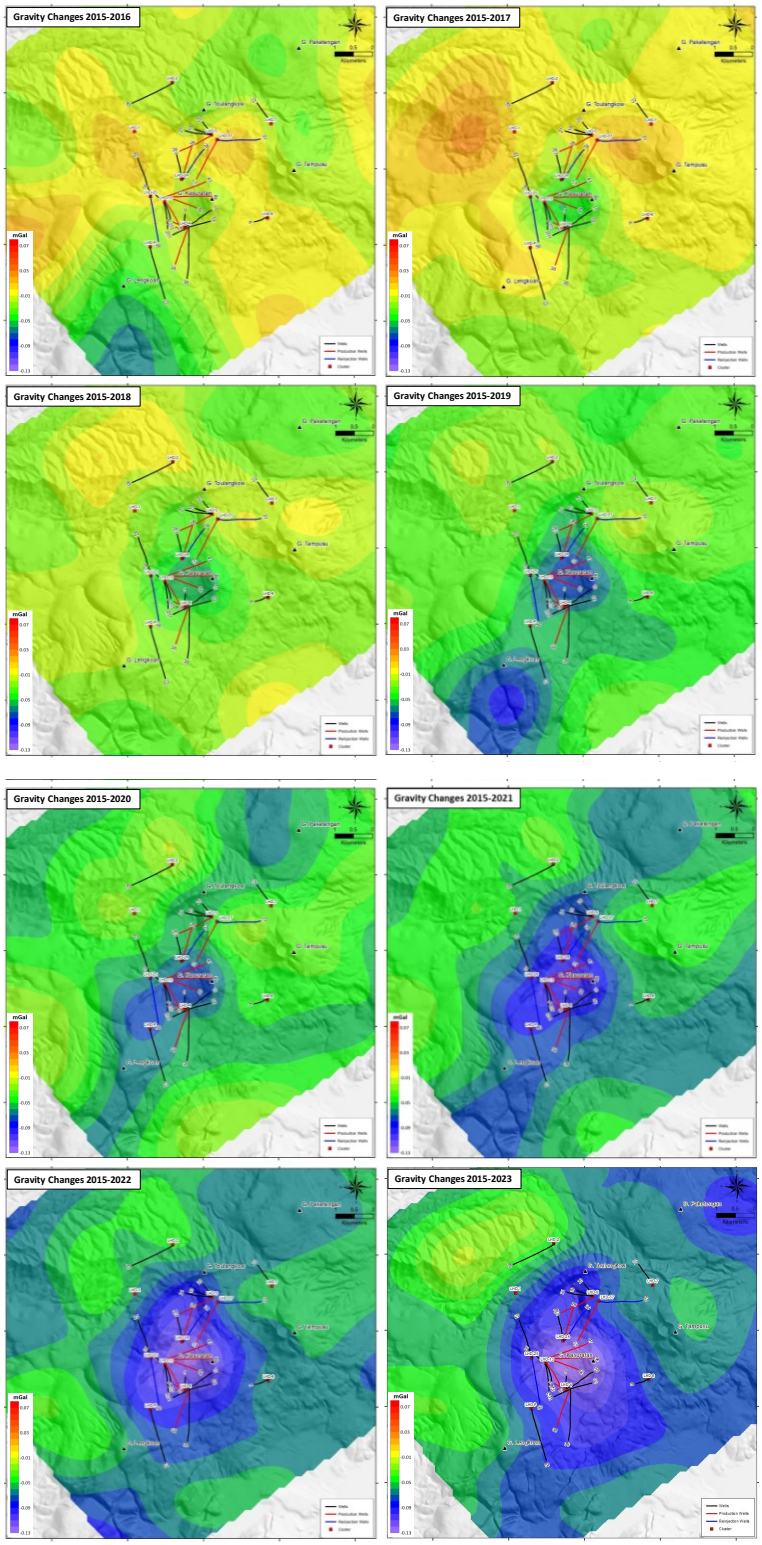

Figure 8: Cumulative map of microgravity changes from 2015 to 2023.

The map of cumulative time-lapse microgravity monitoring results from 2015 to 2023 shown in Figure 8 also provides information that there is an increase in mass in the northern area of the production zone. This is interpreted to be related to production activity in the northern area, originating from wells LHD-7 and LHD-51. This is also in accordance with the map of estimated mass changes resulting from each well, which was previously shown in Figure 5.

To be able to see the position of mass changes both horizontally and vertically, a 3-D inversion was carried out based on the results of time-lapse microgravity monitoring. Because the measured changes in gravity have been

corrected for the effects of changes in elevation and changes in shallow groundwater levels, it is assumed that these measured changes in gravity are only due to the effects of changes in mass in the reservoir. Therefore, the density changes calculated in this 3-D inversion process only originate in the reservoir. The distribution of areas experiencing mass changes in the reservoir in the constraint uses the elevation distribution of the Base of Conductor (BoC) in Lahendong as the Lahendong Top Reservoir. Figure 9 shows the elevation distribution of the BoC in Lahendong, from the BoC results to an elevation of -3000 masl as the basis for the area experiencing mass changes in the Lahendong reservoir due to exploitation.

Cumulatively, the results of 3-D time-lapse microgravity inversion from 2015–2023 show that mass changes occurred at elevations of 500 masl to -3000 masl, with a decrease in density focused in areas near production wells with variations between -1 kg/m^3 and -3 kg/m^3 (Figure 10). From Figure 10, it can also be seen that there is an increase in mass of +1 kg/m^3 to +3 kg/m^3 in the North, Sealtan, and a small part near the LHD-28, LHD-29, and LHD-51 wells. This increase in mass in the northern part may be correlated with injection well activity at LHD-7 and LHD-51, while in the southern part, it may be correlated with the entry of natural recharge in the southern area.

The entry of natural recharge in the southern area is also in accordance with pressure and temperature data from the LHD-53/LHD-P1 well in this area, which indicates the presence of cold fluid entering from the south into the Lahendong reservoir zone. This can also be seen from the results of the 3D inversion time-lapse microgravity shown in Figure 11. The addition of mass in the southern area is slowly entering and approaching the reservoir zone from year to year. However, the effect of the additional mass coming from the south needs to be studied further in order to obtain more comprehensive results regarding the impact on production wells due to the influx of fluid from the south and whether it has a good or bad impact regarding the sustainability of geothermal development in Lahendong, considering the 3D results. The mass inversion that occurs in this southern area is relatively shallow, namely at an elevation of -1000 masl.

The results of the 3D inversion time-lapse Lahendong microgravity shown in Figure 11 also help in identifying fluid movements that occur in the northern part of the Lahendong reservoir. The addition of mass from the north near the LHD-7 and LHD-51 wells, which are approaching the reservoir zone, illustrates the recycling of geothermal injection fluid into the reservoir, so it is hoped that a better balance between production and injection can be achieved. In terms of position, the mass addition that occurs in the northern part is at a deeper elevation, namely at an elevation of -2000 masl. The injection fluid is relatively cooler after being utilized at the surface, and it is hoped that this deeper position of mass addition, when re-injected into the reservoir, will have enough time to be reheated before entering the reservoir and being used for generation.

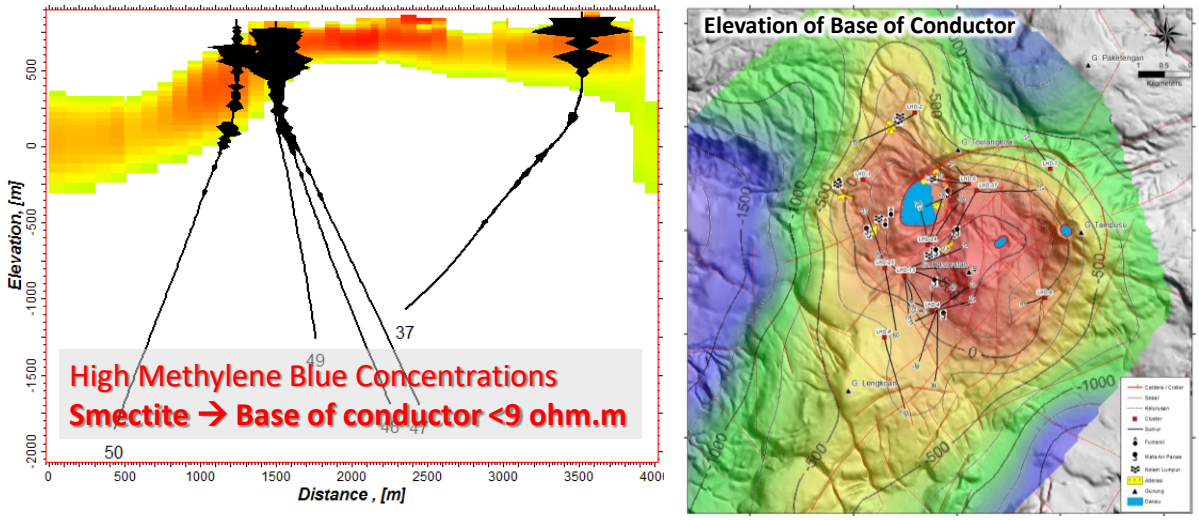

Figure 9: Base of conductor characteristic at Lahendong geothermal Field.

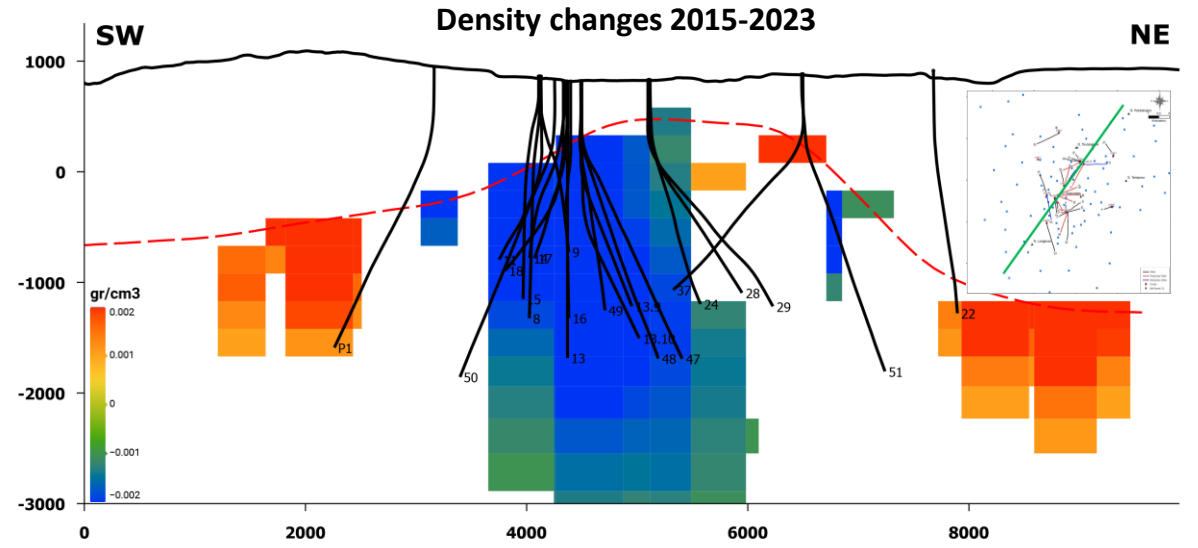

Figure 10: Density changes based on 3D inversion time-lapse microgravity monitoring from 2015-2023.

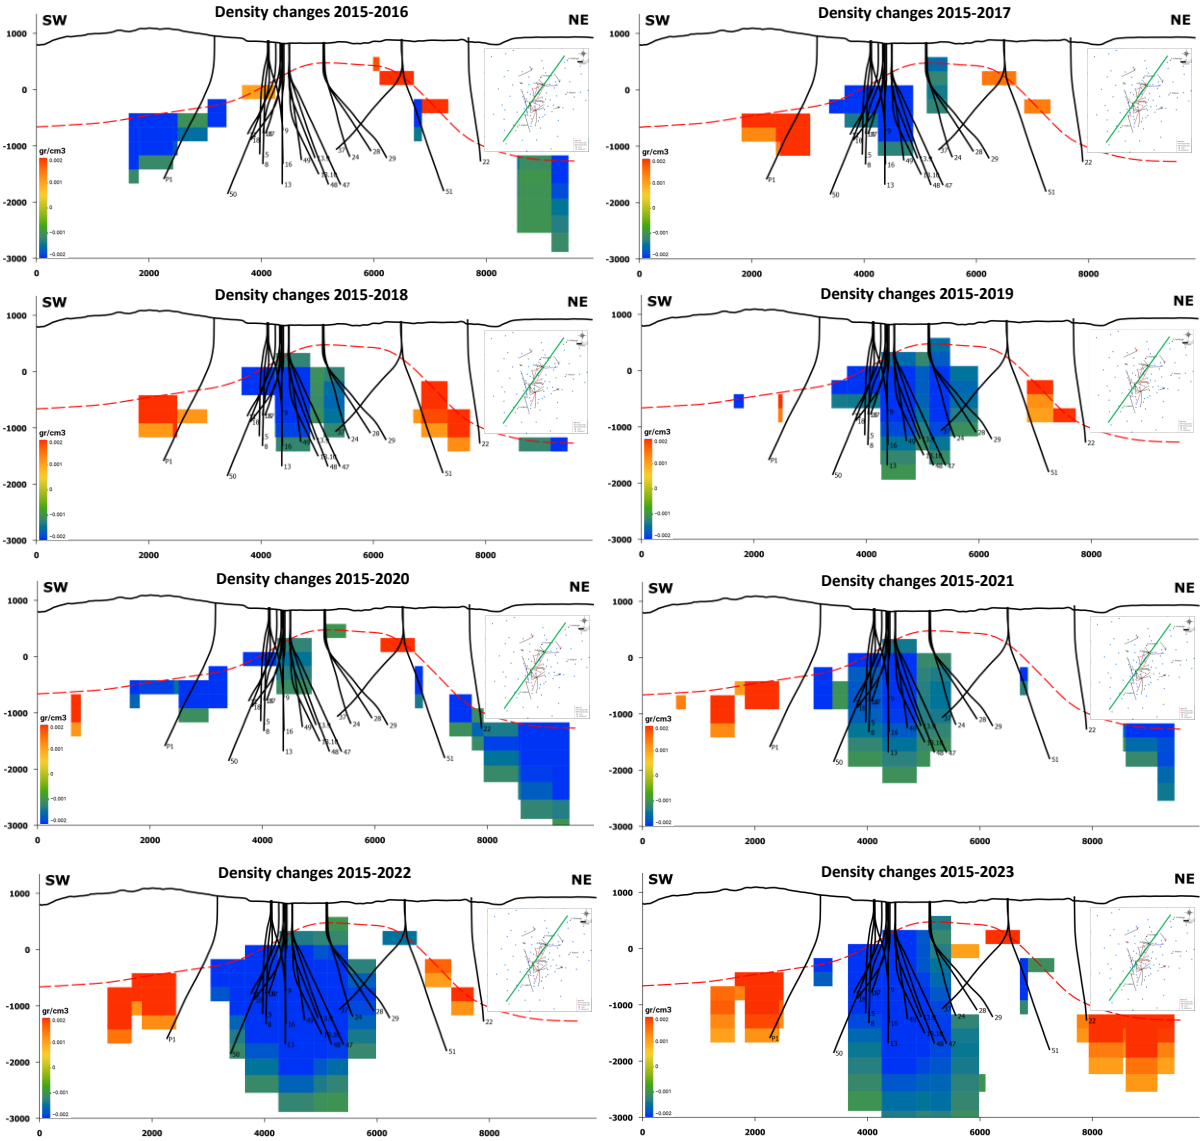

Figure 11: Cumulative annual density changes based on 3D inversion time-lapse microgravity monitoring at Lahendong from 2015-2023.

4. CONCLUSION

An overview of the movement of geothermal fluids in the reservoir can be obtained from the results of time-lapse microgravity monitoring in Lahendong. The position of mass changes in the reservoir, particularly in relation to depth, can be determined through 3D inversion calculations from time-lapse microgravity monitoring. The density decrease in the Lahendong reservoir, which is typically in close proximity to production wells in Lahendong, was observed at elevations ranging from 500 masl to -3000 masl, which is interpreted of mass loss.

The results of 3D inversion time-lapse microgravity monitoring can also be used to identify the dynamics of the injection fluid movement from the LHD-7 and LHD-51 wells. Initially, the injection fluid was detected at an elevation of approximately -2000 masl. Later, the fluid relocated to the production zone at a shallower elevation. The results of 3D inversion time-lapse microgravity monitoring also revealed the movement of natural recharge fluid in the southern part of the Lahendong reservoir. In contrast to injection fluid, the movement of natural recharge fluid in the southern region is characterized by lateral movement at an elevation of approximately -1000 masl. In order to evaluate the impact of the influx of these fluids on the productivity of the reservoir's wells, it is necessary to conduct additional monitoring of the effects of the movement of injection and production fluids.

ACKNOWLEDGMENTS

We express our gratitude on this special occasion to acknowledge the invaluable support provided by the management and geophysics team of the PT. Pertamina Geothermal Energy Tbk during the data collection process, software, and equipment for this study. Further- more, we would like to express our sincere appreciation for the constructive comments provided by the peer reviewer(s) who carefully reviewed and offered insightful feedback on this manuscript.

Keywords: Electrical Resistivity, Gradient Thermal, Sumani, Way Selabung, Kadidia

ABSTRACT

Geothermal field exploration is still not fast due to the high risk of drilling failure (in some fields, it can reach more than 60%). Therefore, additional data, besides magnetotelluric model results, is needed to reduce well drilling failures. One way to decrease drilling failure is by finding the relationship between the electrical resistivity modeling results from Magnetotelluric (MT) data and thermal gradient data from shallow well temperature slope data. This research was conducted in Sumani, Way Selabung, and Kadidia. The preliminary analysis results of the MT cross-section model with well data in the Sumani, Way Selabung, and Kadidia fields show variations in the relationship between electrical resistivity and thermal gradient. In general, the correlation analysis results between electrical resistivity and temperature gradient show an inverse relationship, where an increase in resistivity tends to indicate a decrease in the temperature gradient.

In the Sumani field, the gradient is -1.29 with a coefficient of determination of 0.38. In the Way Selabung field, the gradient is -0.07 with a coefficient of determination of 0.81, and in the Kadidia field, the gradient is -0.0039 with a coefficient of determination of 0.0005. The strongest relationship between the two variables is found in the Way Selabung geothermal field. The variation in temperature gradient values is not only influenced by electrical resistivity values. Several other factors, such as geological conditions, lithology, the amount and type of clay minerals, and water content in the formation, should be considered in this empirical relationship result.

1. INTRODUCTION

1.1 Background

Geothermal energy is a potential renewable energy source alternative to conventional energy sources. Indonesia is one of the countries with the largest geothermal energy potential in the world. Sumani, Way Selabung, and Kadidia geothermal fields are three areas that show significant potential in the exploration and utilization of geothermal energy in Indonesia. The magnetotelluric method is commonly used in geothermal exploration to examine subsurface characteristics. The 2D model of this method can show the electrical resistivity value per depth. A correlation analysis between electrical resistivity and thermal gradient was conducted to support the development of geothermal energy in Indonesia.

1.2 Geology

1.2.1 Sumani

The Sumani geothermal area had lithologies in the form of metamorphic rock units, sedimentary rocks, intrusive rocks, volcanic rocks, and surface deposits. Old (Tertiary) rock units occupied the rocks in the eastern part of the area. The western part of the area generally consisted of younger rock units, except for Meta Limestone, which was exposed in the northwest.

The fault structure in this area generally followed the northwest-southeast direction of the Sumatra fault and the southwest-northeast direction of the fault as a secondary structure. These fault structures controlled the emergence of hot springs at the surface, indicating the presence of geothermal potential at the study site.

The geothermal system in the Sumani area was formed by the residual heat of the magma chamber due to the last volcanic activity of the Tinjau Laut complex during the Pliocene. The residual heat acted as a heat source that heated the subsurface water, which then rose through cracks/fractures and was trapped in a geothermal reservoir. This reservoir was thought to be found in the Meta Limestone rock unit, which was rich in fractures and permeable.

1.2.2 Way Selabung

Based on the tectonic setting, the Way Selabung geothermal field was located in a magmatic arc and right on one of the southern Sumatra fault segments. The constituent rocks in the survey area were dominated by volcanic rocks and clastic sedimentary rocks from the Tertiary to Quaternary ages. The rock units in order from young to old were as follows: Akarjangkang Lava, Sandstone, Asadimana Lava, Pematang Gong Lava, Old Breccia, Ranau Pyroclastic Flow, Sapatuhu Pyroclastic Flow, Ranau Pyroclastic Fall, aai Lava, Bengkong Lava, Pandan Lava, Gedang Lava, Perean Lava, Tebat Gayat Lava, and Aluvium deposits.

The dominant geological structure in the survey area had a northwest-southeast direction pattern that was cut by faults with southwest-northeast and north-south directions. The faults in the survey area were grouped into three main direction patterns: northwest-southeast, north-south, and southwest-northeast. The northwest-southeast fault pattern was cut by other faults with north-south and southwest-northeast patterns that were thought to be younger. The north-south fault pattern followed the Sunda pattern, which formed in the Eocene and was thought to be an old fault. The southwest-northeast fault pattern was in the opposite direction from the Sumatra fault. This fault was thought to be its antithesis.

1.2.3 Kadidia

The Kadidia geothermal area was composed of volcanic products such as lava rocks and andesite breccia. The process of magmatism had produced plutonic granite. This plutonic granite rock was estimated to be from the Plio-Pleistocene era. It intruded on older rock units and was associated with the heat still present in the underlying rock units. At least eight lithologies of plutonic rocks have formed since the formation of the metagranite.

Regionally, the Kadidia geothermal area was controlled by the Palu Koro fault to the west. This fault trended northwest-southeast. Additionally, there was the Koala Rawa basement fault, which trended almost north-south. This fault was suspected to form a permeable zone. In the Kadidia geothermal area, there was a pull-apart mechanism that created a pull-apart basin. This basin was filled with sedimentary materials such as colluvium, lake deposits, alluvium deposits, and alluvial fans.

2. METHODS

2.1 2D Magnetotelluric Inverse Modeling

The data used in this study are *.EDI files were obtained from magnetotelluric measurements in the Sumani, Way Selabung, and Kadidia geothermal fields. An inverse modeling process was then conducted to obtain a model of the resistivity distribution as a function of depth and horizontal distance (2D model). This process was done using WinGlink interpretation software. The 2D electrical resistivity modeling results were analyzed to determine its correlation with the temperature gradient.

2.2 Calculated the thermal gradient

The thermal gradient was calculated at each depth layer with the same electrical resistivity value to determine the correlation between electrical resistivity and thermal gradient. The calculation results were presented as a curve where the electrical resistivity alue was on the x-axis, and the thermal gradient was on the y-axis. The linear regression method obtained a straight-line equation describing the relationship between the two variables. The relation between electrical resistivity and temperature gradient is then correlated with lithological conditions and characteristics based on shallow well data.

3. RESULT AND DISCUSSION

3.1 Result

3.1.1 Sumani

A conductive rock layer is modeled in the 2D resistivity section (Figure 1), thickening towards the northeast. This layer exhibits resistivity values ranging from 2 to 15 Ωm. In the area around the hot spring manifestation, the conductive layer is modeled from the surface to an elevation of -500 meters above sea level.

The SMN1 temperature gradient well is located between points MTSM56 and MTSM50, with an elevation reaching -156 meters above sea level. Six temperature gradient values were obtained by correlating with the same resistivity values (Figure 2). A high-temperature gradient increase, reaching 20.5 ℃/100 m, is observed from the surface to 400 meters above sea level. Subsequently, the temperature gradient significantly decreases to 10.1 ℃/100 m until an elevation of 180 meters above sea level. The temperature gradient then rises again to 10.8 ℃/100 m, reaching an elevation of -156 meters above sea level.

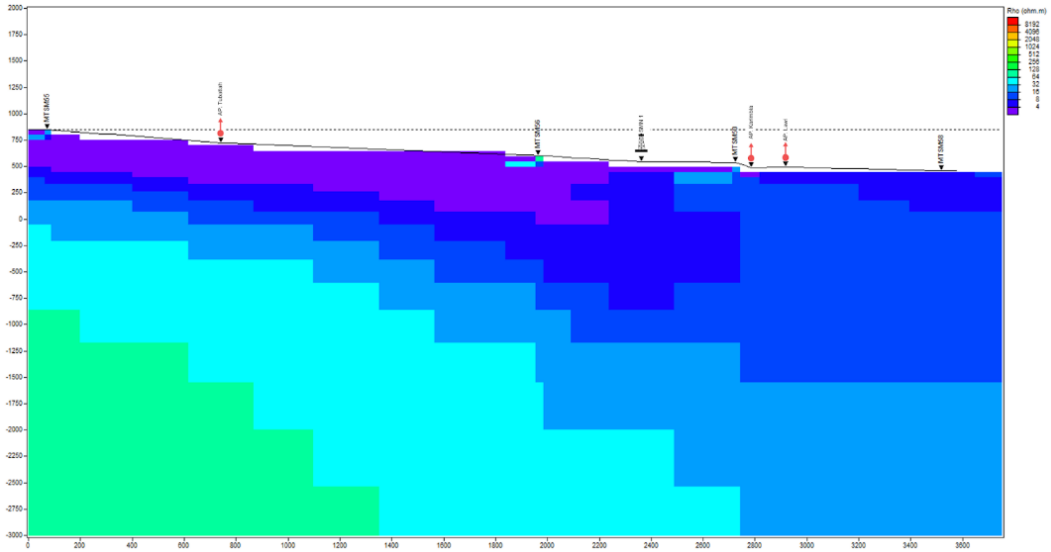

Figure 1: The resistivity model of Sumani geothermal field. The model included magnetotelluric survey points MTSM55, MTSM56, MTSM50, and MTSM58. The SMN1 is location of the temperature gradient well, which is at an elevation of 544 m above sea level and had a depth of 700 m.

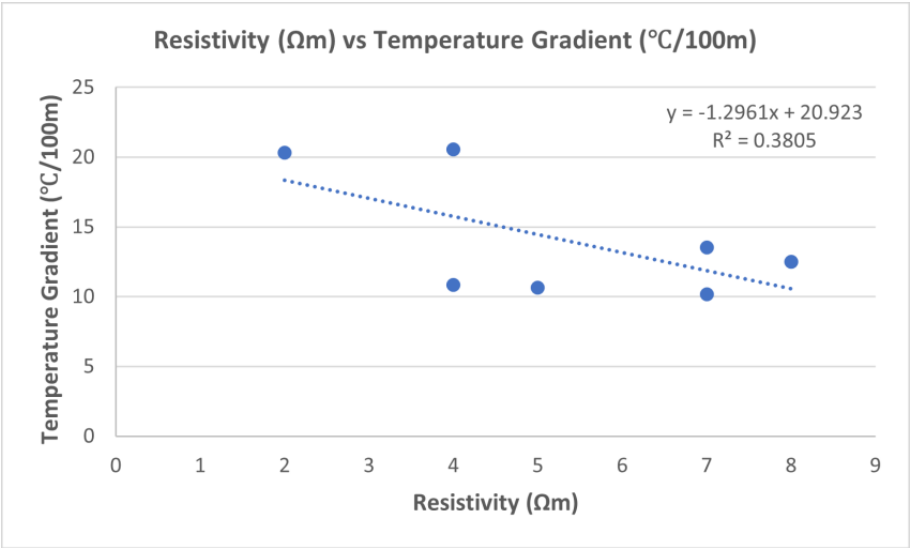

Figure 2: A comparison graph of electrical resistivity values with temperature gradient values per 100 meters showed negative gradient values, indicating that in the Sumani field, as resistivity increases, the temperature gradient decreases.

The 2D resistivity cross-section (Figure 3) shows a layer of rock with low resistivity in the southwest and northeast at a depth of about 550 – 1250 m. This low resistivity is caused by alteration rocks that become the cap rock of the Way Selabung geothermal system. Below the low resistivity zone is a medium resistivity, interpreted as a reservoir zone. To the northeast, the medium resistivity is associated with sedimentary rocks. The high resistivity at the bottom is considered resistive compact sedimentary rock. In contrast, in the southwest, the high resistivity below the medium resistivity layer is considered igneous rock, which is the heat source of the geothermal system.

Temperature slope well WSL1 is located between points MTWS43 and MTWS43A at a depth of 700m to an elevation of -150m above sea level. By correlating the resistivity values, nine temperature gradient values were obtained (Figure 4). The increase in temperature gradient is high, reaching 5.74°C/100 m from elevation 167.9 to 63.5 meter above sea level, while at the surface up to elevation 388.46 meter above sea level, the temperature gradient tends to be low at 1.96-2.05 °C/100 m.

3.1.2 Way Selabung

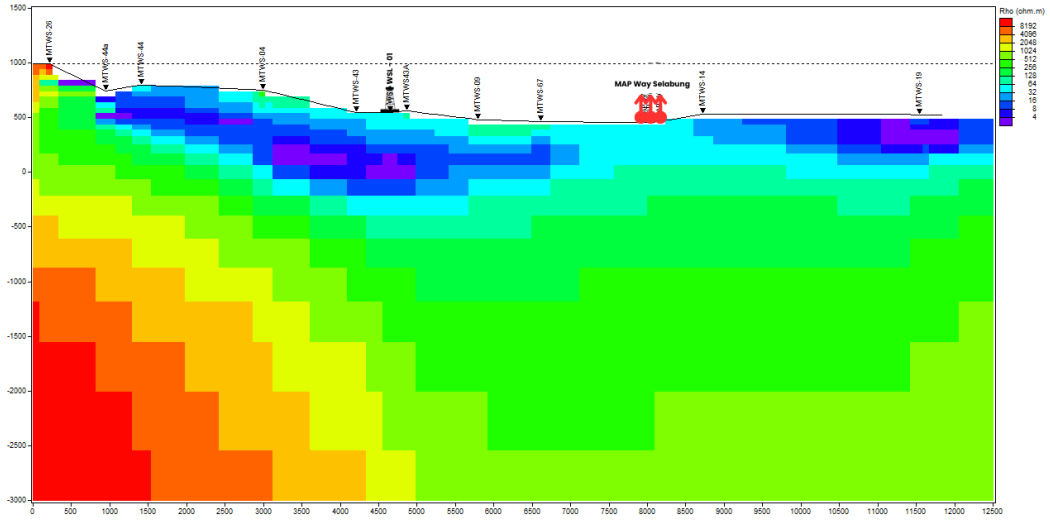

Figure 3: The resistivity model of Way Selabung geothermal field (Line 5). The model included magnetotelluric survey points MTWS-04, MTWS-09, MTWS 14, MTWS-19, MTWS-26, MTWS-43, MTWS-43a, MTWS-44, MTWS-44a, and MTWS-67. The WSL-01 is location of the temperature gradient well, which is at an elevation of 550 m above sea level and had a depth of 700 m.

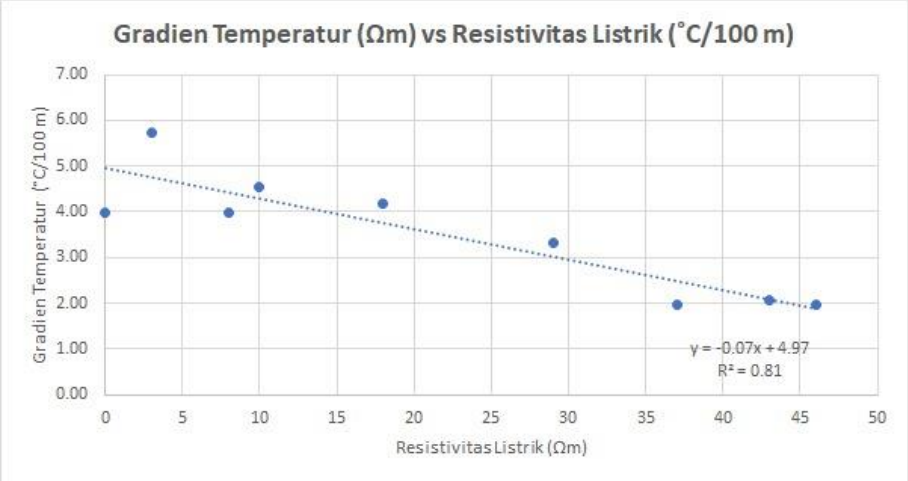

Figure 4: A comparison graph of electrical resistivity values with temperature gradient values per 100 meters showed negative gradient values, indicating that in the Way Selabung field, as resistivity increases, the temperature gradient decreases.

3.1.3 Kadidia

There was a conductive layer in the electrical resistivity model of Kadidia Line 8, which extends from south to north. This layer was located at around 300 meters above sea level. There was a manifestation of a hot spring at point MTKD34. Near this point, there was a temperature gradient well.

The KDD-1 well (Figure 5) had a depth of 700 meters and was situated at an elevation of 632 m. According to the well data, the temperature at the lowest depth was 27 ˚C. At a depth of 700 meters, the temperature was 96.8 ˚C. The temperature gradient value obtained for this well was 12.8 ˚C/100 m.

3.2 Discussion

At the Sumani field, the temperature gradient graph as a function of resistivity is obtained with the linear equation y = -1.3x + 20.92 R2 = 0.38. A moderate negative relationship is observed between electrical resistivity and the temperature gradient. An increase in electrical resistivity tends to be followed by a decrease in the temperature gradient. The coefficient of determination value indicates that approximately 38.05% of the variability in the temperature gradient can be explained by changes in electrical resistivity. Most of the variation in the temperature

gradient is caused by factors other than electrical resistivity, such as variations in lithology types, clay mineral content and type, alteration intensity, water content, and geological structure.

At 495.9 to 398.0 meters above sea level elevations, low resistivity values (2 – 4 Ωm) correspond with high-temperature gradients (20.3 – 20.5 ℃/100m). This correlates with lithologies consisting of Tuff Breccia, Andesite, and Andesite Breccia with weak to moderate alteration intensity. The dominant secondary minerals are clay minerals, including smectite and montmorillonite.

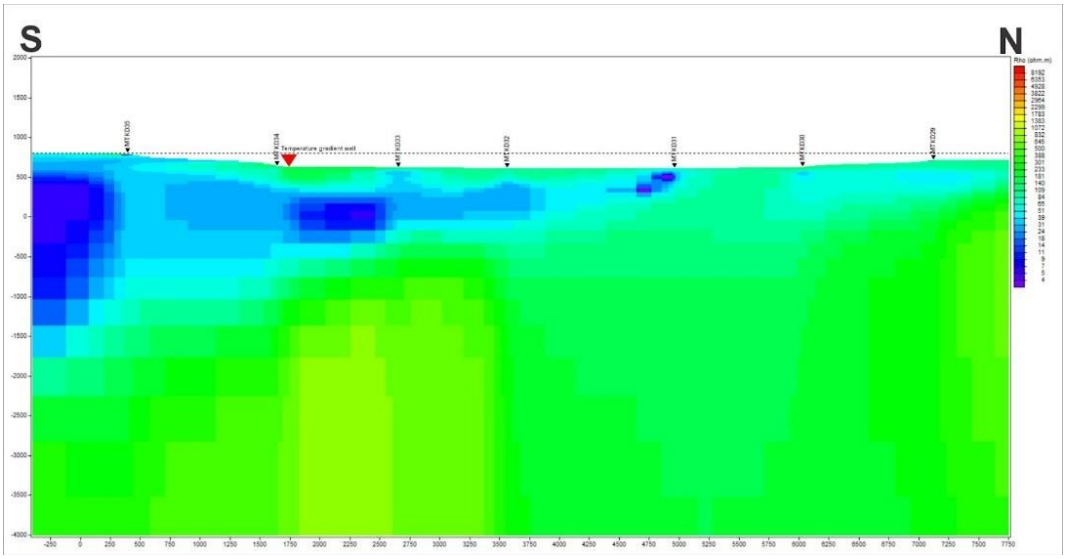

Figure 5: The resistivity model of Kadidia Line 8. The model included magnetotelluric survey points MTKD 35, 34, 33, 32, 30, 29. The red triangle indicated the location of the temperature gradient well, which is at an elevation of 632 m above sea level and had a depth of 700 m.

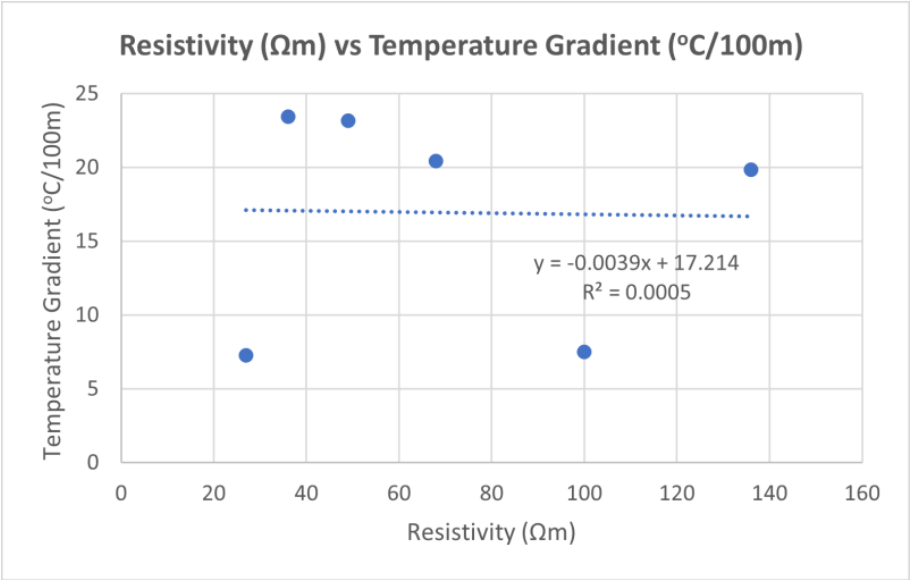

Figure 6: A comparison graph of electrical resistivity values with temperature gradient values per 100 meters showed negative gradient values, indicating that in the Kadidia field, as resistivity increases, the temperature gradient decreases.

At 398.0 to 178.3 meters above sea level, the thermal gradient experiences a significant decrease. This correlates with Ca (Calcite) and Ch (Chlorite) minerals, which are quite dominant. Calcite and Chlorite minerals have a higher specific heat capacity than smectite, significantly decreasing the thermal gradient. At 266.9 meters above sea level elevations to -156 meters above sea level, the resistivity values decrease, which is suspected to be due to contact with water formation in the area.

At the Way Selabung field, a linear equation y = -0.07x + 4.97 R2 = 0.81 is obtained from the temperature gradient graph as a resistivity function. There is an opposite relationship between electrical resistivity and temperature gradient, where an increase in electrical resistivity tends to be followed by a decrease in temperature gradient. The

coefficient of determination shows that about 80% of the variability in temperature gradient can be explained by changes in electrical resistivity. This indicates a strong relationship between the two variables.

At 539.3 to 168 meters above sea level, the resistivity values decreased from 46 Ωm to 10 Ωm. In contrast, the temperature gradient increased from 2˚C/100m to 5.7 ˚C/100m. This corresponds to the increasing intensity of alteration and decreasing Iron Oxide content in the soil, Breccia Tuff, and Tuff lithologies. The temperature gradient decreased to the maximum depth of the well at elevation -137 meters above sea level with a value of 4˚C/100m. The decrease in resistivity value to the bottom of the well reflects the sedimentary rock layer that begins to appear at a depth of 663.9 m.

At the Kadidia geothermal field, the temperature gradient graph (Figure 6) showed the linear equation $y = -0.0039x + 17.214$ with $R^2 = 0.0005$. A negative correlation was shown between the temperature gradient and electrical resistivity values. The higher the resistivity value, the smaller the thermal gradient value.

At a depth of 35 m, the thermal gradient value was 19.8℃/100m with a resistivity value of 135 Ω m. At that depth, the lithology was soil. The alteration level present was classified as weak. Next, at depths down to 181 m, there was a decrease in the thermal gradient value to 7.5 ℃/100m. This correlated with sandstone lithology, which has very low alteration levels. There was also a circulation loss, causing an imbalance between the hydrostatic mud and formation pressure.

At 181 m to 319 m depths, the thermal gradient gradually increased from 20℃/100m to 23℃/100m. The resistivity values decreased from 68 Ωm to 36 Ωm. This correlated with conglomerate lithology interspersed with sandstone and quartz sandstone. The alteration level also increased at these depths. Subsequently, from depths of 319 meters to 700 meters, the thermal gradient value decreased to 7.2℃/100m. The lithology at those depths consisted of alternating breccia, sandstone, claystone, and breccia at the bottom. There was loss circulation below a depth of 550 m, with an increase in the alteration level reaching strong at the bottom of the well.

4. CONCLUSION

The graph comparing temperature gradient values at the Sumani, Way Selabung, and Kadidia geothermal fields showed a negative relationship. When resistivity values decreased, the temperature gradient values increased. Kadidia had the highest gradient value in the comparison graph, while Sumani had the lowest. The differences in gradient values on the resistivity and temperature gradient comparison graph might have been influenced by the type of heat source at each geothermal field. The Sumani field had a notably lower gradient than Kadidia. Way Selabung exhibited intermediate gradient values. Each field's unique geological characteristics likely played a role in these variations.

ACKNOWLEDGEMENT

The author wishes to sincerely thank IIGCE 2024 for the opportunity to write this paper. Special thanks are due to Ms. Sintia for her invaluable guidance and encouragement throughout this process. Her expertise and insights have significantly enhanced the quality of this work. Thanks to Mr. Asep Sugianto and Mr. Tony Rahadinata from PSDMBP for their assistance and support. Their contributions have been vital in the completion of this research. The author values their willingness to offer valuable information and resources.

Keywords: Wayang Windu, geothermal laboratory, laboratory accreditation, laboratory analysis, geochemical fluid, laboratory management

ABSTRACT

Wayang Windu Geothermal Field (WWGF) has been operating since 2000. Its successful operation has been significantly supported by the in-house laboratory, which has been functioning since the construction of the first unit. The laboratory provides water and gas analyses as part of Wayang Windu reservoir surveillance and monitoring program in managing reservoir performance and Power Plant Operation. Beyond internal assets, the laboratory also analyzes samples from other companies and commercial laboratories as part of its quality control management, known as the blind test procedure. In 2012, the laboratory was revitalized in alignment with the company's development strategy to achieve an efficient, high-performance facility. Since then, it has expanded its capabilities to analyze major water and gas parameters for reservoir surveillance monitoring, steam purity, environment, domestic needs, and resource assessment for exploration prospects. The laboratory also conducts Hazardous & Non-Hazardous Waste Management during activity. Over the years, this revitalization has maintained high-quality analysis procedures, annual cost savings, and a commitment to becoming a trustworthy laboratory. The laboratory achieved ISO17025 accreditation in 2018 as a testing laboratory under the umbrella of ISO9001. These milestones were not limited to the certification process but also reflected the goal of enhancing human resources alongside facility and equipment capabilities. Most importantly, the continuous development of laboratory management has provided sustainable support for the company's growth.

1. INTRODUCTION

Wayang Windu Geothermal Power Plant is one of Indonesia's biggest operating geothermal fields, currently operated by Star Energy Geothermal (SEG). It started the operation with the first unit in 2000, further expanding its capacity with the 2nd unit in 2006 to generate 227 MW of electricity. The current generation is taken from 28 production wells and 2 injection wells. Among those 28 production wells, 4 of them are two-phase wells. With such power plant operation, the fluid chemistry must be monitored to ensure the safety operating procedure, track the reservoir process, and continuously update the conceptual model. Considering this critical necessity for geothermal operation, Wayang Windu established a non-commercial laboratory, later called as in-house lab, which supports fluid sampling and analysis for internal SEG needs. It is located in the power plant building of Wayang Windu Geothermal Field (WWGF) (Figure 1).

The operation of in-house lab began since the exploration stage in 1997 with limited capabilities, continuously improving over time until able to fully support geochemistry surveillance for more than a decade. Fluid chemistry sampling and analysis that conducted regularly, has become a main scope of in-house lab activities. Monitoring wells for reservoir performance is the primary deliverable which covers more than 50% of the laboratory scope (Figure 2). Power plant is the next client supported by the in-house lab through sampling and analysis conducted in several sampling points in pipeline, scrubbers, and cooling towers. Additional scope for domestic water and environment samples are also covered by the lab.

2. CONTINUOUS IMPROVEMENT OF LABORATORY CAPABILITIES

The geothermal laboratory plays a crucial role in advancing geothermal technology by providing valuable data and insights for continuous improvement and importantly for reservoir management. The facility enables the scientist to analyze and collect samples from the geothermal wells, manifestation, and other locations (surface line, environment, domestic, etc.), monitor changes in fluid chemistry over time, investigate the issues, and develop strategies to improve the performance.

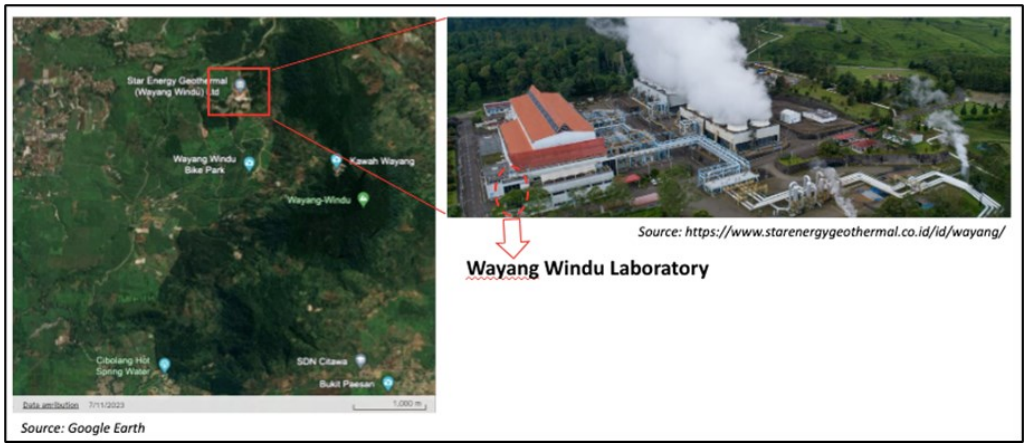

Figure 1: Aerial view of the Wayang Windu Geothermal Field and power plant facilities. Wayang Windu laboratory located inside the main building.

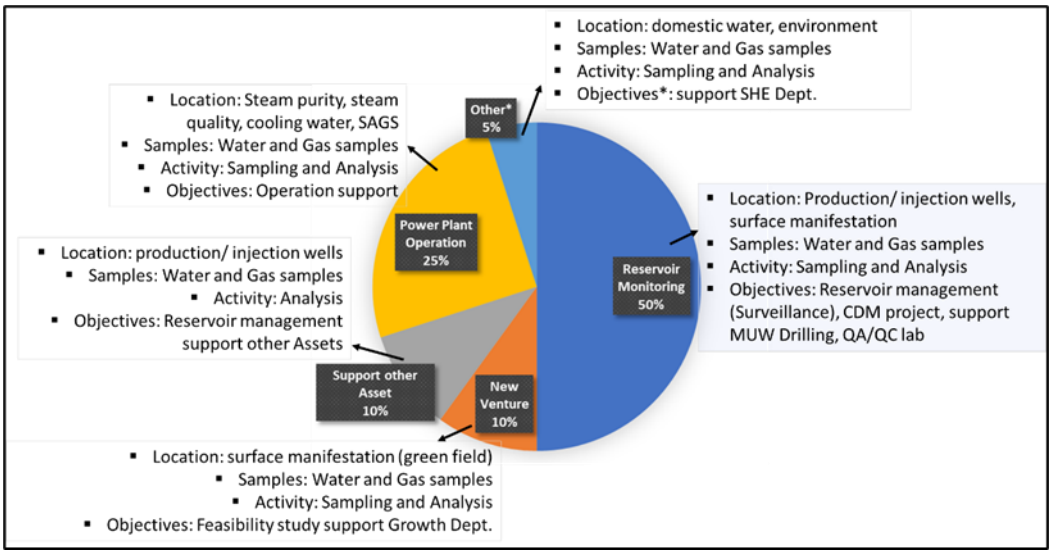

Figure 2: The proportion of scope of services and clients of the in-house laboratory.

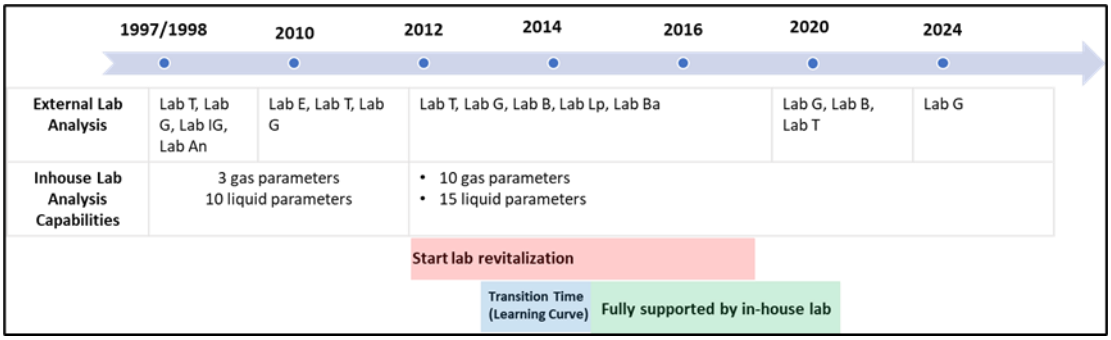

Figure 3: The involvement of external lab was changed overtime, followed by improvement of in-house lab capabilities. The table shows a significant addition of parameters after lab revitalization began, and reduced the number of external laboratories.

With the scope of work majority on the fluid analysis, it becomes crucial that the in-house laboratory establishes a proper management system called Good Laboratory Practice as first stated in The New Zealand Testing Laboratory Registration Act of 1972 (Faridah, 2018). Thus, Wayang Windu Laboratory initiated the Laboratory Revitalization Project in 2012 to implement the good laboratory practice referred to ISO17025 regulation.

Several commercial laboratories involved since the beginning of Wayang Windu Unit-1 which contributed to major improvement of the current processes (Figure 3). It has historically reduced the use of external laboratory services, by adding major equipment like Ion and Gas Chromatograph that significantly contributed to cost savings and increased laboratory personnel laboratory capabilities at the same time. It made the in-house lab add more 7

gas and 5 liquid parameters to analyze (Figure 3), which are the complete parameters necessary for reservoir characterization. However, those commercial labs are positioned as the external QC tool to Wayang Windu laboratory or involved in a blind test procedure (Figure 4).

With the complexities of sampling and analysis activity, the laboratory performance must maintain its quality to get reliable results. Routine calibration and maintenance are crucial actions to keep the equipment in good performance, blind tests and external audits are also considered as the key to good laboratory practice (Faridah, 2018). Those processes were not only considered as a routine, but it is a laboratory management tool to prevent nonconformities, improve, and maintain the quality of the test result.

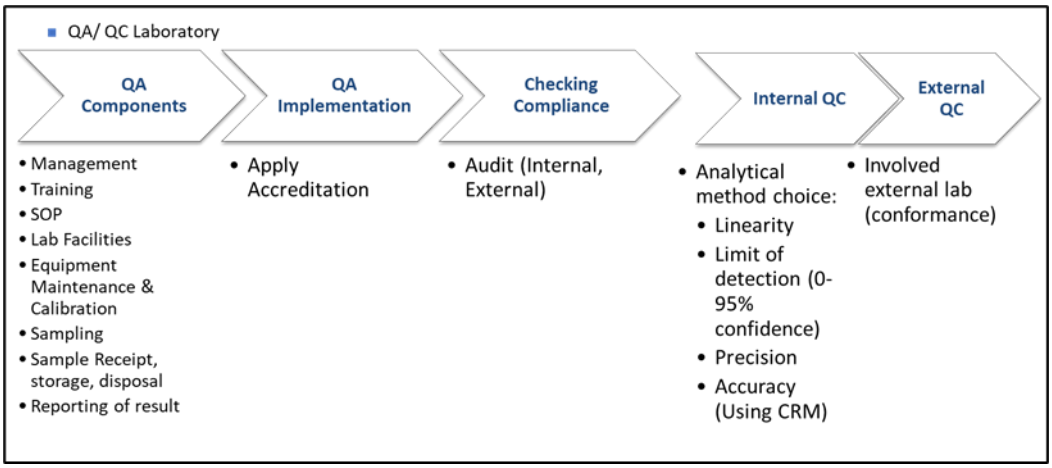

Figure 4: Implemented of the QA and QC methods in Wayang Windu laboratory.

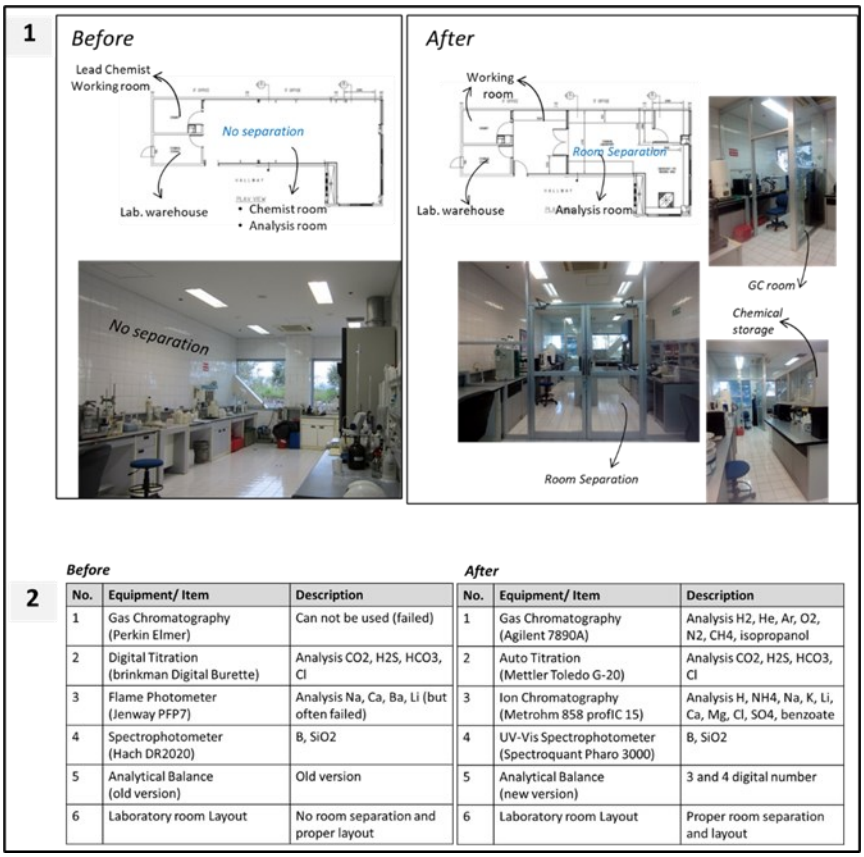

Before

No.	Equipment/ Item	Description
1	Gas Chromatography (Perkin Elmer)	Can not be used (failed)
2	Digital Titration (brinkman Digital Burette)	Analysis CO2, H2S, HCO3, Cl
3	Flame Photometer (Jenway PFP7)	Analysis Na, Ca, Ba, Li (but often failed)
4	Spectrophotometer (Hach DR2020)	B, SiO2
5	Analytical Balance (old version)	Old version
6	Laboratory room Layout	No room separation and proper layout

After

No.	Equipment/ Item	Description
1	Gas Chromatography (Agilent 7890A)	Analysis H2, He, Ar, O2, N2, CH4, isopropanol
2	Auto Titration (Mettler Toledo G-20)	Analysis CO2, H2S, HCO3, Cl
3	Ion Chromatography (Metrohm 858 profIC 15)	Analysis H, NH4, Na, K, Li, Ca, Mg, Cl, SO4, benzoate
4	UV-Vis Spectrophotometer (Spectroquant Pharo 3000)	B, SiO2
5	Analytical Balance (new version)	3 and 4 digital number
6	Laboratory room Layout	Proper room separation and layout

Figure 5: Comparison of before and after laboratory revitalization which involved: 1) laboratory layout changes, 2) additional parameters due to renewal or additional equipment.

2.1 Fluid Analysis

Over the years, Wayang Windu Lab has expanded its analysis as the result of the revitalization process. It is successfully analyzing 15 water parameters and 10 gas parameters following the standard procedures. Those

additional services are the result of the strategic decision in selecting key equipment required to revitalized, such as the installation of Gas and Ion chromatograph equipment. However, the improvement doesn't stop there, but should follow with establishing new procedures, setting up regular maintenance, performing external audits, and manpower skill upgrades. The revitalization also involves laboratory building layout modification as seen in Figure 5. The layout follows the standard regulation of the ISO17025, e.g. room separation has to be clear to store the samples, working room, and confined space for gas chromatography.

This paper shares the critical instruments operate in Wayang Windu laboratory such as Ion Chromatograph (IC) and Gas Chromatograph (GC). Besides, the lab is also equipped with another important instrumentation such as UV-VIS Spectrophotometry, Auto titrator, etc.

2.1.1 Ion Chromatograph

The Ion Chromatograph (IC) in Wayang Windu laboratory is an 850 Professional IC-AnCat-MCS (2.850.3030) type, it is one of the model versions of the professional IC line of instruments manufactured by Metrohm company. This equipment is used for the ion chromatographic determination of cations and anions, which take sixty minutes for each sample to analyze. This Professional IC instrument contain the crucial components such as eluent degasser, supressor module, separation column, high pressure pump, conductivity detector, etc. The instrument is also operated with MagIC Net Software, and its automatically recognize the instrument and check its functional readiness (Manual Book 850 Professional IC AnCat). This configuration helps the analyst to conduct their job and avoid analytical errors. Moreover, the advantages for the Wayang Windu laboratory by having Ion Chromatograph are as follow:

a. Accuracy and precision in analysis (short retention time for each ionic compounds)
b. Flexibility an application related and can be adjusted with analysis needs (configuration and method adjustable)
c. Time and cost efficiency

2.1.2 Gas Chromatograph

The Gas Chromatograph (GC) instrument type is the Agilent 7890B to separate a mixture gas compounds into individual components. There are three major steps involved with separating and identifying components of a mixture using GC, such as injecting the sample into GC (Inlet Valve), separating the sample into individual

components (Column), and detecting what compounds were in the sample (Detector). The configuration system uses Agilent's Open Lab software or Masshunter software to automatically recognize and check its functional readiness (Manual Agilent 7890B). Some features are crucial to help Wayang Windu Laboratory for gas analysis, such as:

a. Retention Time Locking (RTL) to maintain exact retention times from injection to injection, column to column, instrument to instrument, and lab to lab.

b. Capillary Flow Technology (CFT) provides unique instrument capabilities, such as multi-dimensional gas chromatography (GC-GC/Deans switch), comprehensive two-dimension gas chromatography (GCxGC) with flow modulation, and backflush at the beginning, middle, or end of the analytical column.

c. Detectors that consist of single filament TCD, auto-ranging FID, and integrated SCD/NCD. The TCD does not require a separate reference gas, does not require manual potentiometer adjustment, and provides a stable baseline with a minimal amount of signal drift. The FID provides the ability to detect and quantitate from parts per billion (ppb) to parts per thousand in a single injection. The integrated SCD/NCD (sulfur or nitrogen chemiluminescence detector) provides low ppb detection, equi-molar response, and quantitation for sulfur or nitrogen contaminants without quenching from matrix.

d. Helium conservation module and alternative carrier gas solutions dramatically reduce the amount of helium used to offer flexibility and cost savings for your laboratory.

Meanwhile, other parts are also supporting the system such as Hydrogen Sensor Module, Large Valve Oven (LVO), Multimode inlet (MMI), Agilent Inert Flow Path, and Low Thermal Mass (LTM) modules.

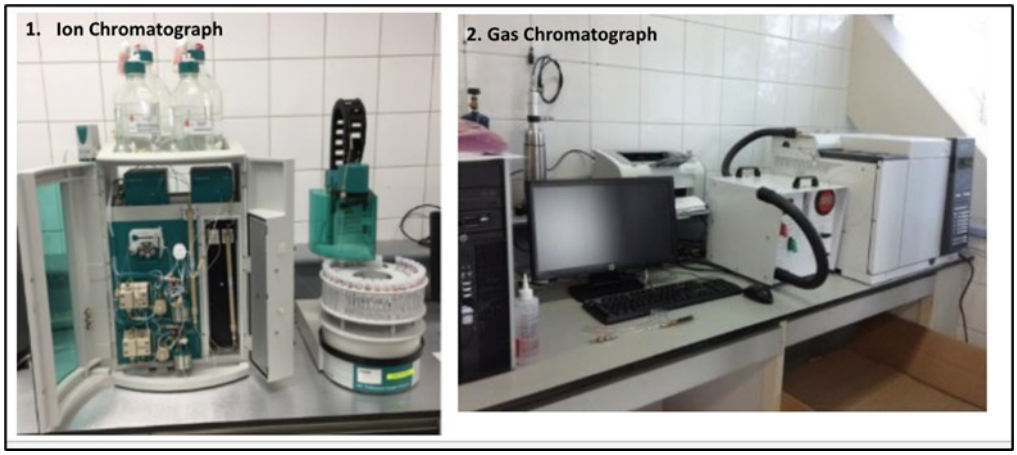

Figure 6: The key equipment installed in Wayang Windu Laboratory for the water and gas analyses : 1) Ion Chromatograph, 2) Gas Chromatograph.

2.2 Equipment calibration and maintenance

Calibration, as defined by ISO/IEC GUIDE 99:2007, establishes a relationship between quantity values and corresponding indications. It involves determining uncertainties associated with measurements. Calibration took to several equipment like IC and GC instrumentation in certain period depend on its type.

The IC instrumentation must be maintained regularly due to routine analysis that is conducted using this instrumentation. Wayang Windu Laboratory established a package of contract with the business partner to perform preventive maintenance service including calibration twice a year. It is crucial to select which part of the instrument that should be maintained or calibrated regularly, that Wayang Windu Lab has selected Filters (inline filter, eluent filter), Pump cleaning (head pump, peristaltic pump, and MSM rotor), Column (conditioning or regeneration), and Leak test.

The GC instrumentation also maintained regularly similar to IC due to routine analysis. Wayang Windu Lab also established the service contract similar to IC to perform preventive maintenance including calibration in three times a year. The preventive maintenance services are recommended to cover activities such as Column conditioning, Gas Standard Injection and calibrated, and Check noise and Drift test.

The output from the services will consist of recommendations regarding the condition of instrumentation, whether there is spare part that should be replaced or keep maintained.

2.3 Internal/ External Audit

The internal audit in Wayang Windu Lab conducted several times and most intense when close to the accreditation process. It collaborates with in-house Management System Department whose regular surveillance audit refers to ISO requirement that also comply with company regulation. The output from the audits are crucial for Wayang Windu Lab as a continuous improvement and enhance the performance.

2.4 Blind Test

A blind test is a procedure to maintain quality by performing analysis involving commercial laboratories or other geothermal field laboratories preferably using the Certified Raw Material (CRM). The result was then compared to check both precision and accuracy. The test started on 2001 since the beginning of Wayang Windu Laboratory operated, and consistently performed in certain period. Figure 7 shows the analyses result in conformities graphs to evaluate historical performance of Wayang Windu Laboratory at various parameters and samples. It shows that Wayang Windu Lab has a consistent result over 60% conformance. Besides, accuracy test evaluated by the repetition of analysis, such as Test #1, 2, and so on. The latest repetition test on 2024 shows a slight discrepancy from the test#1 and 2 which is good to provide the reliable results.

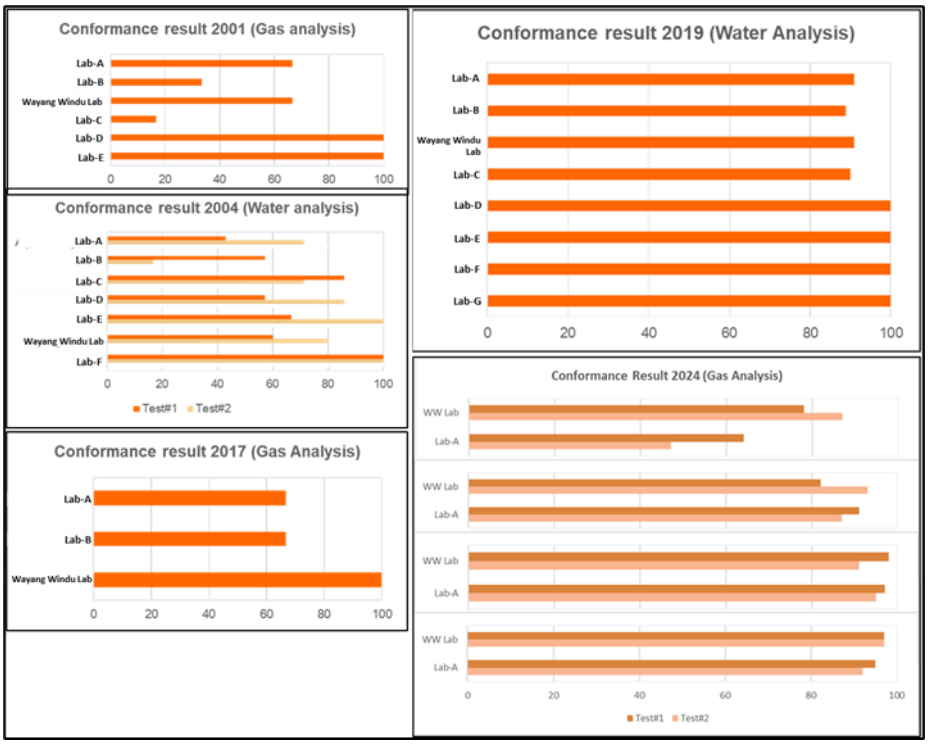

Figure 7: Graphs show the analysis quality represented by conformities. The analyses were taken at various parameters and various commercial and other geothermal field laboratories.

Broadened capabilities were carrying other parties or non-commercial clients such as other geothermal company and institution researchers to participate in a cross reference or blind test. Such activities are good to open and maintain connections and most importantly to open room for improvements. Thousands of samples are the average amount per year that should be conducted by the in-house lab, so that it require more efficient and effective method to accomplish the analysis. Customer satisfaction or feedback form is one the procedures to easily engage the users as stated in ISO17025 guidance. With this approach, Wayang Windu Lab also can maintain the quality of analysis based on customer / client's satisfactory survey and comparation result from another company's clients.

The example in 2023 as seen in Figure 8 is the analysis result in a collaboration test conducted by other geothermal field company. It involves several commercial labs including Wayang Windu Laboratory. The samples taken at other geothermal field from the company and analyzed at each participating labs for complete water parameters. The standardization of the reports are using the Z-scores to evaluate the results. Besides, this method also enables the evaluation to prevent the difference in reference range among laboratories (Duran, 2017). The applied number is within the range of $+2.5 < Z < -2.5$ categorized as acceptance value, and out of that shall be repeated the analysis.

Location	Laboratory	Na (mg/L)	K (mg/L)	Li (mg/L)	Ca (mg/L)	As (mg/L)	Fe (mg/L)	B (mg/L)	SiO_2 (mg/L)	Sampling date
Geothermal Field X	Lab 1	356	97	3.13	<0.04	NA	<0.02	25	933	1/18/2023
	Lab 1	354	106	2.96	2.12	NA	<0.02	27	951	2/4/2023
	Lab 2	304	81.9	2.93	1.49	2.42	0.01	24	873	2/4/2023
	Lab 3	NA	NA	NA	NA	NA	NA	28	1186	1/18/2023
	Lab 3	435	101	3.93	7.79	3.03	<0.01	26	1025	2/4/2023
	Lab 4	350	97	3.43	1.2	NA	NA	60	919	1/18/2023
	Lab 4	364	98	5.72	0.8	NA	NA	577	939	2/4/2023

Z-SCORE Result

Lab	No	Sodium	Potassium	Lithium	Calcium	Boron	Silica
1	1	-0.03	0.00	-0.46	-1.30	-0.43	-0.12
	2	-0.04	0.20	-0.52	0.43	-0.42	-0.07
2	3	-0.33	-0.33	-0.53	0.68	-0.44	-0.29
	4	0.00	0.00	0.00	0.00	0.00	0.00
3	5	0.00	0.00	0.00	0.00	-0.42	0.59
	6	0.44	0.09	1.32	1.19	-0.43	0.14
4	7	-0.06	0.00	-0.34	-0.33	2.40	-0.16
	8	0.02	0.03	0.53	-0.67	1.07	-0.10

Wayang Windu Lab is Lab 4

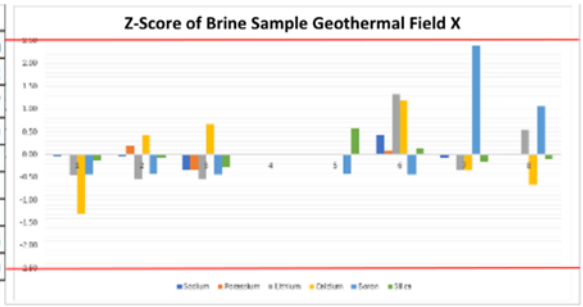

Figure 8: Table above shows the analysis result of each parameter and repetition sample for accuracy test. Table and graph below is a Z-Score result at each parameters. The red line in graphs is the upper and lower range of the Z-Score value, and shows the involved labs including Wayang Windu are within the range (reliable result).

The evaluation of the Z-score shows Wayang Windu lab positioned in-lined with the acceptance value that is similarly to other commercial labs. But the room to improve still exist such as slightly high for Boron analysis in sample#7, even the ranges is acceptable. Overall, those kinds of collaboration are highly important and show that the quality of Wayang Windu Laboratory analysis has a good performance especially for water parameters analysis.

3. THE BENEFITS

The continuous improvement of the in-house lab is a future investment that could be aligned with the future company strategy. The advantage of the laboratory revitalization for more than 10 years in Wayang Windu laboratory was a generous impact on the manpower, services, and company cost-saving. The momentum of laboratory accreditation of ISO17025 in 2018 was considered as a bonus of implementation laboratory revitalization process. By this time, it continues with the cost-saving process. Another advantage is related to manpower or skill upgrade, which is by doing the significant revitalization, it successfully increases independency, manpower skill upgrade, and starts becoming a trustworthy laboratory.

3.1 Accreditation ISO17025

By the process, the lab proposed for the certification and achieved in 2018 tied to ISO 9001. This achievement is not a goal but a bonus from the hardworking yet consistent and continuous effort to maintain the lab performance. Wayang Windu Laboratory has registered fourteen parameters consisting of six gas parameters and eight water parameters as the scope of accreditation which is included in routine analysis conducted in the lab. During accreditation period which starting from 2018 until 2022, Wayang Windu Laboratory is committed to adhere the requirement of ISO 17025 clause with surveillance audit which conducted by Komite Akreditasi Nasional (KAN) as formal representative every year. This is very important as part of maintaining the lab performance including lab personnel abilities, equipment performance or calibration, management contribution and commitment, quality assurance procedure, etc. This approach allows continuous improvement in lab performance based on surveillance finding during external audit by KAN. The benefit of ISO 17025 implementation for laboratory in detail explained as follow (Faridah, 2018):

a. Provide a reference for obtaining formal recognition (accredited) as a competent testing laboratory therefore could improve laboratory's reputation and image.

b. Laboratory management system could improve the consistency of testing and calibration data quality.

c. Facilitate interlaboratory and/or inter-agency collaboration in exchanging information, experience, and harmonization of standards and procedure.

d. Become a baseline for mutual recognition the validity of testing and calibration data on both national and international scales.

3.2 Cost-Saving

Cost saving is one of the benefits directly impacting the company. Since operating the in-house lab, the minimum cost saving can be achieved by at least IDR 200 million / years (see Figure 9). The cost was compared to external analyses, with running operation costs and regular maintenance and calibration. The annual maintenance/ calibration that costs around IDR 50 million/ year is still worth when it compared to a fully external analysis by a commercial lab. Nevertheless, collaboration with other commercial labs is important and needs to be done regularly as part of quality control on a blind test procedure as stated in the Figure 4.

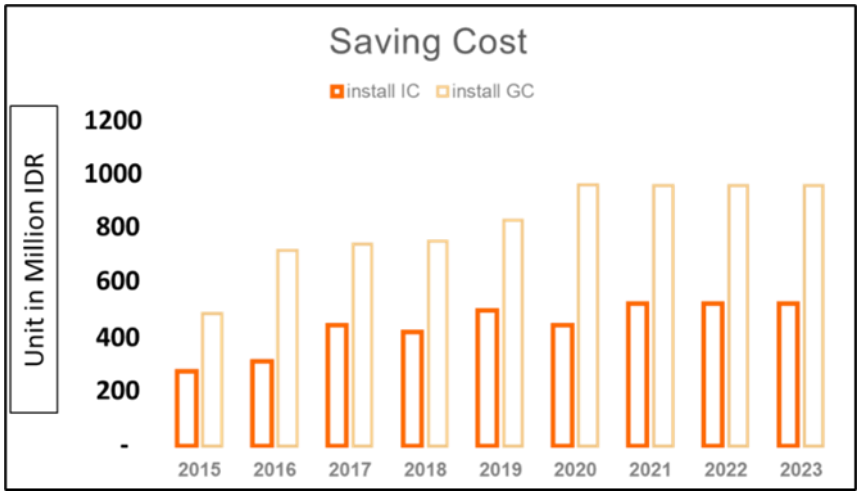

Figure 9: Graph showing cost savings after laboratory revitalization process focusing on installing Ion Chromatograph (IC) and Gas Chromatograph (GC).

4. CONCLUSION

The key points of managing a geothermal fluid laboratory are not only to understand the properties or behavior of the geothermal fluid for reservoir management purposes but also to optimize the efficiency of the operation and most importantly the cost-saving activities. Moreover, managing the laboratory involves implementation of quality control measures to ensure accurate and reliable results. This includes maintaining proper sampling protocols, calibrating the instruments regularly, adhering to safety guidelines for handling hazardous fluid, documenting experimental procedures meticulously, and collaborating with multidisciplinary teams to interpret findings effectively.

The current Wayang Windu Laboratory is continuing the activities as part of the QA/QC lab, including the three-monthly to annual blind tests, equipment calibration and maintenance, and external audit on a call basis. Those activities cost less than half of the equipment prices according to Wayang Windu's condition. It is a worth condition to keep maintaining the current operational cost even if in the future require major equipment renewal such as the more advanced technology of IC and GC.

In summary, managing an in-house laboratory is not an easy task yet not a goal, but it is to develop a ‘culture’ that can create continuous innovation while the base business is running as usual. The continuous laboratory improvement in Wayang Windu is still growing with the settled QA/QC program and is ready to support company strategy.

The Assessment of The Boundary Reservoir Expansion Based on Magnetotelluric and Wells Data of the Sorik Marapi Geothermal Field in North Sumatra, Indonesia

Keshan Apriliyanthy, Alfiady, Tio Fernando,Wishnu Triananda, and Zammy Sarmiento

keshan.apriliyanthy@ksorka.com

Keywords: Resources Assessments, Magnetotelluric, Wells Data, BOC, TOC, Sorik Marapi

ABSTRACT

It is essential to regularly assess the data obtained during the development of a geothermal field to increase production capacity, particularly in understanding the boundary expansion of the reservoir. One of the key parameters in understanding the reservoir characteristics of the geothermal field is the Top of Reservoir (TOR). During the exploration phase, the base of conductor (BOC) from Magnetotelluric (MT) data is often used as the basis to determine the TOR. However, the actual findings after drilling have shown various ranges of separation between BOC and the commercial TOR. Integrating the MT data with actual drilling data, such as Methylene Blue (MeB) test, alteration mineralogy, and downhole temperature data is crucial.

The wells that were drilled towards a hypothetical upflow exhibit significantly deeper temperature over resistivity (TOR) values compared to BOC, while the wells in the productive outflow show a strong correlation between TOR and BOC. Moving further to the North-East of the Sorik Marapi reservoir, the conductive layer appears thicker, and well data suggest a thick layer of sedimentary rocks. As a result, the conductive layer in the Northern and Eastern areas is interpreted to be associated with the sediment infill of a pull-apart basin, rather than hydrothermal alteration.

It was intended to evaluate reservoir expansion areas for the next development program by combining BOC correlation, alteration mineralogy and downhole temperature to determine the P-10, P-50, and P-90 TOR and their distribution. The end result is used to gain a stronger understanding of the TOR distribution across the field so as to determine the right area in the next development program and minimize the uncertainty in planning drilling targets.

1. INTRODUCTION

Sorik Marapi Geothermal Power (SMGP) is located in North Sumatra, Indonesia, approximately 590 km south of Medan city. It lies within the Mandailing Natal Regency and the nearest major town is Panyabungan, 20 km to the north. The Sorik Marapi concession area has a total area of 629 km2. It encompasses more than 50 km of the Great Sumatran Fault (GSF) zone which is a major geologic tectonic structure that runs the length of Sumatra and controls the location of most of the volcanic and geothermal activity on the island. Apart from being related to the presence of GSF, some surface thermal activity is also associated with the Sorik Marapi volcano (2145 masl), an active andesitic stratovolcano located on the western side of GSF. Phreatic eruptions have occurred several times in recorded history. The volcano has surface solfataric hydrothermal activity in and around the summit crater.

Sorik Marapi power plant currently has installed unit 4 of 160 MW which is on the east flank of Sorik Marapi volcano, where as a whole the Sorik Marapi area has several prospects including Sibanggor, Roburan and Sampuraga. The current development focus is on the Sibanggor prospect, where more than 40 wells from 5 pads have been drilled since 2016, the initial exploration until now development drilling is still ongoing. The results show that the Sorik Marapi field has a geothermal system with neutral pH and high temperature (reaching 320°C from existing pad-T wells that are drilled toward the southwest and south and an indication of potential resources extending to the west of the Sibanggor prospect. Previously, additional geophysical surveys have provided initial guidance for potential southwestward resource expansion before drilling on the Pad-T.

2. GEOTHERMAL CONCEPTUAL MODEL

The Sorik Marapi geothermal field is a typical volcano hosted geothermal system situated along the Great Sumatran Fault (GSF) zone where many commercial geothermal fields are being developed. The Sorik Marapi has a total area of 629 km2 and encompasses more than 50 km of the GSF zone. Temperature as high as 320°C had been encountered from what is inferred to be near the upwelling zone towards the Sorik Marapi volcano – W-SW of wells T-05, T-09, T-11, and A-107.

The models consist of mixtures of fluids and magmatic gases that ascend vertically from the main upwelling zone, at the summit of Mount Sorik Marapi and from there discharge magmatic gases, highly saline fluids with very low pH in Namenek and Siambang thermal areas. Part of the mixture of fluids finds its way laterally and migrates from fractures or faults leading to the Sibanggor Julu and Sibanggor Tonga fumarolic areas. As the fluids migrate, the acidic fluids interact with the rocks and the overlying aquifer forming a mature geothermal system with a neutral pH which is manifested in the thermal springs. The encounter of 320 °C fluid at the latest Pad T wells suggests the presence of a dedicated heat source beneath.

Surface manifestations consisting of fumaroles and vents are distributed fairly along the slopes and into the graben structure in the Sibanggor Julu and Sibanggor Tonga and to as far as 17 kilometers in the Sampuraga lowland with boiling hot springs. It is inferred that the upwelling zone is located in the proximity W-SW of the currently drilled area in Pad A and Pad T. The upwelling is well depicted with a high resistivity anomaly centered within the Sorik Marapi – Sibangor Julu – Sibanggor Tonga areas and overlain by a low resistive layer.

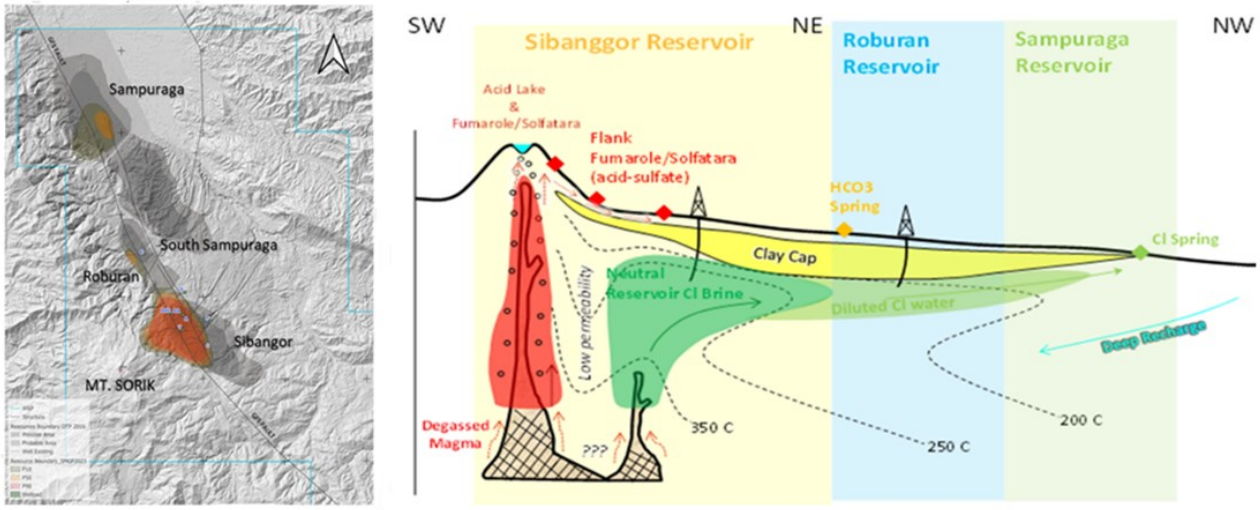

Figure 1: Geothermal conceptual model of Sorik Marapi.

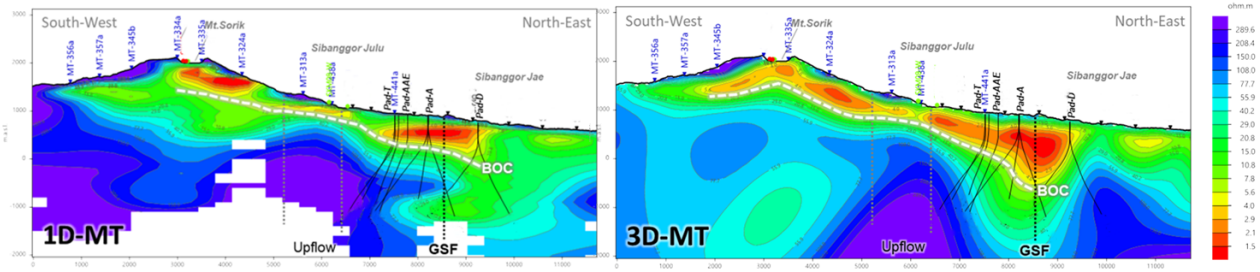

Figure 2: 1D and 3D MT inversion results.

3. MAGNETOTELLURIC RESISTIVITY

The Magnetotelluric (MT) method is an electromagnetic (EM) exploration technique that operates on the principle of passive detection of EM field variations, which induce electric currents in the subsurface. Measurements of electric and magnetic field fluctuations are collected at the surface (Vozoff, 1991). In geothermal exploration, the MT method is widely acknowledged as a valuable geophysical approach for mapping conductive clay cap zones. As a result, MT is frequently employed as a preliminary tool to determine optimal drilling locations in numerous geothermal exploration projects.

3.1 MT Data Processing

MT inversion involves a mathematical approach to create an accurate model of the subsurface resistivity using apparent and phase resistivity data recorded at the surface. It's important to note that the quality of the inversion greatly relies on the quality of the input data, particularly the rho-phase curve. Good input leads to a reliable inversion model, while poor input results in an inaccurate or false inversion model. Before conducting the MT inversion process, it is essential to carry out the classification of MT quality, investigation of sounding curve type,

and correction of static shift. The input data for MT inversion is the apparent resistivity curve, while the output is the true resistivity.

The MT data quality of Sorik Marapi is generally good and acceptable to support 3D inversion and depth-limited 1D inversions used in the interpretation. Based on Figure 2, 1D inversion produces a reliable resistivity model image in the shallower regions and is in good agreement with the base of the conductor (BOC) pattern seen in the 3D inversion. The average 6 Ohm-m value of the BOC in the Sorik Marapi field is also well correlated with the drilling results, particularly evident from the lower boundary of the argillic zone.

Furthermore, the 3D inversion provides a clearer picture of deeper resistivity. It reveals that low resistivity appears to increase in thickness towards the east, indicating an outflow area. Additionally, low resistivity in the eastern part of the GSF influences the sediment formation associated with the pull-apart basin of the GSF. On the western and northeastern flank of Mount Sorik, the low resistivity anomaly seems to diminish under the Sibanggor Julu manifestation, with hot ground alteration, bubbling pools, and acid chloride-sulfate springs indicating the possibility of an upflow zone in this area. This is further supported by the temperatures recorded in wells drilled in that direction, with the hottest temperatures reaching approximately 320 °C.

3.2 Base of Conductor

The conductive zone distribution uses a low resistivity value of 6 Ohm-m which refers to the results of 1D and 3D inversion models, especially in the Sibanggor prospect, an area that has been drilled and is currently being developed. The distribution of Base of Conductor (BOC) showed an updoming pattern that opened from existing Pad A and Pad T in the Sibanggor area around the elevation of 100 masl and up towards Mount Sorik at around 500 masl, where this area is the future well target in planned Pad V which is located inside forestry area. Drilling data on current Pad T wells show the lower part of claycap that ranges from an elevation of 100 - 300 masl as well as the intensity of smectite and illite-smectite minerals. This argillic alteration zone is correlated with the distribution of MeB from drilled wells, the detailed explanation will be described in next section.

The updoming of low conductive anomaly also looks a bit flat towards Mount Sorik (towards Sibanggor Julu and Namenek thermal area) around the elevation of 700 - 900 masl and correlates with the spread of surface manifestations in the form of fumaroles and acid chloride-sulfate springs. In addition, in the Southeastern part of Mount Sorik (towards the Huta Baringin thermal area) there are low conductive anomalies associated with bicarbonate cold springs with an area of BOC at elevation of 1000 - 1400 masl.

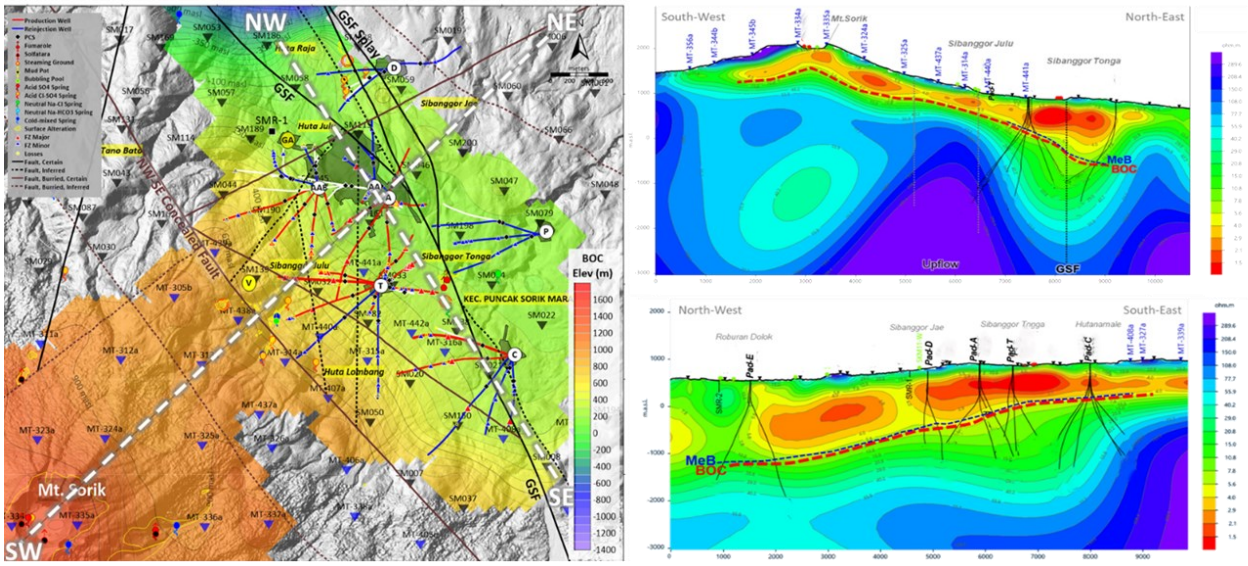

Figure 3: The base of conductor elevation map and 3D MT inversion cross sections with MeB layer. The blue triangle symbol is the MT station surveyed in 2018 and the black triangle symbol MT station was surveyed in 2011.

The wells are in the eastern part of the GSF and also in the northern part such as in Pad P, Pad D, and Pad E are more influenced by volcanic layers mixed with sediment filling which show low resistivity anomalies and low gravity openings which are in the path of the GSF structure. The drilling results in the northern part of the Sibanggor prospect show that under the volcanic layer, there are sedimentary rocks such as tertiary sandstone, limestone, and also thin layers of coal and paleosol. Meanwhile, the BOC in the northern prospects area (Roburan

– Sampuraga) is related by the pull-apart basin structure of GSF, as seen from the deep BOC pattern (around -500 to -1000 masl) and NW-SE oriented.

4. DRILLED WELLS RESULTS

It is important to integrate the MT data with actual drilling data such as Methylene Blue (MeB) test, alteration mineralogy, and downhole temperature data. The wells that drilled towards hypothetical upflow show significantly deeper TOR as compared to BOC while the wells in the productive outflow show a good correlation between TOR and BOC. Further to the northeast of Sorik Marapi reservoir, the conductive layer is thicker and well data suggest a thick layer of sedimentary rocks. As a result, the conductive layer of the Northern area and Eastern area is interpreted to associate with the sediment infill of the pull-apart basin rather than the hydrothermal alteration.

4.1 Lithology

Lithology plays an important role in understanding geothermal systems. Lithology data was acquired from stereoscopic cutting identification and petrography analysis. A total of 46 drilled deep wells have been evaluated and correlated to understand lithology in Sorik Marapi. Stratigraphically, Sorik Marapi consists of seven formations: Paleozoic/Mesozoic Granite, Paleozoic/Mesozoic Metasediments, Tertiary Limestone, Tertiary Sediments, Tertiary Altered Volcanics, Tertiary Limestone, Quaternary-Tertiary Volcanics and Intrusive.

The heat source of Sibanggor prospect (which is found in the Sorik sector and the GSF sector) hypothetically correlates with Quaternary-Tertiary Intrusive. Fine felsic intrusion has been penetrated by wells located at the western side of GSF. Permeability of the reservoir is generally found at metasediments and felsic intrusion. It is suggested that metasediments permeability is influenced by GSF activation, whilst fine felsic intrusion permeability was generated by both fractured areas due to intrusion and also GSF activation. Quaternary-Tertiary Volcanics play at Cap Rock at Sorik Marapi field, especially the Sibanggor prospect. Several wells are drilled to the eastern GSF and penetrate Tertiary Sediments as the basin fills. The evidence of basin fill was also observed when wells at the Northern of Sibanggor were drilled and brought up coal, paleosol, and volcaniclastic sediment to the surface. The basement of Sorik Marapi is high-grade metamorphic rock and granite which are very hard and tight evidence from 2 wells drilled deep to the southwest and penetrated these basement rocks.

The other prospect that was drilled deeply is the Roburan prospect where there are 2 deep wells drilled perpendicular to the GSF and GSF splay. However, poor results were obtained in this area because a thick volcanic claycap layer of about 1200 – 1500 meters followed by a Tertiary sediment layer below it including several paleosol and coal layers indicates that the basin fill sector is getting thicker to the north of the prospect which has a thick and deep of Tertiary sediment product as shown as Figure 4.

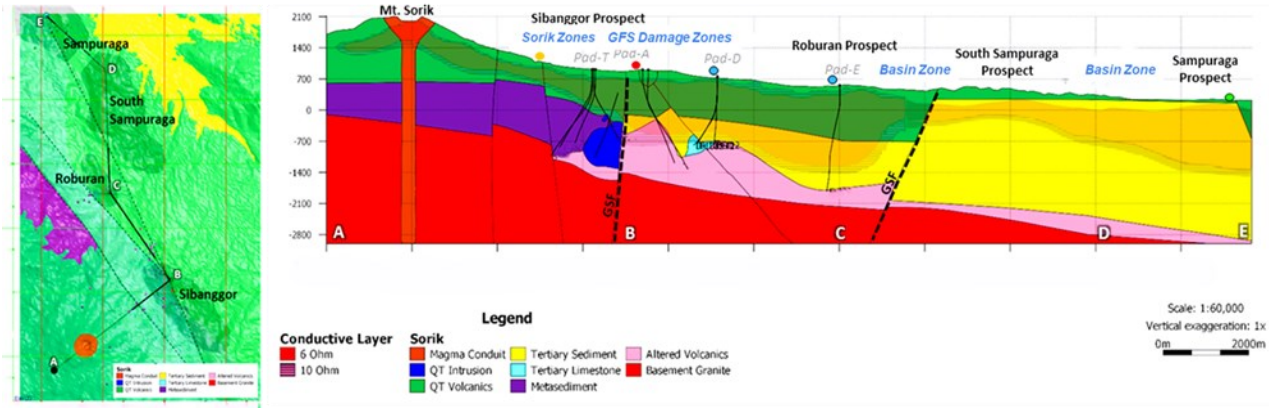

Figure 4: General lithology and distribution of deep wells and prospect locations in the Sorik Marapi field

4.2 Methylene Blue Analysis

Methylene blue (MeB) is an organic dye that shows a high selectivity for adsorption by smectite (swelling) clays in the interlayer site. It has been used to determine the cation exchange of swelling clays since the 1950s (Johnston, 1995 from Harvey, 2000). Geothermal alteration assemblages including smectite or mixed-layer illite-smectite are typically found at temperatures below 200 °C (Harvey, 2000). Because of the very high cation exchange capacity of smectite and mixed layer illite-smectite clays, rocks containing them have very low electrical resistivity (Gunderson, 2000). MeB analyses have routinely been performed for drilled wells in the Sorik Marapi field. It confirms MT's low resistivity anomaly that generally represents the clay cap (Figure 5). The MeB result of drilled wells located at eastern GSF (basin sector) shows a consistent correlation with low resistivity anomaly

(Figure 5), but not with drilled wells at western GSF (GSF sector). This is caused by clay-rich siltstone and sandstone, part of Tertiary Sediment formation, that play role as basin fill of GSF. Some wells drilled to northern Sibanggor have MeB spikes deep below the bottom of clay, suggesting paleosol occurrence as one of the mixed materials at the GSF damage zone and basin fill.

4.3 Alteration Zone

Hydrothermal alteration is a complex process involving mineralogical, chemical, and textural changes, resulting from the interaction of hot aqueous fluids with the rocks through which they circulate, under physio-chemical conditions (Pirajno, 2009). Hydrothermal alteration plays an important role in understanding the geothermal system, as it is the product of hydrothermal activity in the system and it reflects the hydrothermal fluid characteristic. There are factors affecting hydrothermal alteration including temperature, permeability, fluid composition, initial composition of rocks, duration of activity, number of superimposed hydrothermal regimes, and hydrology (Reyes, 1998). Using the petrographic technique, there are several data that can be gleaned including temperature estimation, fluid chemistry, permeability, processes, and thermal history (Reyes, 1998).

Based on mineral assemblage collected from drilled wells data in Sorik Marapi, there are 5 types of alteration zones including Argillic, Transition, Phyllic, Propylitic, and Advanced Argillic; which are derived from the latest alteration sequence. Potassic alteration was possibly observed at two wells drilled toward the southwest (T-07 and AAE-02) at deeper elevation depth, indicating high temperature at the time of formation, with observed patchy - fine grain biotite and k-feldspar alteration minerals. However, at this depth, it may be relict alteration because the Phyllic and Propylitic assemblage is more dominant, with the characteristic of several of these alteration minerals together with epidote which is commonly encapsulated in later quartz, calcite, prehnite, and wairakite.

The argillic zone at Sorik Marapi has various thicknesses from 300 to 500 meters vertical depth (Figure 5). It consists mainly by smectite, accompanied by hematite, pyrite, quartz, and calcite. Sometimes kaolinite and/or low-temperature zeolite are also observed. Phyllic zone is mainly dominated by sericite associated with quartz-pyrite and anhydrite assemblage. The wells drilled towards the upflow or Sorik sector (Figure 5) have thick Phyllic alteration characterized by dominant fracture filled and replaced by anhydrite-quartz-calcite-sericite assemblage that suggested a pressure dropdown at the past which hereafter be a Phyllic zone, this zone becomes impermeable due to fracture sealed and then becomes a gap between bottom of clay and top of the reservoir. Nevertheless, the well drilled to the center shows a consistent trend between the bottom of the clay and the top of the reservoir (Sorik sector at 5).

Propylitic zones of the Sorik Marapi field are mainly defined based on the appearance of continuous epidote, but the results of the petrographic analysis show a texture that characterizes that many epidotes is relict. The latest alteration sequence mostly produces an assemblage of wairakite-adularia-calcite, with some wells also including prehnite as the propylitic assemblage. Advanced argillic was observed at some wells that penetrated GSF splays or minor faults (which are in the Sorik – GSF sectors) (Hendri et.al, 2021). It consists mainly of kaolinite, alunite, diaspore, and pyrophyllite. The appearance of advanced argillic zones suggested shallow acid condensate influx through the GSF splays. Drilled toward the outflow and penetrating GSF, show no propylitic zone (GSF-Basin sector and Basin sector in Figure 5). Although epidote was observed at those wells, it is the product of relict alteration and is contained in sedimentary rocks and old altered volcanic rocks.

5. DISCUSSION

The role of the MT distribution in observing the horizontal and vertical distribution of resistivity, which characterizes the existence of geothermal prospects, is very important before further drilling is carried out. However, before carrying out the mapping of rock resistivity, a hypothetical model based on geology and geochemistry must first be made to find out the general structural patterns, rock regions, and the distribution of manifestations. These are the steps that have been carried out in the Sorik Marapi field, where the low resistive anomaly indicates the spread of this conductive layer starting from Mount Sorik, Sibanggor, Roburan and Sampuraga prospects. However, this conductive layer is not entirely a clay cap which is related to hydrothermal alteration, such as the Roburan prospect, the Sampuraga prospect, and the eastern Sibanggor prospect low resistivity is influenced by mixed Tertiary sediments and located in the

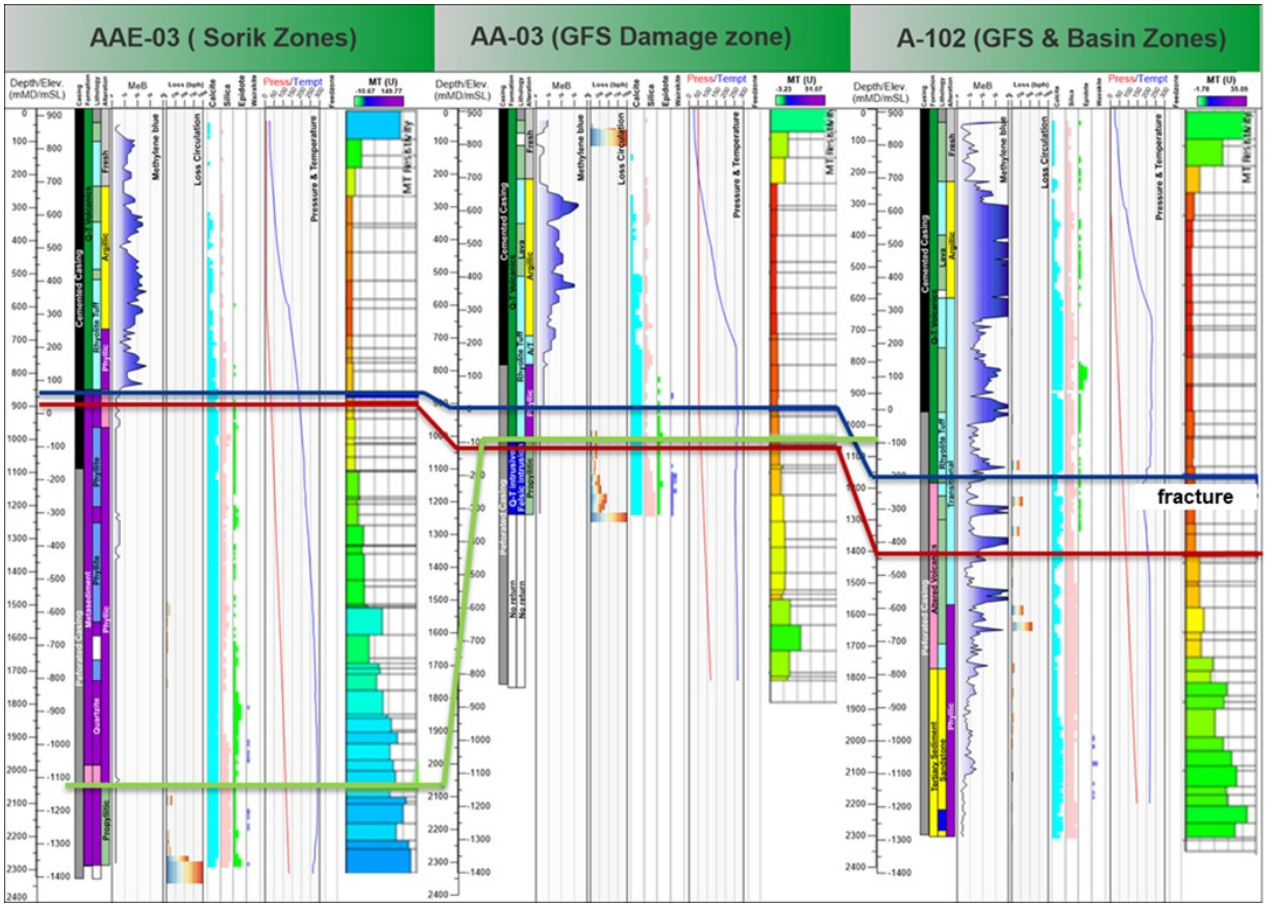

Figure 5: Compiled log of representative well sectors at the same elevation consisting of casing configuration, formation, lithology, alteration type, MeB chart, loss circulation chart, drilling break plot, log of calcite, silica, epidote, wairakite, pressure & temperature chart, feed zone plot and MT resistivity chart.

basin sector. The distribution of low gravity anomalies also supports the structure of this pull-apart basin.

SMGP is involved in the development of several sectors, particularly in the Sibanggor prospect. These sectors are related to low resistivity patterns, feed zone distribution, and TOR distribution patterns. Specifically, they include the Sorik zones, GSF Damage Zones, and Basin Zones. It's worth noting that the most interesting discussion point is the gap between the BOC and TOR in the Sorik Zones.

The low resistivity MT anomaly shows a correlation with the rock units from Quaternary-Tertiary Volcanics and is quite consistent with the distribution of bottom MeB in several zones. Wells drilled to the East and Northeast have thicker low resistivity anomalies. However, the argillic zone thickness is generally the same as an argillic zone of wells drilled toward the Southwest and West (near the upflow zone). The response of low resistivity anomaly from wells drilled to the outflow is caused by the presence of sedimentary rock and old altered volcanic that are rich in smectite. These rocks mean that the drilled wells already penetrated the GSF and basin zones. The TOR in the GSF damage zones appears to have the same correlation as the BOC, this is characterized by the characteristics of the feed zone which is located at a lower elevation that is distributed in felsic intrusion rock and local fracture of damage zone from the GSF structure. The presence of steamcap indications on several wells drilled towards the GSF and there are fumaroles around the Sibanggor Tonga area.

Meanwhile, in the Sorik Zones, the gap between the BOC and TOR is due to indications of alteration of natural boiling minerals presented such as calcite, silica, and anhydrite minerals which fill the factories resulting in an impermeable Phyllic gap. The location of the feed zone is also at deeper elevations and propylitic alteration is also distributed at deeper elevations compared to the wells drilled around the GSF damage zones. The isotherms of the wells drilled at the Sibanggor prospect also show a deep temperature convective trend towards upflow. Only the wells drilled in the upflow direction had temperatures of over 300 °C, such as T-05, T-07, T-09 and T-12.

In the Sorik Zone, the gap between BOC and TOR is caused by changes in the naturally occurring boiling minerals, such as calcite, silica, and anhydrite. These minerals fill the factory, resulting in a Phyllic gap that is impermeable

or becomes a permeable zone at the intrusion contact in the area. The upflow is characterized by an updoming pattern, and the BOC is thinning while the TOR is getting deeper with hotter temperatures, as shown by the isotherm data of wells drilled in the Sibanggor prospect. This data also demonstrates a deep temperature convective trend toward the upflow. Only wells drilled in the upflow direction have temperatures above 300°C, such as T-05, T-07, T-09, and T-12. Therefore, drilling a Step out drill (semi exploration) is necessary to extend the productive reservoir area in this interesting area.

6. CONCLUSIONS

The Sorik Marapi geothermal field (especially the Sibanggor prospect which is currently being developed) is a field located near a vapor core or associated with a magmatic vapor. This is a typical geothermal field in Sumatra which is characterized by a tendency to have a wide gap between the bottom of the conductor (BOC) and the top of the reservoir (TOR) due to boiling and/or condensate percolation, as well as there is Phyllic alteration of mineral assemblies (silica-calcite-anhydrite-sericite) deposited at the mentioned gap as fracture infill. From some of these analyses, it can be integrated that the expansion of prospects in the SMGP field (especially the P-90 TOR as the top of the commercial reservoir) uses an approach such as BOC (low resistivity value of 6 Ohm-m) distribution, MeB trend, appearance of continuous epidote and wairakite minerals, population of propylitic alteration zone, feed zone distribution and isothermal trend as shown a Figure 7.

Keywords: unstable formation, geothermal borehole, paleosol, coal

ABSTRACT

Borehole instability has been a common issue in drilling, with geological factor as one of the controllers. Incompetent rock tends to cause sloughing if not treated well, whilst clay-rich rock tends to swell. Those may contribute to drilling problem, even stuck pipe, thus need to be considered as hazard. To understand about expected drilling hazard, identification of unstable formation needs to be done. The identification could be mitigated from geological analysis combine with GIS interpretation, regional geology, and geophysical data. Then, all those hypothesis analyses will be answered by drilling cutting. However, it is quite challenging to identify precise geological information from drill cutting due to its fine size, therefore specific characteristic of drill cutting need to be defined to determine whether its potentially problematic or not. This paper is also intended to share visualization and detail description of unstable formation, which also possibly found problematic in other geothermal fields. Drill cutting was used as real-time initial information when the drilling was undergone. This included rock and mineral characterization through stereo microscope, methylene blue test and cutting size observation. Supporting information acquired including estimated hole size diameter, drilling breaks, parameter anomaly and operation chronology of tag, fill and stuck pipe.

1. INTRODUCTION

The Sorik Marapi Geothermal Field is located about 650 km south-southeast of Medan, the capital city of North Sumatra province and situated within the administrative area of Mandailing Natal district. This field (Sorik Marapi) is located on the lower northeast flank of Sorik Marapi volcano and along a major active strand of the Sumatra Fault System in North Sumatra (Figure 1). Sorik Marapi was initially studied by industry and academia in the 1980s and 1990s (Hochstein & Sudarman, 1993). The first comprehensive geothermal assessment of Sorik Marapi was completed in 2011, and involved geology, geochemistry, and geophysics studies, in addition to drilling three shallow slim wells (SKM, 2011). This assessment concluded that up to 4 possible resource areas were present along discrete parts of the SFS NE of the Sorik Marapi volcanic edifice. Currently Sorik Marapi Geothermal Power (SMGP) has drilled >40 wells in Sibanggor area (southernmost of SKM interpreted area) since 2016 and has proven a ~245° to 325°C and already produced the electricity of 160 MW.

Sorik Marapi geothermal (Figure 2) area is a part of Western Bukit Barisan volcanic range which extends along the length of Sumatran Island. This zone forms a volcanic range separated by graben from the late Mesozoic meta-volcanics and meta-sedimentary which was covered by volcanic sediment of Miocene age. It was then overlain by the quaternary volcanic rocks made up of andesitic to dacitic pyroclastics and lava.

The active Sumatra fault zone runs through the whole length of Sumatra, within the Bukit Barisan, from Banda Aceh to the Sunda Strait, and is paralleled by a line of quaternary volcanoes. The overall shape of Sumatran Fault is sinusoidal, the northern half of which is gently concaved to SW, whereas the southern half is concaved to NE. There is an irregularity in the fault geometry termed “bifurcation”. The Bifurcation started near Sibual-buali and Lubuk Raya towards the Southeast into two principal active strands (Figure 2). The two strands are separated from each other (Natawidjaya, D. H., 2002). The western branch of bifurcation does not rejoin the eastern branch which continued toward the southeast of Sumatra. Sorik Marapi geothermal field lies at the center of the western branch of Sumatran fault. Most of local fault which parallel to NW-SE major fault trend provide less promising permeability except the NE-SW and N-S trend which are believed to provide good permeability in Sorik systems.

The lithologic units in the Sorik Marapi may be summarized into five units based on updated integrated observations from binocular microscope and petrographic analysis which resulted in the identification of several new lithologies and grouped into five formations: 1) Quaternary Intrusions, 2) Quaternary-Tertiary Volcanics, 3) Tertiary Sediments, 4) Mesozoic or Paleozoic granite, and 5) Mesozoic or Paleozoic metasediments (Figure 3).

The potential problem that arises during geothermal well drilling may vary, with frequent issues being lost circulation, stuck pipe, wellbore instability, wellbore reduction, temporary zone closure, cementing job trouble, and a problem related to quality operability, skill, and experience drilling crew. Anadrill (1997) defines a stuck pipe as when the drill string is unable to move up, down, or rotate. A few common causes of stuck pipes are bad hole geometry, poor hole cleaning, and formation problems. In Sorik Marapi Geothermal Field in Sumatera, several wells drilled in Pad XX dealt with reactive and problematic formation, which caused bottom hole assembly (BHA) loss in hole (LIH). Although stuck pipe also occurred at a high percentage at the other pads in the past, the cause was not fully understood, hence the solution could not be defined and the problem could not be properly mitigated. The stuck pipe incidents in Sorik Marapi have allowed the subsurface team to identify and mitigate such a risk.

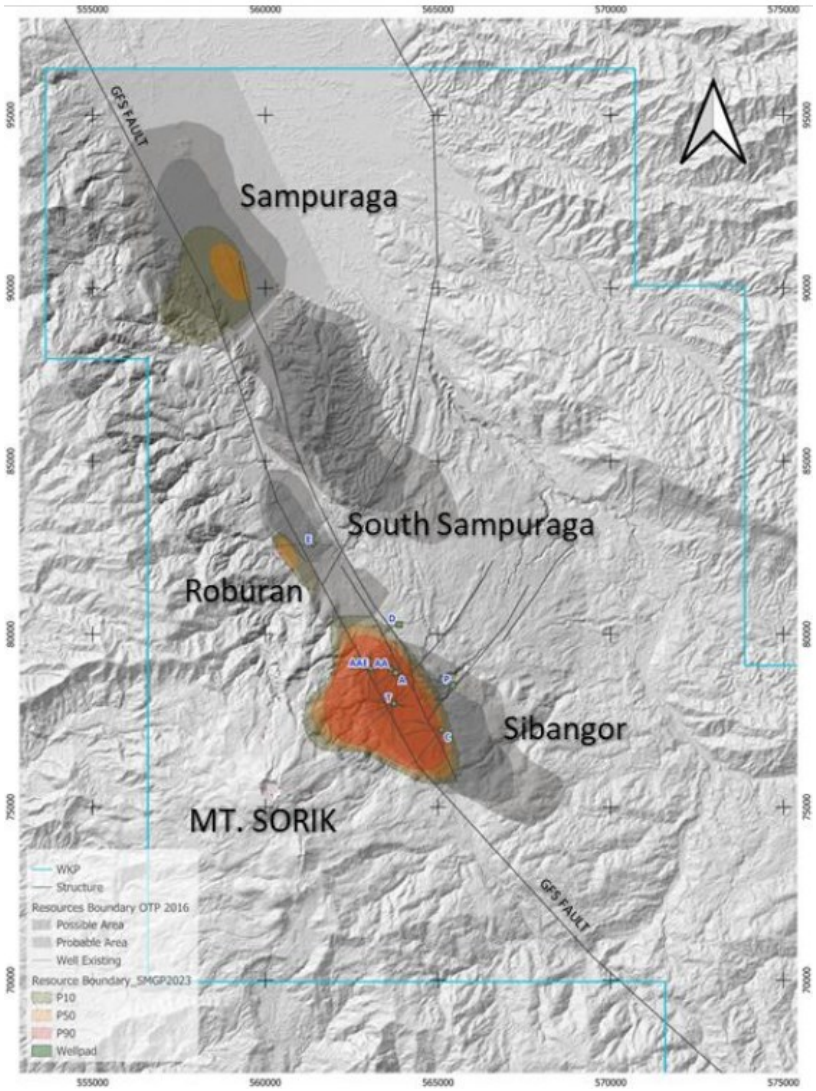

Figure 1: Location map of Sorik Marapi field.

2. METHODOLOGY

2.1 Cutting description

At the rig site, cutting return brought by drilling fluid was regularly sampled every 3 meters. Stereoscope was used to obtain detailed rock and mineral texture, color, size, shape, composition and hardness. Since composition estimation from stereoscope is semi-quantitative, it may differ from each well site geologist, thus modal percentage chart (Shvetsov et al., 1955) was used as reference. Hardness is a bit tricky cause it is qualitative data, especially for specific mineral hardness. For the wells studied, Mohs Scale Hardness Picks was used as it can eliminate handful of possibilities in determining the name of the mineral (Broz et al., 2006).

2.2 Petrography analysis

After studied wells was drilled, several samples from different depth interval were shipped to laboratory. Petrography analysis was performed for 19 samples taken from, 12-1/4" open hole section, the reservoir. Thin section sample preparation and petrography analysis were performed at laboratory. This analysis was conducted to verify cutting description from the rig site and to determine the name of rock and mineral. Besides, it visualizes specific texture that indicate qualitative permeability and semi-quantitatively provides intensity of hydrothermal alteration mineral on cutting samples.

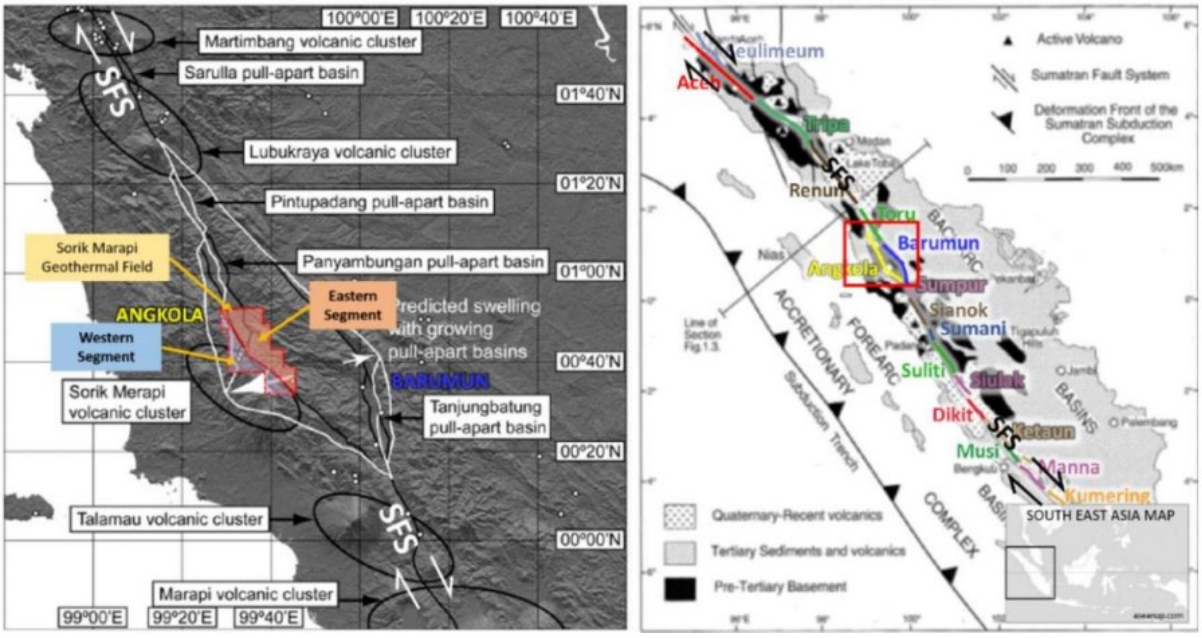

Figure 2: Map of Regional Tectonic setting of Sorik Marapi (left) located along the Sumatran Fault System after Muraoka et al., (2010). GSF segments (right) by (Sieh & Natawidjaja, 2000).

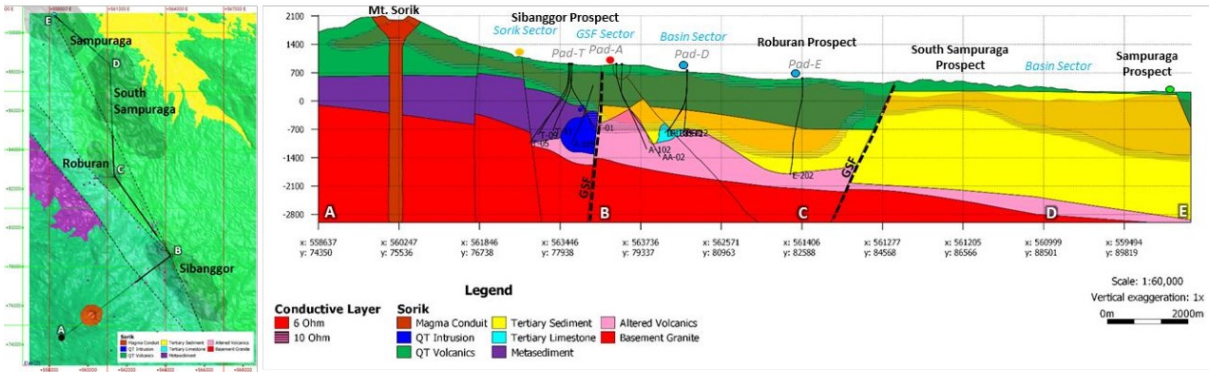

Figure 3: General lithology and distribution of deep wells and prospect locations in the Sorik Marapi field.

2.3 X-Ray Diffraction

X-Ray diffraction analysis (XRD) is a nondestructive technique that provides detailed information about the crystallographic structure, chemical composition, and physical properties of a material. Same as petrography analysis, some samples are selected after the drilling was completed. There is a total of 7 sample chosen for analyze physical properties such as phase composition, crystal structure and orientation of powder, solid and liquid samples.

3. UNSTABLE FORMATION IDENTIFICATION

In Sorik Marapi, there are several lithologies that cause unstable formation, such as paleosol and coal. Based on megascopic analysis, the abundant reddish fragments are suspected to be Paleosol. The fragility is indicative of what was mentioned. It is supported by the presence of hematite, magnetite, and montmorillonite. Paleosol appears in the reservoir zone, and the appearance of paleosol is marked by the presence of MeB spikes in the reservoir zone. Apart from that, there are also coal layers that appear in several Sorik Marapi wells that have the

characteristics of being brittle, black, dull, grainy, don't have a shiny luster (probably low-grade coal), but some fragments have black, shiny, or olive laminae, have 90-degree cleats, and have a wood-like texture.

3.1 Paleosol

In geoscience, paleosol (paleosol in Great Britain and Australia) is an ancient soil that formed in the past. The definition of the term in geology and paleontology is slightly different from its use in soil science.

In geology and paleontology, a paleosol is a former soil preserved by burial underneath either sediments (alluvium or loess) or volcanic deposits (lava flows or volcanic ash), which in the case of older deposits have lithified into rock. In Quaternary geology, sedimentology, paleoclimatology, and geology in general, it is the typical and accepted practice to use the term "paleosol" to designate such "fossil soils" found buried within sedimentary and volcanic deposits exposed in all continents.

In soil science the definition differs slightly: paleosols are soils formed long ago that have no relationship in their chemical and physical characteristics to the present-day climate or vegetation. Such soils are found within extremely old continental cratons, or in small scattered locations in outliers of other ancient rock domains.

Rye & Holland (1998) laid out five criteria for identifying a paleosol. While this was prompted by the need for more stringent identification of Precambrian paleosols, it is applicable to paleosols of any age. The criteria are:

- Formed in situ on bedrock
- soft-sediment deformation at the top of the profile, and
- up-profile changes in chemistry, texture, and mineralogy consistent with terrestrial weathering processes.

In geothermal fields, paleosol is classified as a reactive formation layer and can potentially cause significant hole problems. While drilling previous wells in the formation, the operator experienced five consecutive stuck pipe events and two lost-in-hole (LIH) bottomhole assembly (BHA) incidents that increased drilling time and costs to target depth (TD).

In many of the Indonesian geothermal fields, thin zones of impermeable, dehydrated, fine grained tuffs and paleosols containing a large proportion of smectite clay are routinely found within geothermal reservoirs at temperatures ranging from 200 to 350 C. Smectite in such conditions is inert but, when disturbed by drilling, rock containing it becomes physically unstable.

In Sorik Marapi field, the presence of paleosols near the surface is a common finding in all wells in Sorik Merapi because the layers are still in the argillic alteration zone, which is rich in smectite. Paleosol usually contains argillic minerals (clay content) such as smectite (Daviel et al., 2011), but smectite does not necessarily always indicate the presence of paleosol. When starting to enter the propylitic alteration zone (reservoir area), the percentage of smectite will decay with increasing depth. Among the common clay minerals, smectite has the strongest swelling ability. Problems associated with the swelling clay include caving, sloughing, stuck pipe, bit balling, excessive torque & drag, heaving, suspended drilling activity, and lost revenue.

However, problems will only occur if the presence of this argillic mineral is found in the propylitic zone. This can be indicated as the presence of paleosol in the reservoir zone and when it’s reacted with drilling fluid, which has a high concentration of chemical content, it can be ascertained that swelling will occur and squeeze the drilling pipe which may cause the pipe to be stuck. One way to identify the presence of paleosol in the reservoir is by monitoring through the methylene blue analysis done in cutting as has been implemented in one of Indonesia's geothermal fields. MeB peaks in the reservoir zone may correspond to dehydrated smectite-rich paleosol zones and potentially can cause drilling hazards.

3.1.1 Cutting Analysis

Cuttings are the small pieces of rock that are chipped away by the bit while a well is being drilled. The rock fragments are transported by the mudstream from the bit to the surface where they can be “caught” and analyzed. Identifying paleosols in cuttings is the first thing that can be done before being validated by petrography and XRD analysis. Based on the cutting retrieved in XX-06 well (figure 5) strong evidence of paleosol was observed in these wells, it shows the presence of paleosols that appear in cuttings with the characteristics of dark reddish-brown colour, soft hardness, translucent waxy component (clay-altered lithic/glass), and sedimentary-like brown matrix.There are several ways to identify Paleosol: Cutting analysis, MeB analysis, and Shaker monitoring.

3.1.2 MeB Analysis

The smectite content of the cutting can be detected by Methylene Blue (MeB) analysis (Gunderson et al., 2000). The MeB index is expected to be high when drilling through the clay cap zone. Sihotang (2021) found that smectite clays decrease in the drilling rock cuttings indicated by the MeB index value lower than ten when approaching the top of the transition zone. Figure 6 shows that after passing the clay cap at around depth 1000 mMD, the MeB

index remains constant at around 3. In XX-06 the MeB index observed a sudden increase below the production casing shoe (1500 mMD). As mentioned previously, aerated water was applied once total loss circulation (TLC) was encountered in the reservoir zone and the drill string got stuck not long after. This condition is also similar in XX-07 wells – where a spike reading in MeB was observed below the production casing shoe (1200 mMD).

Figure 5: Paleosol on cutting borehole sample.

3.1.3 Shaker Monitoring

As an initiation to analyse the drill cutting faster and in a timely manner, the shaker was periodically monitored, especially when the drilling depth is near a prognosed potential subsurface hazard. At the shaker, paleosol could be assumed if the mud colour turned to reddish-brown and sticky. Some reddish-brown clots are usually observed at the shaker if there is paleosol. However, reddish-brown mud colour does not always indicate paleosol. Hematite-bearing Andesite Lava and Tuff also make the mud colour reddish-brown but are not considered potential subsurface hazards.

Figure 7: Paleosol at shale shaker.

3.2 Coal

Coal is a sedimentary deposit composed predominantly of carbon that is readily combustible. Coal is black or brownish-black, and has a composition that (including inherent moisture) consists of more than 50 percent by weight and more than 70 percent by volume of carbonaceous material. It is formed from plant remains that have been compacted, hardened, chemically altered, andmetamorphosed by heat and pressure over geologic time.

The most common classification is based on rank, referring to the degree of coalification that has occurred. The rank of a coal is determined primarily by the depth of burial and temperature to which the coal was subjected over time. With increasing temperature, peat is converted to lignite, a very soft, low-rank coal. With further increases in temperature, lignite is transformed into subbituminous coal and then into bituminous coal. At even higher temperatures, usually accompanied by intense deformation generated by the folding and faulting of the Earth's crust, anthracites, the highest rank of coal, are produced.

In Sorik Marapi Field, this coal is found in the reservoir in the northern part, where its availability is influenced by the splay of GSF, especially in the northwest part of GSF. This coal thins towards the west and disappears in the east. The splay of this coal is found locally with a thickness of approximately 10 m. This coal becomes a subsurface drilling hazard because of its soft to brittle nature and has many cleavages (flakes) so that the coal interval can become a rubble zone.

There are several ways to mitigate when encountering coal formations in the Sorik field, such as:

1. Separate problematic formation with loss zones
2. Cover problematic formation with blank liner
3. Utilize high performance water-based mud
4. Perform coal drilling procedure
5. Optimize window time (swelling time based on statistic)
6. Proper hole circulation

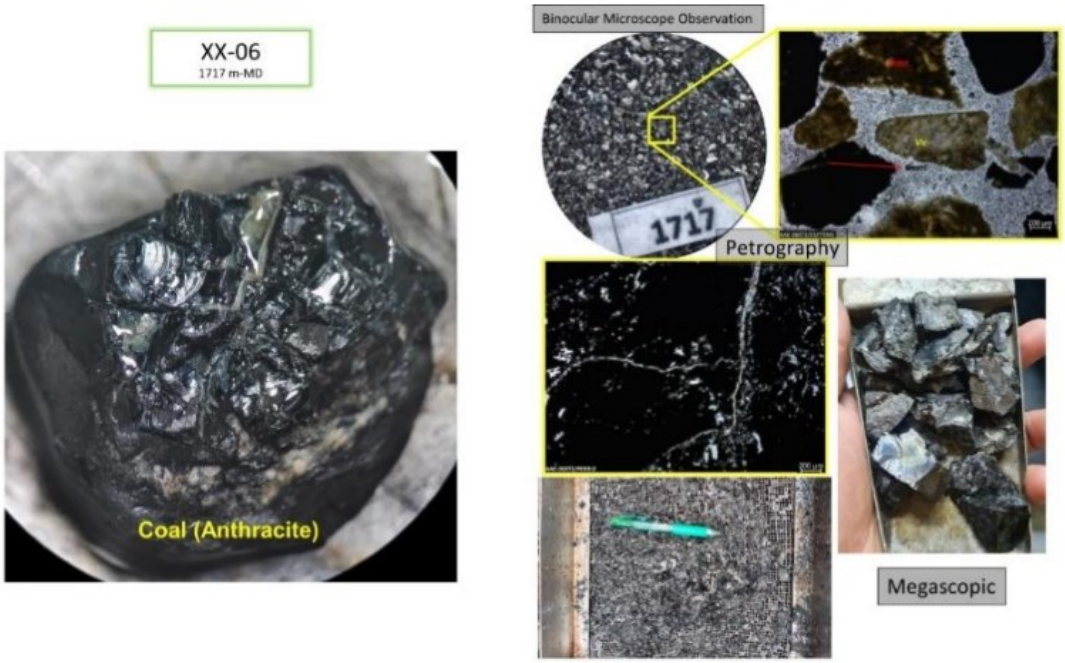

Figure 8: Coal on cutting borehole sample.

4. CONCLUSION

It is concluded that paleosol and coal are the main geological factors in contributing borehole instability in Sorik Marapi. Borehole instability has been a common issue in drilling, with geological factor as one of the controllers. Incompetent rock tends to cause sloughing if not treated well, whilst clay-rich rock has a tendency to swell. Those may contribute to drilling problem, even stuck pipe, thus need to be considered as hazard. In order to understand about expected drilling hazard, identification of unstable formation needs to be done. However, it is quite challenging to identify precise geological information from drill cutting due to its fine size, therefore specific characteristic of drill cutting need to be defined to determine whether its potentially problematic or not. This paper is also intended to share visualization and detail description of unstable formation at Sorik Marapi, which also possibly found problematic in other geothermal fields. Drill cutting was used as real-time initial information when the drilling was undergone. This included rock and mineral characterization through stereo microscope, methylene blue test and cutting size observation. Quick-look also exercised by checking the cutting return at the shale shaker periodically. Supporting information acquired including estimated hole size diameter, drilling breaks, parameter anomaly and operation chronology of tag, fill and stuck pipe.

Suspicion of unstable formation arose against hematite-rich soft fragment with elevated MeB value up to 24, which hereinafter called as Paleosol. In XX-07 well, it causes severe sloughing and swelling as evidenced by continuous abnormal cutting size return at the shale shaker and bigger average diameter hole which checked using hi-vis. The paleosol is the part of Altered Volcanic Formation which consisted of clay-rich intermediate to silicic tuff, lavas, tuffaceous sediment and volcanoclastic sediment that also found as swelling formation. Problem was solved after polyamine applied in drilling fluid system to prevent the swelling process. In XX-06, an even worse unstable formation was observed, namely coal, causing wellbore collapse. Abnormal cutting size up to 6 cm

continuously appear and hole diameter become larger, up to 13.7 inches. High mud weight could overcome the collapsing coal, but failed after loss circulation occur. Casing running problem and stuck pipe happened after penetrating coal. It is concluded that paleosol and coal are the main geological factors in contributing borehole instability in Sorik Marapi.

ABSTRACT

The application of geophysical monitoring techniques is important in geothermal fields as they provide insights into reservoir changes during utilization. One of those techniques is the micro-gravity method which is used to study the mass changes in the reservoir due to fluid extraction and retrieval, represented by gravity changes with time. Seven micro-gravity surveys from 2016 to 2023 have been carried out in Tompaso geothermal field in Indonesia. The first measurement acted as a baseline was done in 2016, which was 4 months prior to the commissioning of the power plant of 2 x 20 MW. This study presents analysis of gravity change, 3-D inversion modelling of the cumulative 7-years time-lapse micro-gravity data and mass change calculation on the basis of 3-D density change model resulted from the inversion modelling. The study revealed that the negative density change area took place in the vicinity of production area which is associated with mass depletion. The study also discovered that the anomalous mass change might correlate with the permeable structures of Tompaso, intersected by the production and reinjection wells. The reservoir mass balance was estimated with the production-reinjection flow rates and time-lapse micro-gravity data. The mass change calculation results on the basis of both 3-D density change model and Gauss's theorem calculation are comparable, which give estimates of the reservoir mass balance. The result shows that the mass balance during the 2016-2023 period is in the range of -24 to -47 Mton which implies that the extracted mass was contributed from the natural recharge of approximately 24 to 47 Mton or 47% to 64% which likely originates from the western-, northern-, and southern part of the field, also indicated by the positive gravity anomaly.

1. INTRODUCTION

The application of geophysical monitoring techniques during geothermal utilization is important because they provide insights into reservoir change during utilization. The physical changes of fluid and reservoir rock properties which are induced by fluid pressure, temperature, and flow rate changes can be detected using e.g., micro-seismic tomography, micro-seismic amplitude attenuation, gravity changes, resistivity and magnetic field changes, remote sensing of surface heat-loss, and ground deformation mapping (Bromley, 2018). The result of geophysical monitoring techniques, in many cases, could also help to improve reservoir simulation models as well as contribute to reservoir management strategy.

Gravity monitoring, or time-lapse gravity, or micro-gravity, has been applied in numerous geothermal producer fields to monitor reservoir change which is represented by gravity changes with time. Mass displacement can cause gravity change by their direct gravitational effect and by deformations at the Earth's surface (Torge, 1989). Mass displacement could be due to natural (tectonic, volcanic) or artificial process of which in this case, is harnessing geothermal fluid. The application of gravity for geothermal reservoir monitoring have been published, such as for Wairakei, New Zealand by Allis and Hunt (1986), Hunt (1995), Hunt and Graham (2009); for Salak, Indonesia by Nordquist et al. (2010); and for Reykjanes, SW-Iceland by Gudnason et al. (2015). Performing the 3-D inversion modeling of gravity monitoring have been successfully applied for Kamojang (Agung et al., 2018) and "US" field (Haq et al., 2019) to evaluate the reservoir mass balance. Gravity monitoring data is also commonly used to validate numerical models since it provides important constraints for reservoir modeling, as have been studied by Protacio et al. (2000) and Nordquist et al. (2004) for Bulalo, Philippines. For better understanding and interpretation of gravity monitoring data, numerous additional data are involved in the analysis, including elevation, groundwater level, downhole data (pressure, temperature, water level), production-reinjection flow rates data, and reservoir numerical model parameter (permeability, porosity, saturation).

The Tompaso geothermal field is a high temperature- two-phase water dominated geothermal system with temperature of 260°-320°C, located in Minahasa District, North Sulawesi Province in Indonesia. The location of

the Tompaso field is displayed on Figure 1. Tompaso belongs to the southern part of the Lahendong geothermal concession, which is owned and managed by PT Pertamina Geothermal Energy, Tbk (PGE). Geologically, it is situated in the northern arm of Sulawesi Island, particularly within Tondano depression which lies within the Sangihe volcanic arc in the Minahasa compartment in the northeastern sector of Sulawesi Island. The volcanic arc is believed to been formed by the subduction of the Molucca sea plate resulting from the collision of Sangihe and Halmahera forearcs (Hamilton, 1979).

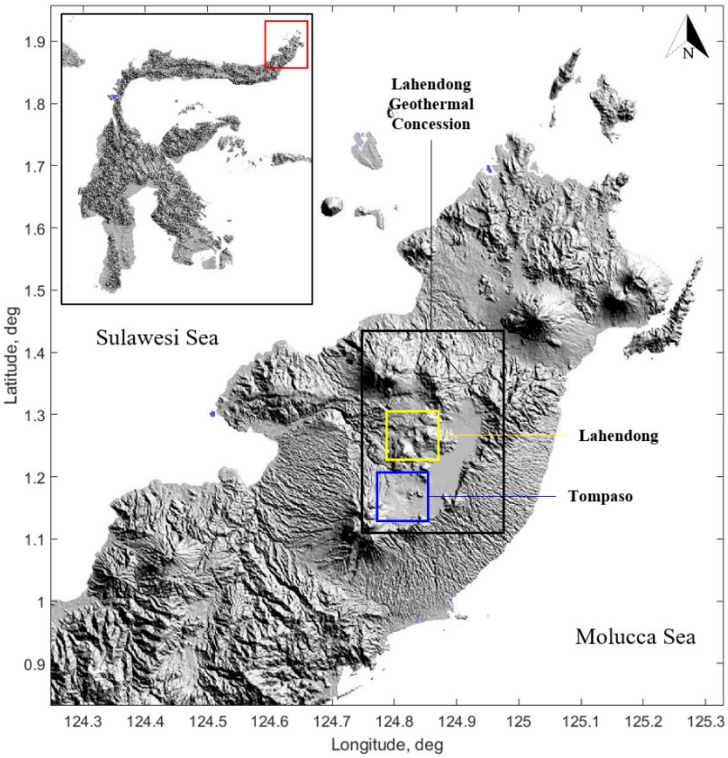

Figure 1: Location of the Tompaso (blue rectangle) and Lahendong (yellow rectangle) geothermal fields in North Sulawesi. The black rectangle shows the Lahendong. geothermal concession. The inset figure shows the Sulawesi Island and the zoomed-in area with a red rectangle.

Tompaso has been generating electricity with an installed capacity of 2 x 20 MWe through two geothermal power plants, Unit 5 & 6 since 2016 (while Unit 1, 2, 3, and 4 are in the Lahendong geothermal field). The Unit 5 and 6 utilize five wells of which all wells are located in Wellpad-C. The hot fluid waste are reinjected to the reservoir through four reinjection wells which are placed in Wellpad-D and E. The location of the wells are shown on Figure 3. The latest geoscientific and reservoir evaluation found the upside potential of Tompaso as confirmed by the recent exploratory wells, hence, PGE intends to develop an additional power plant in the near future.

During 7 years of utilization with continuous production and reinjection, several geophysical monitoring methods such as micro-gravity, elevation changes (ground deformation), and micro-seismics have been carried out in the Tompaso field. In the case of micro-gravity and elevation monitoring, the first measurements were performed in early 2016 prior to the commissioning date, so they serve as a monitoring baseline. Since then, PGE has conducted the data acquisition periodically.

This study presents micro-gravity analysis of the Tompaso geothermal field from 2016 to 2023 to give insight about reservoir changes due to mass displacement during the production and reinjection activities through 3D-density change modelling. The study involved information on production-reinjection flow rates and other supporting data to help the interpretation and to estimate the reservoir mass balance.

2. METHODOLOGY

2.1 Gravity Data

Gravity monitoring is principally performed by repeated measurements at fixed points (benchmarks) within a particular time interval. At the Tompaso geothermal field, gravity measurements for monitoring have been carried out once a year since 2016 until 2023, except in 2020 due to the coronavirus pandemic. The first measurement acting as a baseline was done in May 2016, which is 4 months prior to the commissioning of the power plant in September 2016, followed by new measurements in March the following years. Gravity data were acquired in the

same month each year with the purpose of minimizing the effects of seasonal variations and for periodical analysis and interpretation.

The gravity network used for monitoring in Tompaso covers an area of approximately 90 km^2, of which benchmarks are distributed within the production field, reinjection field, and beyond the reservoir area. The numbers of gravity benchmarks are different between years because benchmarks were added during the following years for better data coverage. The total number of benchmarks were 80 in 2016, 88 in 2017, 108 in 2018 and 2019, and 129 in 2021, 2022, and 2023 (Figure 2). Several benchmarks were lost and destroyed due to unexpected construction work. The gravity monitoring network is depicted in Figure 3. The benchmark TPS-B was assigned as local gravity base point of where all points were tied to, before referenced to the regional benchmark BMKG which was established by the Indonesian Meteorology, Climatology, and Geophysical Agency. The regional benchmark is located about 25 km to the North and is assumed not to be experiencing mass changes or deformation due to geothermal utilization at Tompaso or Lahendong. In addition, it has a known absolute gravity value, hence, it was also used for calibration of the gravimeter. The reference point was measured through repeated data acquisition Base–Regional–Base–Regional–Base and was performed twice which is in the beginning and end of the gravity survey.

The observed gravity data were ensured to be reliable through quality control and correction of tidal effect and drift. Tidal effect is a variation in gravity observations resulting from the attraction of the moon and sun, while drift is a gradual change caused by a heating up of the gravimeter's spring with time. The standard Earth tide correction is applied using Longman's formula which is featured in the gravimeter (Scintrex, 2012). Gravity data at each benchmark were acquired for 15 minutes with recording interval of 30 seconds to ensure stable gravity readings. The gravity data quality control incorporated the standard deviation, tilt, drift, and repeatability at each point. The data show that all the measurement points are of appropriate with an average standard deviation less than 10 µGal, tilt x-y less than 2 arc-sec, drift less than 10 µGal, and repeatability less than 4 µGal.

For the analysis of time-lapse gravity, additional measurements were performed, including precise elevation and groundwater level measurements. The precise elevation measurements were carried out simultaneously with the gravity data acquisition at the same benchmarks. Groundwater level data were collected by measuring the groundwater level at several locations in shallow wells every 1-2 months. The coverage of groundwater level monitoring varies between years as several additional wells were drilled for better data coverage.

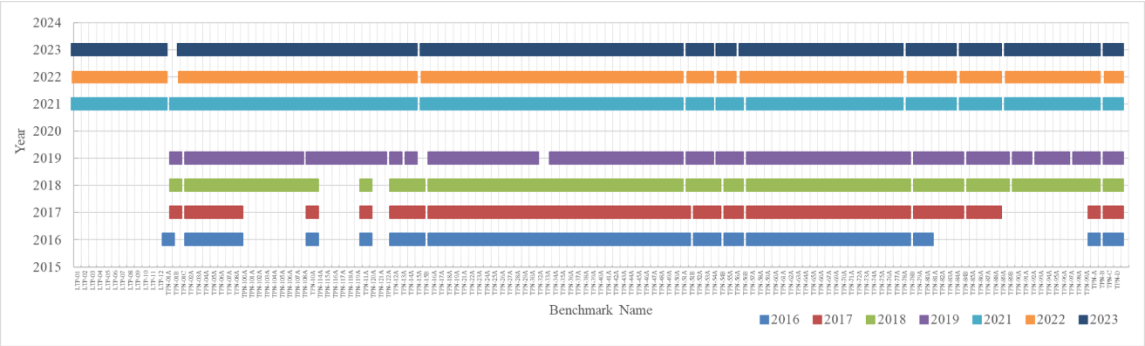

Figure 2: Gravity monitoring benchmarks in 2016 to 2023.

2.2 Production & Reinjection Data

The Tompaso power plant has been generating electricity since September 2016 through Lahendong Unit 5 and 6. The hot fluid has been extracted from five production wells located on well pad C. The production wells are Well-C1, C2, and C3 for Unit 5, and Well-C5 and C6 for Unit 6. Hot fluid is reinjected into the reservoir through four reinjection wells located on well pad D and E which are Well-D1, D2, E1, and E2. The location of the production and reinjection area is shown on Figure 3.

In the analysis of the gravity monitoring data, the extracted- and reinjected mass data from wells are important to estimate the mass balance of the harnessed reservoir. The approximate extracted- and reinjected mass during gravity monitoring periods is shown in Table 1. The extracted mass is defined by negative values corresponding to a mass withdrawal, while the reinjected mass is given as positive values implying a mass retrieval. Until February 2023, the total mass extracted for Unit 5 and 6 was -92.02 Mton. The largest mass was extracted from Well-C5 with mass of -32.01 Mton or 35% of the total extracted mass, followed by Well-C2, C6, C3, and C1. The total reinjected mass was 79.05 Mton which means that 86% of the total extracted mass was reinjected into the reservoir. The largest mass was reinjected through Well-E2 with 30.19 Mton or 38% of the total mass reinjected, followed by Well-E1, D1, and D2. Figure 4 shows the approximate total monthly mass from extraction and reinjection which suggests that in general there is no significant change in the extraction and reinjection scenario

over 7 years of utilization in Tompaso. An enormous extraction mass increase was only observed between November and December 2016 which took place in the beginning of the power plant operation.

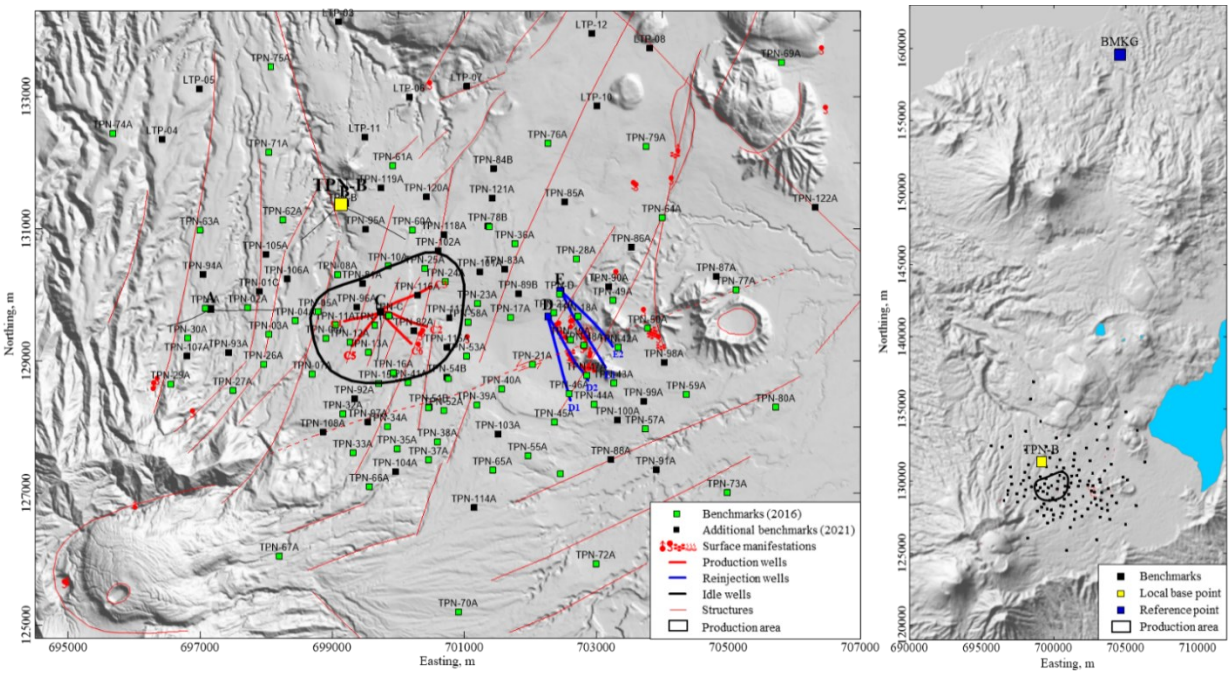

Figure 3: Gravity monitoring benchmarks measured in 2016 (green squares) and additional benchmarks measured in 2021 (black squares) displayed on the left figure, and their location relative to the reference point (blue square) on the right figure. Benchmark TPN-B acted as local gravity base point in the Tompaso field (yellow square).

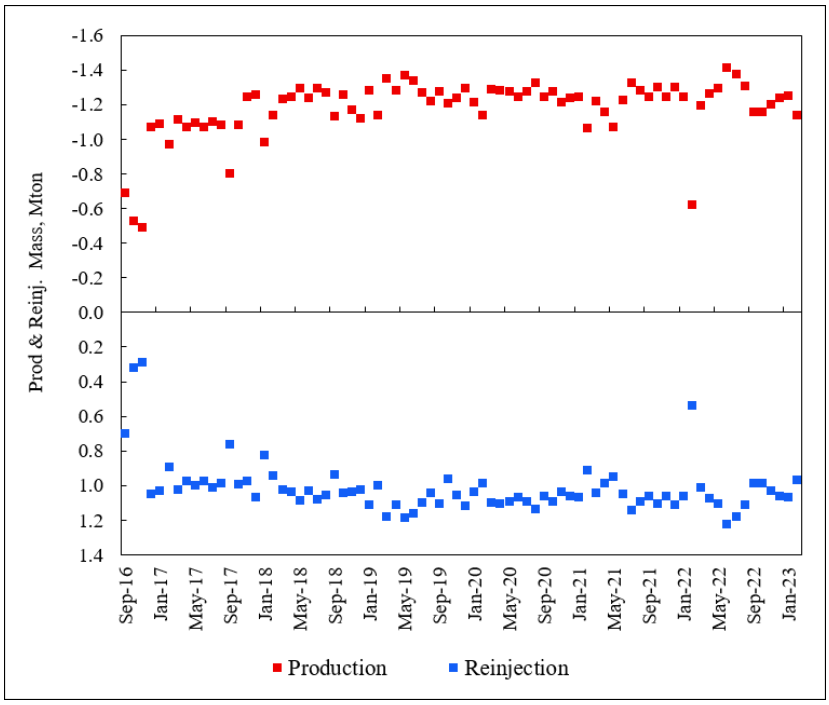

Figure 4: Tompaso geothermal power plant: approximate monthly extraction and reinjection mass in Mton.

2.3 Method

Basically, time-lapse gravity monitoring is a subtraction of observed gravity data at one year from the data of the previous year. Based on yearly data availability as depicted in Figure 2, six periods of observed gravity changes were obtained: 2016-2017 (9 months), 2017-2018 (1 year), 2018-2019 (1 year), 2019-2021 (2 years), 2021-2022 (1 year), and 2022-2023 (1 year). All the measured gravity data are with reference to the reference point BMKG

as the reference point was tied with the base point TPN-B a couple of times during each survey period.

Table 1: Approximate extracted and reinjected mass.

Year	Extracted Mass (Mton)						Reinjected Mass (Mton)				
	Well-C1	Well-C2	Well-C3	Well-C5	Well-C6	Total	Well-D1	Well-D2	Well-E1	Well-E2	Total
2016-2017	-0.68	-0.93	-0.96	-1.52	-0.75	-4.84	0.49	0.53	1.08	2.17	4.27
2017-2018	-1.75	-2.38	-2.22	-4.39	-2.31	-13.06	1.67	1.88	2.92	5.07	11.53
2018-2019	-2.01	-2.72	-2.21	-5.09	-2.66	-14.68	2.50	2.03	2.91	5.02	12.46
2019-2020	-1.83	-3.55	-2.34	-5.16	-2.33	-15.21	2.79	2.77	2.80	4.66	13.02
2020-2021	-1.81	-3.45	-2.29	-5.17	-2.28	-15.00	2.80	2.51	2.95	4.56	12.81
2021-2022	-1.72	-3.08	-2.12	-5.18	-2.15	-14.26	2.76	2.49	2.81	4.12	12.19
2022-2023	-1.79	-3.20	-2.20	-5.50	-2.28	-14.97	2.97	2.41	2.78	4.61	12.77
Total	-11.60	-19.31	-14.34	-32.01	-14.76	-92.02	15.98	14.62	18.26	30.19	79.05
Percentage	13%	21%	16%	35%	16%	100%	20%	18%	23%	38%	100%

In order to capture the gravity effects of mass displacement due to geothermal utilization, the observed gravity changes were corrected for elevation and groundwater level changes. In the case of the effect of elevation changes, the study applied the free-air correction formula to derive the gravity effect due to elevation change δg_h which is given by

$$\delta g_h\,(\mu Gal) = 3.086 \cdot \Delta h \quad (1)$$

where Δh is elevation change in cm. This means that elevation change of 1 cm contributes to a gravity change of 3.086 μGal. The elevation change correction was applied at all benchmarks.

The gravity effect of groundwater level changes can be estimated as a first approximation for uniform changes in homogeneous horizontal layers through a Bouguer plate model (Torge, 1989) of which Bouguer plate reduction δg_b is defined by

$$\delta g_b = 2\,\pi\,G\,\rho\,h \quad (2)$$

where *G* is the Gravitational Constant ($6.67 \cdot 10^{-11}$ $m^3\,kg^{-1}\,s^{-2}$), ρ is density (kg/m^3), and h is thickness (m). By using equation (2), the effect of groundwater level change is given by

$$\delta g_{gw}\,(\mu Gal) = 2\,\pi\,G\,\rho_w\,P\,\Delta h \cdot 10^8 \quad (3)$$

where ρ_w is water density (kg/m^3), P is water-filled pore space (%) and Δh is groundwater level change (m). The water density is assumed to be 1000 kg/m^3. Assuming that the depth to the groundwater is shallow, the porosity is higher than in the reservoir due to less consolidated material. Hence, here, it is assumed that P is around 25% (reasonable value for Tompaso). This means that a groundwater level change of 1 m contributes to a gravity change of ~10 μGal. In this study, one average value was used for every gravity monitoring period to correct for the effect of groundwater level change for the whole area which ranged from -12 μGal to 6 μGal.

The observed gravity changes after being corrected for elevation and groundwater level change were analyzed through; (1) plotting maps and graphs of gravity changes for both the cumulative and each monitoring period, (2) 3-D inversion modelling of gravity changes, (3) mass changes calculation to estimate the reservoir mass balance. The maps of the cumulative observed gravity changes from 2016 to 2023 were plotted using the grid summation technique which allowed the additional data in later years to be included. The gravity change was modelled with a 3-D inversion using VOXI Earth Modelling Extension in Oasis Montaj software (Seequent, 2023) to produce a 3-D density change model.

The total mass change M was then obtained simply by calculating the total of density change of a defined volume, which is given by

$$M = \sum_1^n (\Delta\rho \cdot V) \quad (4)$$

where density change $\Delta\rho$ is expressed in kg/m^3, volume V in m^3, and n is the total number of density changes cube from the 3-D model.

The mass changes on the basis of 3-D density changes model was then validated using Gauss's theorem formula. The amount of mass displacement can be estimated by applying Gauss's flux theorem to gravity data. Even though interpretation of gravity measurements is not unique in determining the distribution of anomalous masses, they can provide an estimate of the total anomalous mass which is corollary of Gauss's flux theorem in potential theory (Parasnis, 1986).

$$M = \frac{1}{2\pi G} \iint \Delta g \, dS \quad (5)$$

$$M = 2.39 \sum (\Delta g \, \Delta S) \quad (6)$$

where Δg is expressed in g.u, the surface area element ΔS in m^2 and M is in 10^3 kg (Mton). The estimate of M in Equation (6) is in some way an underestimate because it is common practices to apply summation in integration over a finite area, while on the contrary, M in equation (5) is over an infinite area (Parasnis, 1986). For Gauss calculation, a MATLAB-based program developed by PGE was used.

Finally, the reservoir mass balance was estimated incorporating the mass change resulting from gravity data and production-reinjection data that considered the percentage of mass recovery from tracer test interpretation.

3. RESULT AND DISCUSSION

3.1 Data Uncertainty

Prior to the analysis, uncertainties were evaluated to ensure the gravity data were acceptable in the analysis and to estimate data uncertainties in general. The uncertainties could be related to the accuracy of gravity and elevation data, benchmark stability, groundwater level change, and reference point. Regarding the accuracy of gravity data, the uncertainty could be given by the mean standard deviation of the measurements, which in this case, is in the range of 1 to 5 μGal, while the uncertainty due to elevation accuracy is between 2 to 5 μGal.

The measurement points should preferably be on a considerably stable bedrock. However, it is difficult to find bedrocks in Tompaso for benchmarks for gravity monitoring due to the soil cover on the surface. Therefore, all measurement points were man-made using concrete which is less firm than bedrock-benchmark. Therefore, they might deform. Such condition could contribute to the uncertainties, although there is no specific technique to assess the uncertainty in these circumstances.

Another factor that contributes to the uncertainty of gravity data in Tompaso is the groundwater level. Besides gravity and precise elevation measurements, ideally, a control point should include the groundwater level measurement to correct its effect. However, such procedures are quite costly. The availability of groundwater level monitoring data from shallow wells are limited to a particular area. As a result, data beyond this area are less reliable than within the area. Due to this limitation, one average value for each period was used to correct the effect of groundwater level change for the whole area which might not be representative at all sites. In addition, the uncertainty of gravity change is also affected by the porosity that is used in the groundwater level change correction, as the effective aquifer porosity is an important parameter that affects the amplitude of gravity change (Bromley, 2018). Based on the data distribution of groundwater level change that has been collected, the uncertainty due to groundwater level change was estimated about 20 μGal.

As discussed earlier, the reference point used in the processing is located at 25 km distance from the Tompaso geothermal area and the data were corrected for the drift and tidal effect. However, due to the reference point's proximity to the ocean which is only about 2.5 km away, the data are possibly affected by residual tidal effects, caused by ocean tidal loading and seismic noise generated from ocean waves. Effect of the ocean tides is one of the largest uncertainties in precise gravimetric measurements and may be corrected for with ocean tide loading models, direct measurement, and removal of a higher order drift function with frequent visits to base stations (Boddice et al., 2018; Orsulic et al., 2019). A study about tidal gravity measurements in Southeast Asia by Melchior et al. (1995) suggests that the oceanic tides contribution to the gravity data at the same reference point used in this study was about 5 μGal.

Based on the uncertainty evaluation as has been described, the total gravity uncertainty is approximately 35 μGal. In this case, the groundwater level change effect has contributed the most in the gravity uncertainty. Therefore, large number and good coverage of groundwater monitoring data are needed for better results.

3.2 Gravity Changes Analysis

The gravity changes between successive monitoring periods (2016-2017, 2017-2018, 2018-2019, 2019-2021, 2021-2022, and 2022-2023 in Tompaso field shows variations in the trend. Considering that there is no significant change in the production-reinjection scenario between years, and all the measurements were done in the same month each year, the gravity change anomaly trend should be quite similar. In this case, such trends could not be found. It might suggest that the gravity measurements detected very small variations. Therefore, to present a more simple understanding, the cumulative gravity change from 2016 to 2023 is analyzed instead. Several data from outer benchmarks are excluded to simplify the interpretation.

The gradual cumulative gravity change from 2016-2023 shows that, despite the uncertainties, in every observation period the trend of cumulative gravity change is consistent, as depicted in Figure 6. The 2016-2017 map shows how gravity changed after 6 months of geothermal production (Figure 6a). In that minimum period, the gravity

change of -50 to 20 μGal is observed, which is acceptable considering the uncertainty of 35 μGal. Moreover, this magnitude is reasonably justified according to study by Agung et al. (2023) that proposed the optimal magnitude of the gravitational-change anomaly to detect which is approximately greater than 25 μgal.

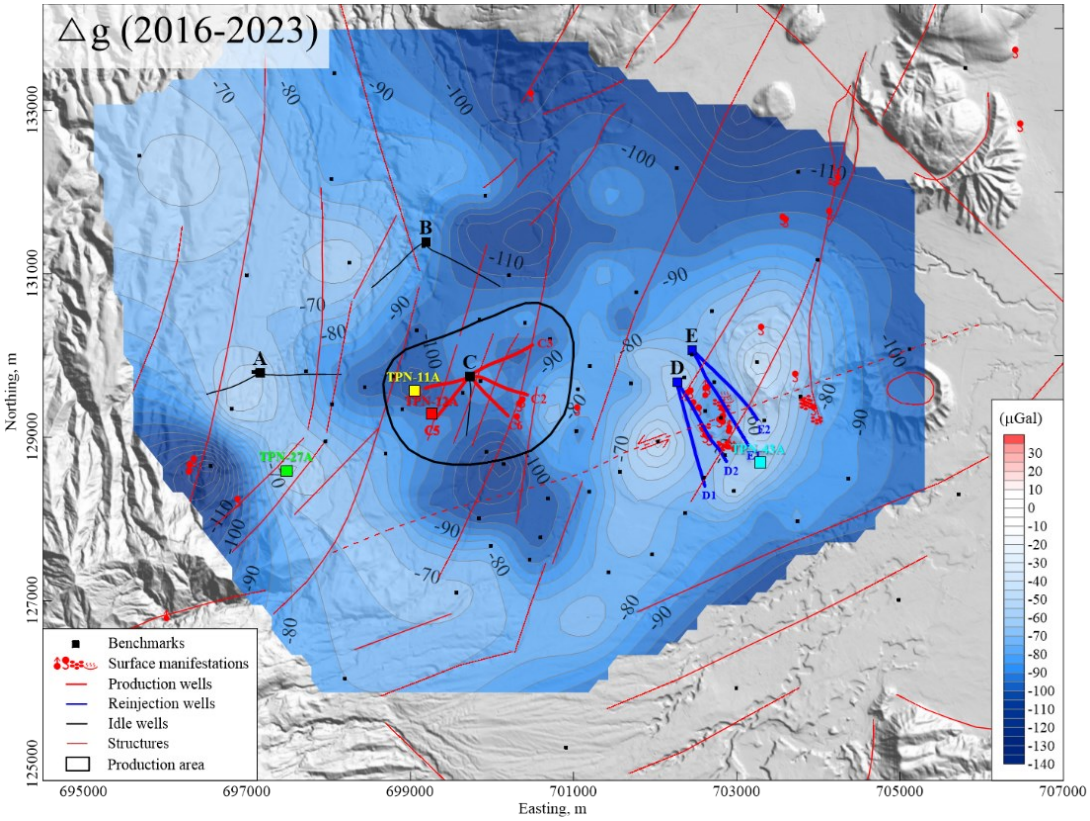

Figure 5: Map of cumulative gravity change of 2016-2023. Benchmark name can be seen in Figure 3. The displayed colored benchmarks (TPN-11A, 12A, 27A, 43A) are discussed further in the study.

The total cumulative gravity change from 2016 to 2023 is negative for the entire area (Figures 5). This could be due to uncertainties, or it could be due to mass changes outside the reservoir. However, the negative gravity changes observed in the northern part of Tompaso are probably affected by geothermal utilization in Lahendong field. Within ~7 years of geothermal utilization, the maximum gravity change reached -80 to -100 μGal in the production area which is comparable with the Reykjanes field in SW-Iceland which experienced a gravity change of -50 μGal during 2 and 4 year periods of production (Gudnason et al., 2015).

Even though negative gravity change takes place in the whole area, the maximum negative gravity anomaly of < -80 μGal is located in and around the production area, which suggests a greater mass depletion with years. The mass depletion might have reached the southern part of the production area as indicated by the extension of the big negative gravity change to the south of the production field. The big negative gravity change is also observed in Bukit Kasih and near reinjection well pad D and E which coincides with the surface geothermal manifestation complex. On the other hand, smaller negative gravity changes are seen around the reinjection area, and in the western to southern part of the Tompaso field. The less negative gravity change around the reinjection area might correspond to the mass retrieval from reinjection fluid in Well-D1, D2, E1, and E2, while the small gravity changes in the western to southern part of Tompaso might be associated with mass supply from outside the reservoir.

The gravity changes at each benchmark were plotted in a graph to give further ideas. The study gave several indications through the graph plots of gravity change at several benchmarks of which this study presents through examples displayed on Figures 7. For instance, the gravity change observed at benchmark TPN-11A (yellow square in Figures 5) that is located in the production area show that in the first phase of production during the 2016-2017 period, significant gravity changes were detected. This is probably due to sudden pressure drawdown and not enough mass support from the surrounding. The gravity changed more gradually in the next periods due to mass balancing process (pressure support). On the other hand, at benchmark TPN-12A (red square in Figures 5) even though it is located within the production field, the gravity changed slightly in the beginning (Figures 7). The observed gravity increase at benchmark 12A might be related to the high permeability zone at the NE-SW Tonsewer Faults that provide fast mass renewal, confirmed by the fact that well C5 delivers the highest mass of

all production wells. The increase of gravity change was also observed during 2017-2018 which implies that there is a quite huge mass inflow in that area.

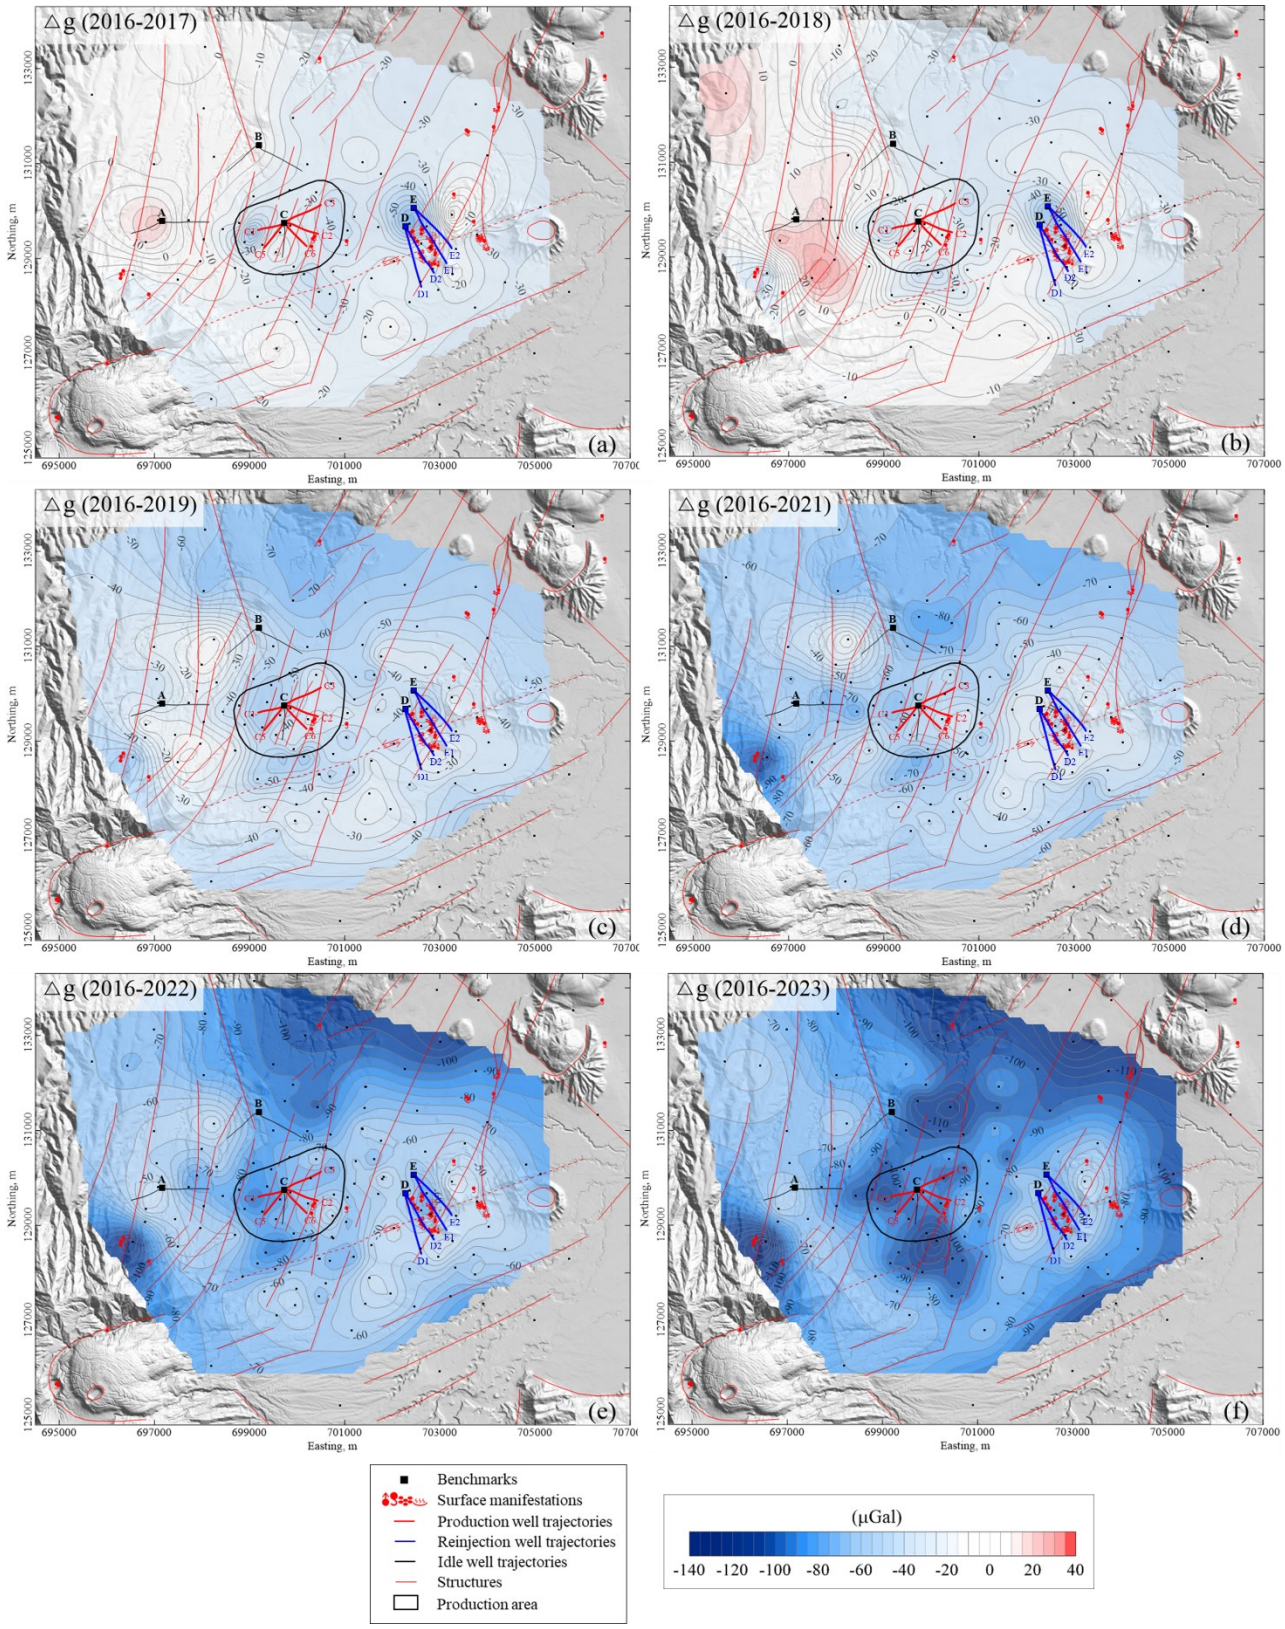

Figure 6: Gradual cumulative gravity changes in Tompaso from 2016 to 2023. Benchmark name can be seen in Figure 3.

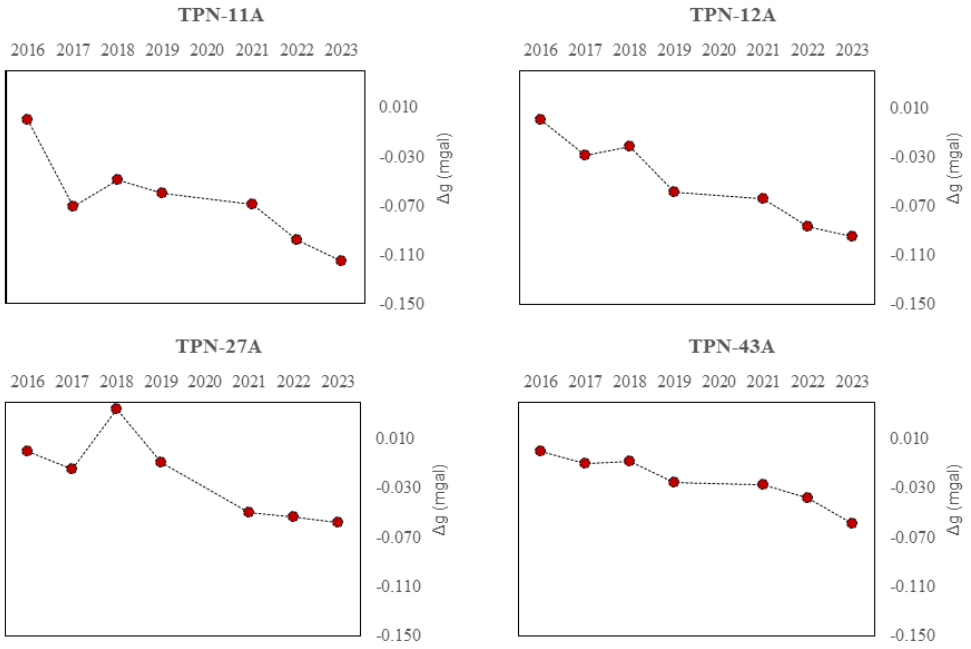

Figure 7: Gravity changes at benchmarks TPS-11A, 12A, 27A and TPN-43A. The location of the benchmarks can be seen in Figure 5.

The high increase of gravity changes during 2017-2018 was also observed clearly in the benchmarks located in the western part of Tompaso field, for example, TPN-27A (green square in Figures 5). Furthermore, the total cumulative gravity changes observed in these benchmarks only reached -50 to -70 μGal which is less than the ones around the production area. These findings suggest that the mass inflow is probably originated from natural recharge which is from the western part of the Tompaso field as indicated by the less negative cumulative gravity changes in that area. In the eastern part, most benchmarks which are located around the reinjection area, for example TPN-43A (blue square in Figures 5) shows gradual gravity change decrease. Furthermore, the total cumulative gravity changes reach -50 to -70 μGal which are comparable with the benchmarks located in the western part. This might correlate with the mass retrieval through reinjection wells D1, D2, E1 and E2.

3.3 The 3-D gravity change modelling

Gravity change modelling was performed to map the density changes in the subsurface. The modelling was performed using VOXI Earth Modelling Extension in the Oasis Montaj software (Seequent, 2023) for 3-D inversion of the cumulative gravity changes from 2016 to 2023. In order to model the gravity anomalies within the reservoir, the bottom of the clay cap was used as top mesh's geometry boundary with the assumption that there are no mass changes in the clay cap. This constraint was applied considering that the gravity change effects at shallow depths have been corrected through the elevation and groundwater level change correction. Hence, the anomaly was assumed to reflect the mass changes in the reservoir where it is located underneath the clay cap.

The inversion result is a 3-D density change model of which in this study is displayed at different depths as shown in Figure 8. The density changes during 2016-2023 are in the range of -0.009 to 0.010 kg/m^3. The result shows that the density change anomalies are well delineated at depths of 500 to 2500 m below sea level (b.sl), where the reservoir zone is found. It implies that the gravity anomalies are caused by the geothermal production-reinjection activity. The negative density change anomaly is observed around the production area which is clearly shown as density change at 1000 to 2500 m b.sl (Figure 8b, 8c, 8d, 8e). It suggests that the mass depletion reached greater depth than the production zone which reaches down to 800 m b.sl. as defined by the deepest production well. On the other side, the positive density change anomalies are detected around the reinjection area, which is interpreted as reinjection mass inflow, found at shallow depth down to 2500 m b.sl. (Figure 8a, 8b, 8c, 8d, 8e) which corresponds to the deepest reinjection well at 2000 m b.sl. The trend of the positive anomaly suggests that the reinjection fluid might flow mostly to the northeast through the NE-SW Totolan-Toraget fault. This interpretation is validated by results from a tracer test that showed interconnection between reinjection wells and manifestation located in the northeast as revealed by recent study (PGE, 2023). Meanwhile, the positive density change anomalies are found in the northern-, western- and southern part which are revealed from shallow depths down to 3000 m b.sl. as response to the natural recharge mass inflow.

Furthermore, the density change model reveals remarkable anomalies, giving further insights into reservoir

behaviour during 2016-2023. One distinctive anomaly is the positive density change observed clearly from 500 to 1000 m b.sl. that occurs in the southwest part of production area and coincides with the trajectory of Well-C5 (Figure 8a, 8b). This positive anomaly could be due to liquid re-saturation caused by recharge inflow into Well-C5 of which the production zone is located from 250 to 750 m b.sl. This interpretation agrees with a preliminary indication that the dryness and enthalpy of Well-C5 were decreasing, possibly as the result of the cold recharge inflow (PGE, 2023). In addition, production geochemistry monitoring data revealed that there is indication of natural recharge influx in Well-C5 as evidenced by the increased magnesium and decreased Non-Condensable Gas (PGE, 2023). This anomaly is also correlated with the gravity change increase in 2017-2018 that is observed at benchmarks TPN-07A, 12A and C which are located near Well-C5. This might be related with the high permeability zone of the NE-SW Tonsewer fault. Another noteworthy anomaly is the negative density change observed from 1000 to 2500 m b.sl. revealed in the south of production Well-C6 (Figure 8b, 8c, 8d, 8e, 8f). The interpretation could be that the production attracted mass from this area where the surrounding has low permeability which causes lack of mass supply leading to a greater depletion.

3.4 Mass Changes and Reservoir Mass Balance

Mass balance estimation was performed based on gravity and extraction-reinjection mass data. Mass change from gravity data was estimated through two methods, one method was through calculation on the basis of density changes resulting from the 3-D model within the defined volume, and the other method was by applying Gauss´s formula to the gravity change. In this study, both methods used the same area which is roughly defined by negative density changes from the 3-D model, interpreted as mass depletion area as depicted in Figure 9. The area used in the calculation excluded the reinjection wells, yet the reinjection mass inflow was taken into account in the mass balance estimation.

Due to uncertainty of the amount of reinjection mass inflow, the mass balance estimation used 2 scenarios for comparison. The first scenario used 25% of the total reinjected mass as indicated by tracer test interpretation regarding mass recovery observed in the production wells. However, this is considered a pessimistic number for mass balance calculation because the defined mass depletion area extended to the northeast and southeast of the production area which is closer to the reinjection wells. Hence, the reinjection fluid inflow in the area was believed to be higher. One hundred percent of reinjection fluid returning to the defined area might be unlikely, therefore, the second scenario used an approximate assumption of 50%. In the case of mass change calculation using density change, several thicknesses were applied; 1000, 1500, 2000, 2500, and 3000 m with the bottom of the clay cap surface used as the top boundary. The result of mass change calculations and mass balance estimations on the basis of density changes is shown in Table 2.

Table 2: Mass balance of 2016-2023 using density change model.

Thickness (m)	Calculated mass change (Mton)	Extracted mass (Mton)	Reinjected mass by 25% (Mton)	Reinjected mass by 50% (Mton)	Mass balance scenario 1 (Mton)[1)]	Mass balance scenario 2 (Mton)[1)]
1000	-8.45				-63.80	-44.04
1500	-17.24				-55.02	-35.25
2000	-25.68	-92.02	19.76	39.53	-46.58	-26.81
2500	-33.29				-38.97	-19.21
3000	-43.63				-28.62	-8.86

[1)] Mass balance = Extracted mass + Reinjected mass – Mass change

In the other method, mass change calculation applied Gauss's formula, given by Equation (6) using MATLAB-based program developed by PGE. Figure 10 shows the surface boundary used for the Gauss´s calculation which is the same area as used in mass changes calculation on the basis of density changes. Table 3 presents the result of the Gauss´s calculation and the mass balance estimation.

Comparing the two methods, both mass balance estimations using the Gauss´s theorem and density changes model show comparable results. From the calculations, it is revealed that the mass balance is negative for the 2016-2023 period. Moreover, the mass balance resulting from Gauss´s calculation for the 2016-2023 period corresponds to a reservoir thickness of 2000 m as revealed from the density change model. The results suggest that there was a natural recharge inflow approximately 24 to 47 Mton that supported the production during ~7 years of operation. The results indicate that the fluid renewal given by the ratio between natural recharge mass and net extracted mass for the 2016-2023 period ranges from 47% to 64%.

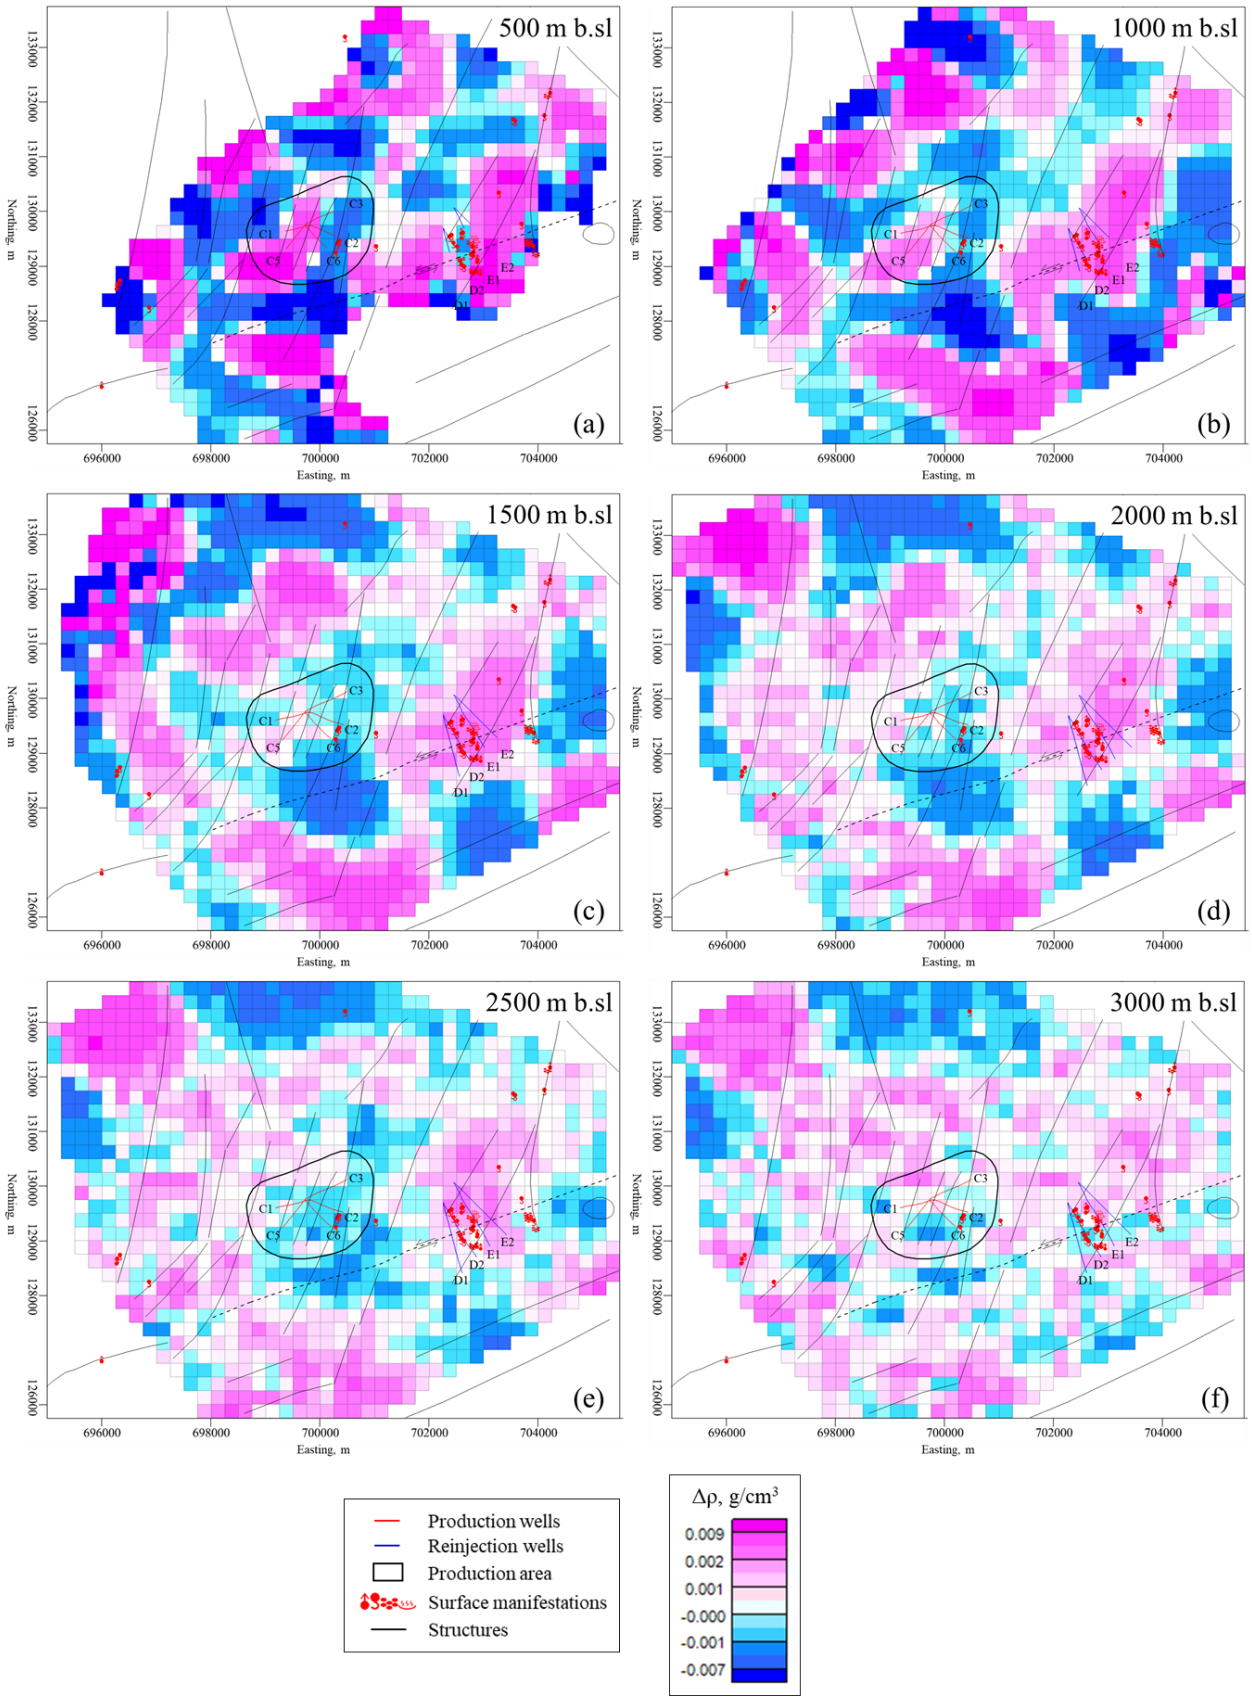

Figure 8: Density change cross-sections for the 2016-2023 period. The negative density change corresponds to mass depletion, while the positive density change is associated with mass gain.

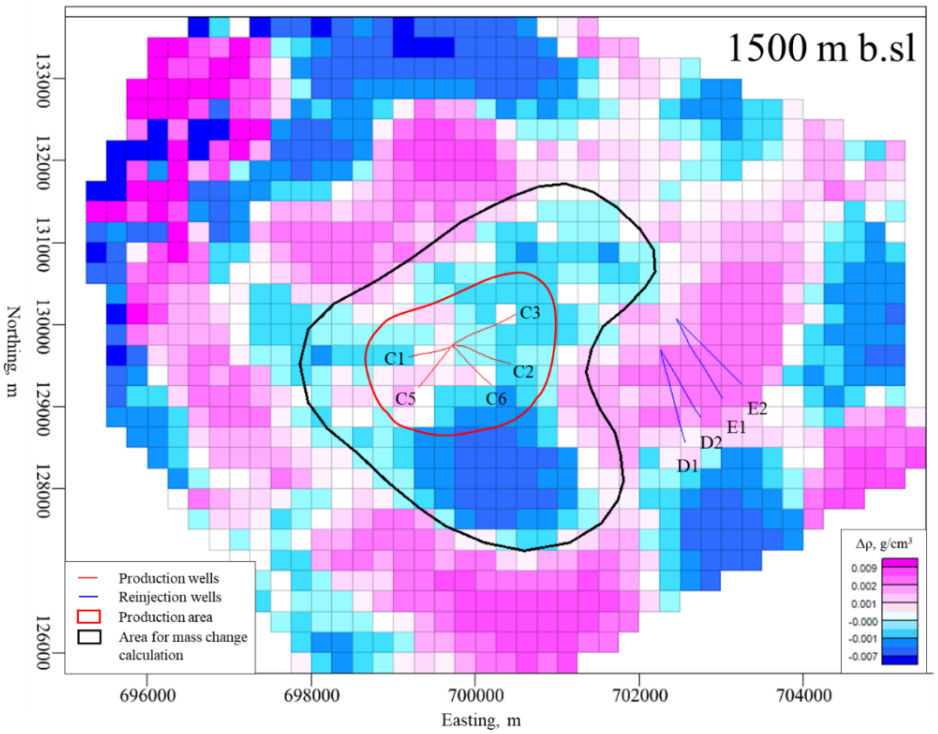

Figure 9: Aea used for mass change calculation.

[1)] Mass balance = Extracted mass + Reinjected mass – Calculated Gauss mass change
[2)] 9 months
[3)] 2 years

4. CONCLUSION

The analysis of gravity monitoring data has successfully revealed the reservoir behaviour in Tompaso during geothermal utilization for electricity generation from 2016 to 2023. Through gravity change modelling, it is revealed that the density change anomalies took place from the top of the reservoir down to 2500 m b.sl., which indicates that the anomalies occurred within the reservoir zone. The negative anomaly around the production area is associated with mass depletion and has extended to the southeast and northeast part of the pre-defined production area. The negative anomaly was observed down to 2500 m depth, which indicates that the extracted mass might originate from greater depth. The result also shows that there was an indication of natural recharge influx from the west within the production zone characterized by a positive anomaly as validated by geochemical data. Meanwhile, the reinjection fluid might flow mostly to the northeast as indicated by the trend of the positive anomaly. The anomalous mass change correlates with the most permeable structures in Tompaso trending NE-SW that were intersected by the production and reinjection wells.

Furthermore, mass change calculations using Gauss´s theorem and the density change model show comparable results which give estimates about the reservoir mass balance. The result shows that the mass balance during the 2016-2023 period is in the range of -24 to -47 Mton which implies that the extracted mass was contributed from the natural recharge of approximately 24 to 47 Mton which most likely originates from the western-, northern-, and southern part of the field. The fluid renewal for the 2016-2023 period is in the range of 47% to 64%.

The study also came up with several recommendations for improvement in the future gravity monitoring works in Tompaso. It is recommended to place an additional base point located 5-10 km from the existing outer benchmarks to the west or southwest that must be measured frequently during gravity surveys (preferably twice a day), as the current base point is likely affected by the geothermal activity. The current reference point should also be reconsidered due to its proximity to the ocean. Furthermore, it is suggested to improve the coverage of groundwater monitoring well data because in the Tompaso case the groundwater level changes contribute significantly to the gravity data.

Keywords: Geothermal, Tanggeung, CBA, TSA, 3D Modelling, LST

ABSTRACT

Geothermal energy represents a significant renewable resource potential for Indonesia, especially given its location between volcanic mountains and tectonic plate intersections along the equator. This study focuses on the Tanggeung Area in Cianjur Regency, West Java Province, which holds considerable geothermal potential. Through a combination of geophysical methods and geological analysis, we conducted modeling and characterization of geothermal manifestations in the area.

Previous research in 2009 suggested the presence of geothermal manifestations acting as outflows in Tanggeung. The lithology in the study area is predominantly composed of clay, tuff, and breccia, with the Jampang Bawah formation as the oldest exposed rock. This study utilized geophysical methods, including Complete Bouguer Anomaly (CBA) maps and Trend Surface Analysis (TSA), toidentify geological structures and geothermal anomalies. 3-D modeling results indicated the presence of a clay cap interpreted as breccia, tuff, and andesitic lava from Mount Patuha, as well as reservoir rocks believed to be tuff and sand from the Cibuni River deposits.

Interpretation of geophysical and geological data indicated significant geothermal potential in the Tanggeung area. High gravity anomalies led to the presence of the Jampang Atas formation with tuff breccia, tuff, and andesitic lava rocks from Mount Patuha. Fault analysis and thermal analysis indicated a heat flow from Mount Patuha towards Tanggeung, subsequently giving rise to geothermal manifestations in Leuwilutung.

Validation results using Land Surface Temperature maps and mineral alteration maps supported the findings of geothermal manifestations in Tanggeung. Land Surface Temperature maps showed temperature anomalies consistent with the presence of geothermal manifestations, while mineral alteration maps indicated mineral distribution indicative of rock alteration processes in the area.

Thus, this study provides a significant contribution to understanding geothermal potential in Indonesia, particularly in the Tanggeung Area. These findings have significant implications for the development of renewable energy and the diversification of energy sources, and may serve as a basis for practical steps in utilizing geothermal energy for power generation and other purposes.

1. INTRODUCTION

The utilization of geothermal energy offers more advantages compared to the use of fossil fuels. Geothermal energy is a stable renewable energy alternative, independent of weather or seasonal changes. Geothermal energy sources in Indonesia are widely distributed, with over 300 recorded points from Sabang to Merauke. This potential can be harnessed as a replacement for non-renewable energy sources such as fossil fuels for electricity generation and transportation. Effective utilization of geothermal energy will reduce dependence on conventional energy sources and help address electricity supply issues, which remain a concern for the Indonesian government (Nurwahyudin & Harmoko, 2020).

Geological structures play a crucial role in geothermal systems because features such as faults function as water channels that allow heat movement. However, in geothermal exploration efforts, determining geological structures has limitations. When geological surveys are conducted to identify rock types and geological structures, only those visible on the earth's surface can be detected. Structures covered by sediment layers above are not visible. Therefore, in geothermal exploration, geophysical methods are key to identifying the presence of geothermal systems. Commonly used geophysical methods include resistivity, magnetic, gravity, and electromagnetic techniques. These are preferred over active seismic methods because most geothermal areas are located in volcanic regions where igneous and metamorphic rocks dominate. Additionally, subsurface structures in volcanic areas are generally not layered, making them difficult to detect with active seismic methods.

The research target location is in the Tanggeung area, located in Cianjur Regency, West Java Province. Previous research conducted in 2009 interpreted hot spring data in Tanggeung. The results of this study indicated the presence of manifestations suspected to be the outflow of the Tanggeung area.

The Tanggeung research location is dominated by claystone, tuff, and breccia lithology. By using the gravity method approach, such as the Complete Bouguer Anomaly (CBA) map, residual anomalies, and the Trend Surface Analysis (TSA) map. The results of the TSA map are then correlated with the alteration mineral map and the Land Surface Temperature (LST) map. This study concludes with 3-D modeling of the manifestations and the obtained volume in the Tanggeung Geothermal area, West Java.

2. METHODOLOGY

The gravity method is a geophysical technique that measures changes in the gravitational field caused by variations in horizontal density below the surface. This method is used to define the architecture of the Earth's crust, identify potential locations for resource exploitation, and build conceptual exploration models for regional Earth characterization. Measurements are taken using a gravimeter, an advanced instrument that measures gravitational acceleration. Gravimeters can be used on the surface or underground if needed (Hinze, Frese, and Saad, 2013).

The presence of a subsurface mass causes a disturbance in the gravitational value, known as a Bouguer anomaly or gravity anomaly. A Complete Bouguer Anomaly (CBA) is derived from gravity data that has undergone various corrections. The equation for CBA is as follows (Telford, Geldart, and Sheriff, 1990):

$$CBA = gobs - g\theta \pm FAC \pm BC + TC \quad (1)$$

Where:

CBA : Complete Bouguer Anomaly (CBA)
gobs : Gravity data obtained from measurement results
gθ : Latitude Correction
FAC : Free Air Correction
BC : Bouguer Correction
TC : Terrain Corection

2.1 Gravity Correction

Gravity methods also include corrections to eliminate noise or additional data obtained from gravity measurements. These corrections are as follows.

2.1.1 Free Air Correction

In geophysics, the free-air gravity anomaly (often referred to as the free-air anomaly) is the gravity anomaly measured after applying a free-air correction. This correction accounts for the elevation at which the measurement was taken, adjusting the gravity measurements to what they would be at a reference level, usually mean sea level or the geoid. Because gravitational values are greatly influenced by distance, it is important to perform an elevation correction from one measurement point to the next. The average value of the free-air gravity gradient is 0.3086 mGal/m or 0.0941 mGal/foot. The following equation can be used to obtain the free-air correction value:

$$FAC = 0.3086\ x\ h \quad (2)$$

Where FAC: Free Air Correction, H: Elevation or height in meters

2.1.2 Terrain Correction

Earth's surface is uneven and wavy according to its topography, So terrain correction is used to level the measuring plane. The formula for field correction is as follows:

$$TC = 0.04193(\rho/n)\ r_2 - r_1 + \sqrt{(r_1^2 + z^2)} - \sqrt{(r_2^2 + z^2)} \quad (3)$$

Where TC: Terrain Correction, ρ : Density of the rock mass, n: The number of segments contained in the zone, r_1: Radius of the inner circle, r_2: Radius of the outer circle, z: The height of a hill or the depth of a valley

2.1.3 Bouger Correction

The Bouguer correction is used to reduce the influence of the gravitational pull of rock mass or material between an observation point and a reference point (mean sea level) when the rock layer is assumed to be infinite. The Bouguer correction formula is as follows:

$$BC = 2\pi G\rho h \quad (4)$$

Where BC: Bouguer Correction, G: Gravitational Constant (6.672 x 10-11 N m2 kg-2), ρ : Rock Density (gr/$cm3$), h: Height above sea level (meter)

2.1 Geology Setting

The oldest rocks exposed in the Tanggeung geothermal area consist of sandstone and claystone, which are part of the Lower Jampang Formation from the Miocene (Tertiary period). Overlying these basement rocks are breccia tuff, tuff, and andesite lava, which belong to the Upper Jampang Formation from the Miocene.

These formations are found along the Cibuni River flow up to the Kadupandak area, which is occupied by alluvial deposits. This area is generally cultivated by the local population for rice paddies, with water sourced from the Cibuni River.

On this geological map, the hot spring manifestations in the "Leuwilutung" area can also be seen. These manifestations are hot springs estimated to be close to the upflow potential of the Tanggeung geothermal area in West Java.

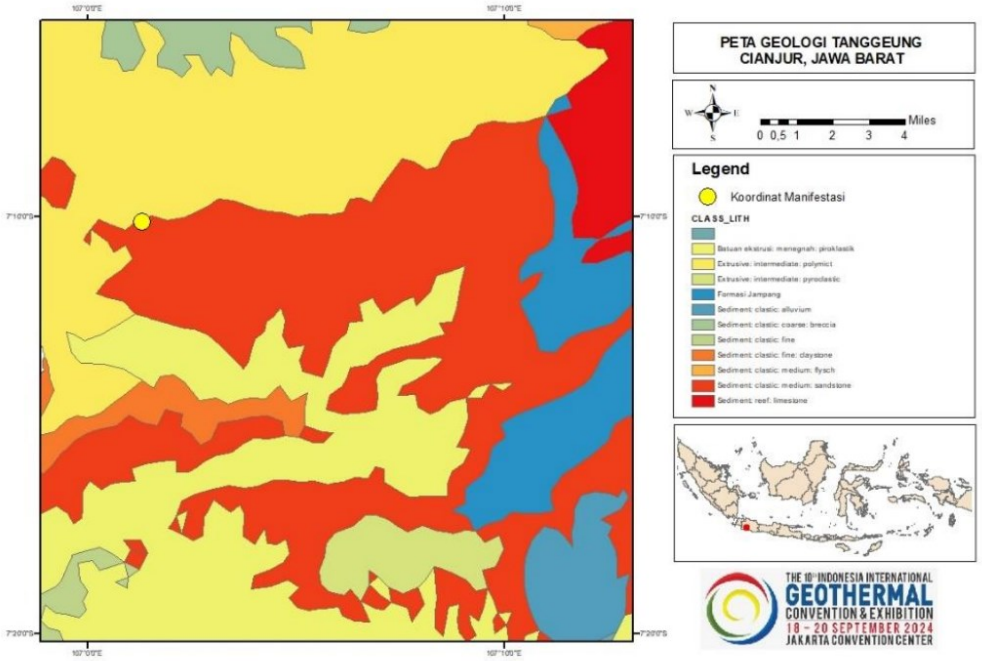

Figure 2: Geology Map of Tanggeung.

2.2 First Horizontal Derivative (FHD)

First Horizontal Derivative (FHD) is the rate of change in gravity horizontally (in the X and Y directions) and is measured in mGal. Sharp changes in anomalies at the contact of bodies will result in maximum FHD values, making it useful for indicating geological structure boundaries based on gravity data. The FHD value is calculated using the following equation:

$$FHD = (g_{(i+1)} - g_i)/\Delta x \quad (5)$$

Where FHD: First Horizontal Derivative (mGal), g: Anomaly (mGal), Δx: The difference in distance along the trajectory

2.3 Land Surface Temperature

Land Surface Temperature (LST) is defined as the temperature condition of the outermost part of an object on the ground surface. LST data can be used for various applications, such as exploration, development, monitoring, and geothermal management, as well as for environmental studies related to geothermal.

Land Surface Temperature (LST) is the ground surface temperature that can be measured using satellite data such as Landsat 8. Landsat 8 has two thermal bands (band 10 and band 11) that record thermal radiation emitted by the earth's surface.

To obtain the final Land Surface Temperature (LST) values, thermal band data processing is required to obtain the Top of Atmosphere (TOA) Radiance, Brightness Temperature (BT), and Land Surface Emissivity (LSE) values (Anandababu et al., 2018).

LST values are converted from satellite temperature values using the following equation:

$$LST = Ts/[1 + (\lambda C_2) \ln e]$$

Where LST: Land surface temperature, Ts: Temperatur satelit, λ: Panjang gelombang satelit citra lansat 8, C2: 14388, e: Emisivitas

2.4 3D Analysis

3-D analysis in gravity methods allows for cubic analysis of gravity data. This technique is useful for various purposes, such as determining the distribution of rocks, identifying geological structures, and making volumetric estimations, such as assessing the potential fluid storage capacity in a given area.

Below is the flowchart of the research conducted in the Tanggeung Geothermal area, West Java.

3. DISCUSSION

3.1 Digital Elevation Model

The topography of the area shows that the research area has a topographical range between 28 to 588 meters above sea level. The southern part of the research area has low topographical values, ranging from 28 to 169.4 meters above sea level, and is dominated by the southern part of the study area, which is suspected to be near the South Java coast in Cianjur, hence the low elevation. Conversely, the central and northern parts of the research area have high topographical values extending eastward, ranging from 177.5 to 588.4 meters above sea level, and are suspected to be hills leading to Mount Patuha from the research location. It can also be seen that the majority of geothermal manifestations are located in areas with medium to high elevation. The manifestation with the highest temperature is located in the upper northern part of the research area, known as the "Leuwilutung" manifestation.

3.2 Complete Bouger Anomaly (CBA)

The Complete Bouguer Anomaly (CBA) map of the study area below shows that the gravity field anomaly values ranging from 157.8 to 203.8 mGal. The high anomaly spreading in the southern part and heading southwest can be interpreted as the Upper Jampang Formation, consisting of breccia tuff, tuff, and andesite lava. These rocks are suspected to originate from the formation in Mount Patuha, extending towards Tanggeung. This high gravity field anomaly ranges between 203.8 and 180.7 mGal. The low gravity field anomalies, with values ranging from 157.8 to 180.7 mGal, are mostly located in the northern part of the research area. This low anomaly correlates with alluvial deposits and sandstone stretching from west to east in the northern part of the study, with the low anomaly area also occupying the manifestation area considered to be the outflow in the research location, namely Leuwilutung.

The CBA map still shows a considerable degree of ambiguity because the anomalies on the map are a combination of residual anomalies (shallow sources) and regional anomalies (deep sources). Therefore, separating the anomalies is still necessary to eliminate this ambiguity.

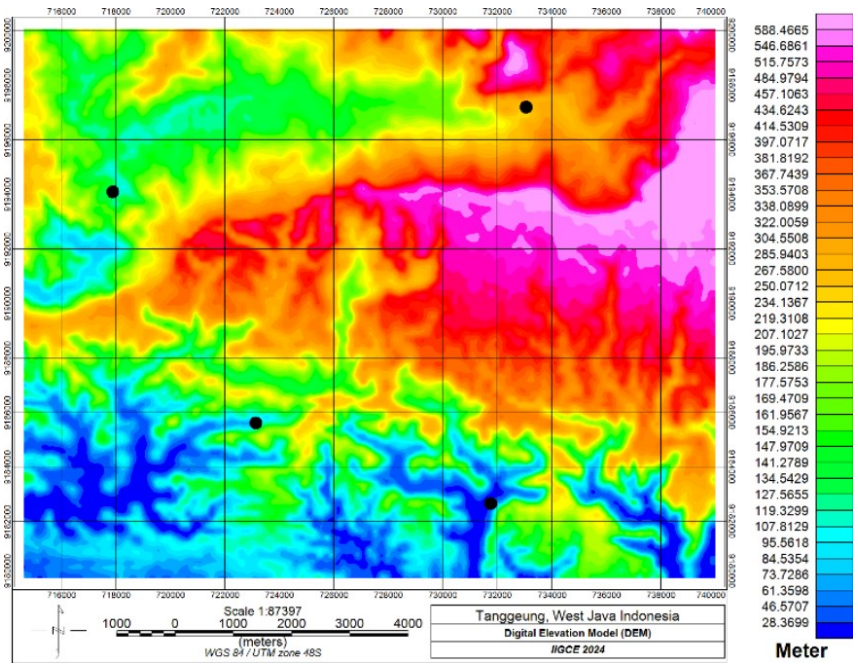

Figure 3: Digital Elevation Model Map.

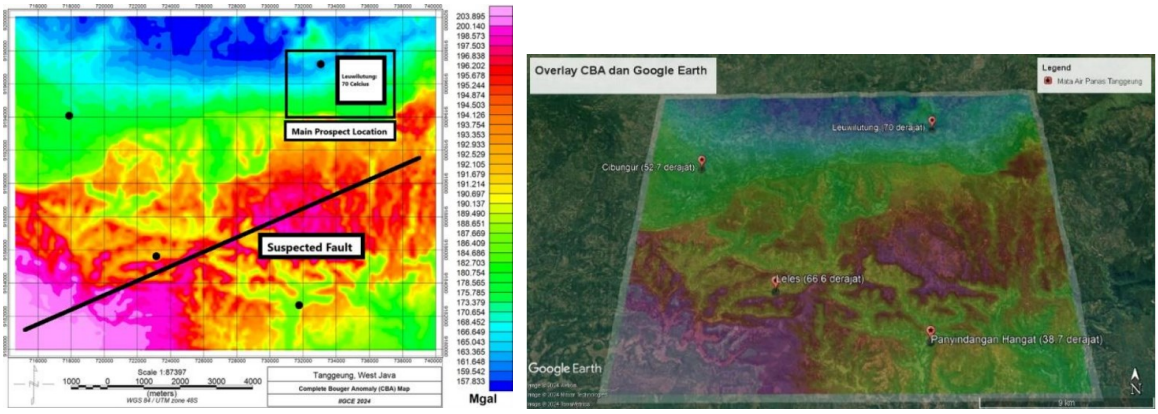

Figure 4: Complete Bouger Anomaly (CBA) Map.

3.3 Regional Gravity Map

After separating the anomalies on the CBA map using a bandpass filter, regional anomalies (deep zone) and residual anomalies (shallow zone) were obtained. On the regional anomaly map, it can be observed that the contours are similar to those on the CBA map. However, the regional anomaly contours appear smoother compared to the CBA map. This is because regional anomalies depict conditions far below the surface, representing layers and rocks in the deep zone. The deep zone in the Tanggeung area shows homogeneous characteristics. The regional anomaly map shows that the gravity anomaly values in the study area range from 158.1 to 203.8 mGal. The relatively high gravity anomalies, ranging from 181.1 to 203.8 mGal, are located in the southern to southwestern parts of the study area. These high anomalies are interpreted as the Upper Jampang Formation, consisting of breccia tuff, tuff, and andesite lava. These rocks are suspected to originate from the formation in Mount Patuha, extending towards Tanggeung. Conversely, the low gravity field anomalies, with values ranging from 158.18 to 179.12 mGal, are mostly located in the northern part of the study area. This low anomaly correlates with alluvial deposits and sandstone stretching from west to east in the northern part of the study. This low anomaly area also occupies the manifestation area considered to be the outflow at the research location, namely Leuwilutung.

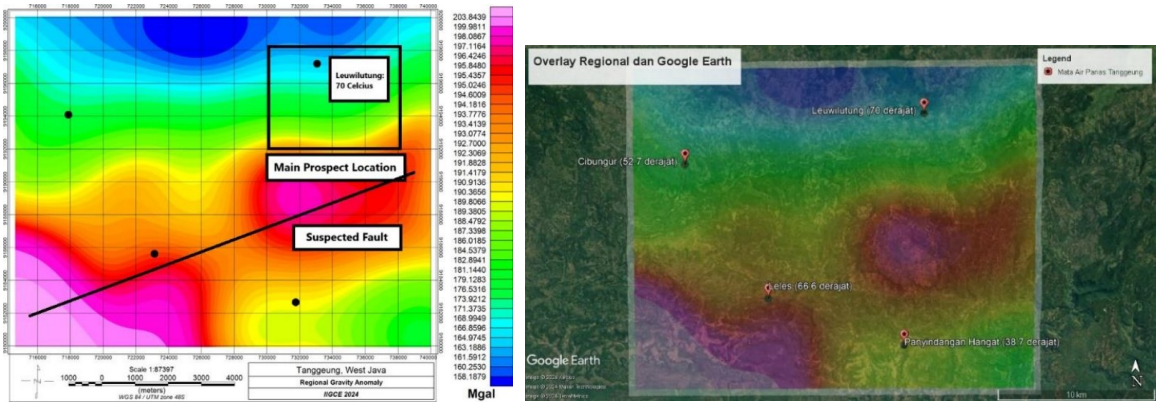

Figure 5: Regional Gravity Map.

The residual anomaly map in the study area shows that the contours exhibit varying degrees of variation. The residual anomaly contours are more diverse and slightly rougher compared to the regional anomalies. This difference arises because residual anomaliesrepresent conditions closer to the surface or shallow subsurface, where the layers and rocks in the shallow zone have heterogeneous properties.

On the residual anomaly map of the study area, gravity anomaly values range from -5.4277 to -4.7858 mGal. The relatively high gravity anomalies, ranging from 5.4277 to 0.6743 mGal, spread in all directions, but there is a noticeable continuity of high anomalies in the central part, which can be considered as faults or rocks with high density such as breccia tuff and andesite lava originating from Mount Patuha and extending towards Tanggeung. Conversely, the low gravity anomalies, with values ranging from 0.6743 to -4.7858 mGal, are mostly located in the northeast, considered as alluvial and tuff deposits because they are near the Cibuni River.

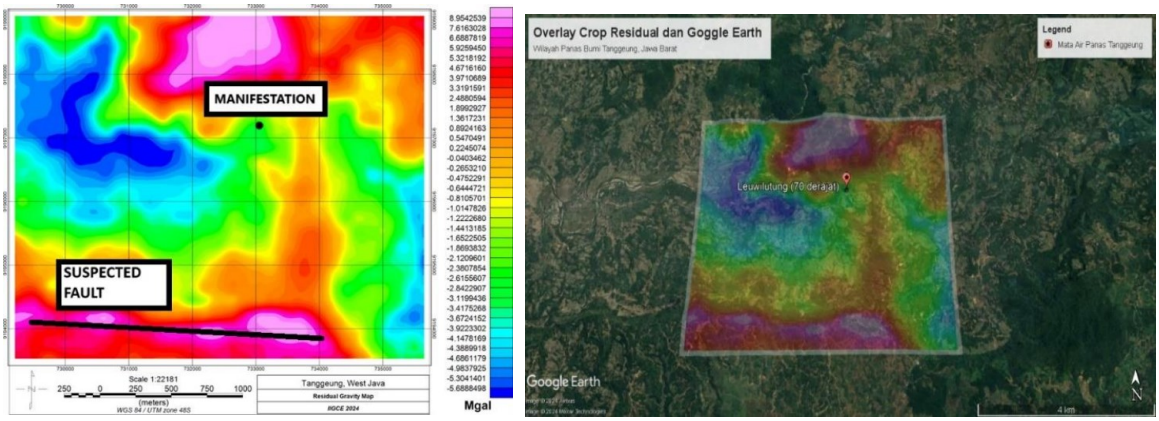

Figure 6: Residual Crop Gravity Map.

The results of the residual map after focusing on the northeast, which has the hottest manifestations with temperatures exceeding 70 degrees celsius, show that in the southern part, there are high gravity anomaly values associated with faults or rocks with high density such as breccia tuff and andesite lava originating from Mount Patuha and extending towards Tanggeung. Additionally, this map shows a flow-like shape moving from the Mount Patuha rocks in the south towards the north. This can be interpreted as a heat flow moving towards the manifestation (outflow) in the north through faults originating from the upflow in the southern part of the study area. The result of the outflow gives rise to the geothermal manifestation known as "Leuwilutung."

This interpretation is further reinforced by the results of trend surface analysis and fault analysis. The trend surface results provide a clear view of the residuals. The TSA results, ranging from order 1 to order 3, with order 3 being the most indicative of the surface, show that the research area is flanked by high-density rocks in all directions. This results in a low anomaly value that is wedged between these high anomalies. This assumption can preliminarily suggest that the area is a basin or a deposition site for tuff rocks, as interpreted by the geological sheet of the study area.

Meanwhile, the fault interpretation is strengthened by the FHD analysis and advanced FHD analysis, which show high values from south to north, clearly indicating a continuity of high anomalies considered to be faults in the research area.

In the cropped FHD map, a clearly visible fault running from west to east is evident, suspected to be a structure originating from Mount Patuha. In the middle, a black dot marks the "Leuwilutung" manifestation. Additionally, there is a path from the major fault in the south leading to the manifestation in the north of the study area. This can be interpreted as a fault that shapes the geothermal structure to be modeled below.

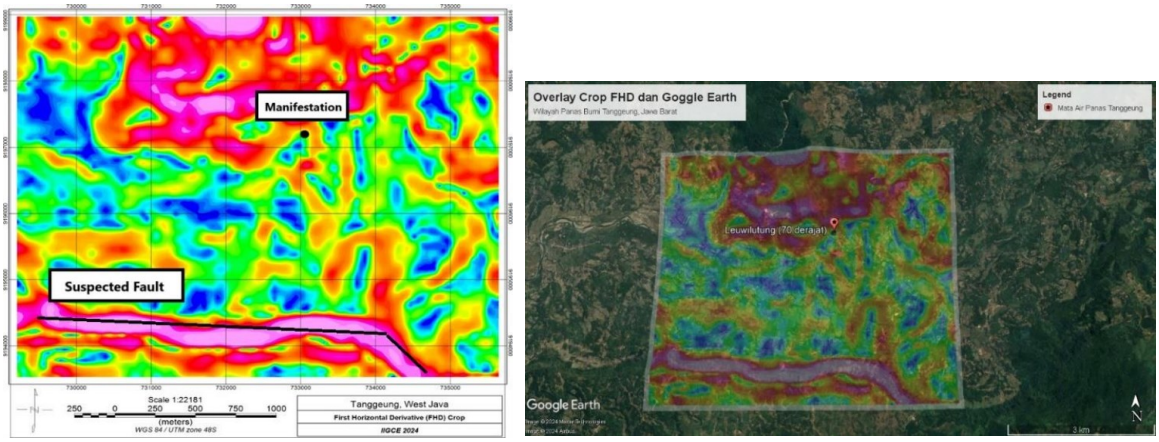

Figure 7: First Horizontal Derivative (FHD) Map.

In order to know where the edge of fault, FHD map will be correlated with the Fast Sigmoid Based Edge Detection (FSED) map. This is an advanced derivative analysis, a fault analysis technique used to identify edges in a fault. The image shows the same area as the cropped FHD map. The edges of the fault are indicated in red, extending from the dominant fault in the south towards the north, leading to the "Leuwilutung" manifestation.

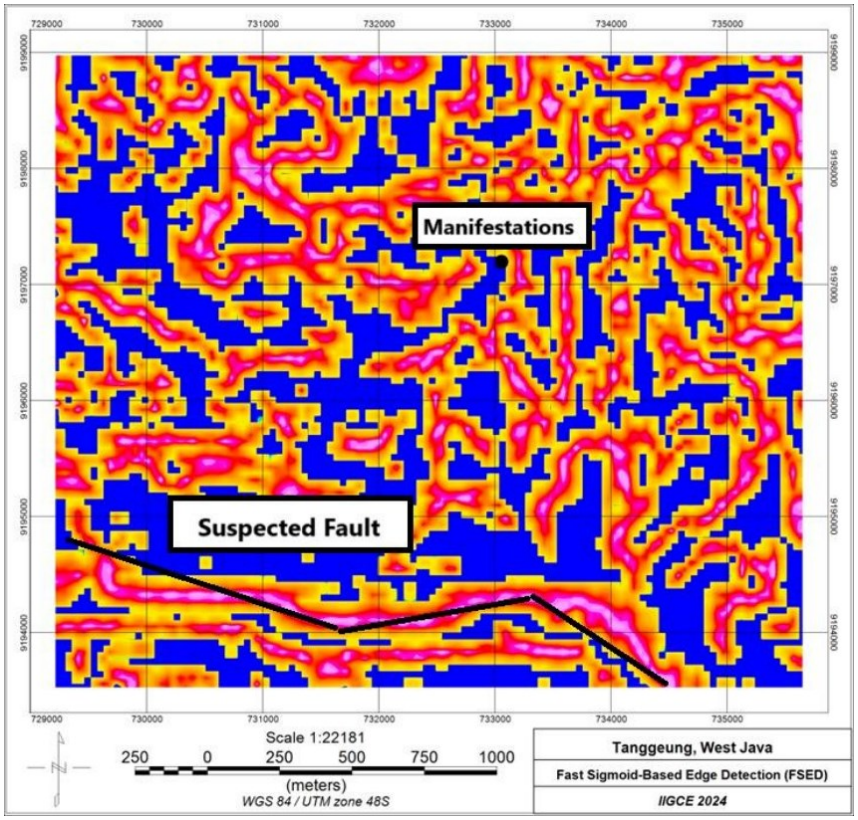

Figure 8: Fast Sigmoid Based Edge Detection (FSED) Map.

3.4 Land Surface Temperature Map

After obtaining and validating the Trend Surface Analysis and fault analysis, additional data is needed to validate that the identified manifestations are accurate points based on the mineral conditions and temperature conditions in the area. The Land Surface Temperature map is used to observe the distribution of temperature and temperature anomalies. Below is the map of the manifestation location at Leuwilutung.

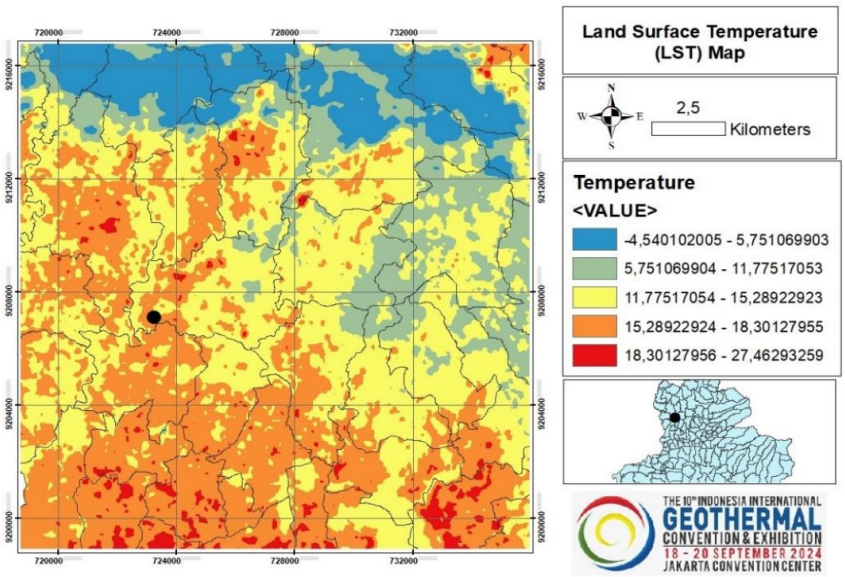

Figure 9: Land Surface Temperature (LST) Map.

It can be seen on the land surface temperature map at the manifestation location that there are notable anomaly values. The majority of the temperatures in the northern part decrease from 15.2 to 11 and down to 5. However, at the manifestation point, marked by a black circular shape, there is an anomaly-colored orange to red in the

northern part, ranging between 15.2 and 27.4℃. Meanwhile, the black color at the southern end represents error and noise. Additionally, the alteration mineral map shows a uniform distribution of clay minerals and iron minerals in the manifestation area, which is an indicator of rock alteration in that region.

3.5 3D-Gravity Map

As mentioned above, the residual map will be made into a 3-D cross-section consisting of three slices, namely A-A', B-B', and C-C', as follows. On average, all slices show the presence of a capping rock considered to be breccia, tuff, and andesite lava from Mount Patuha, with a density value of 2.45 – 2.5 g/cm3 and an average depth of 0 – 700 meters from the surface. Below this, reservoir rock with a density value of 2.4 – 2.3 g/cm3 is deposited, having an average depth of 700 – 1500 meters. The reservoir rock is interpreted as tuff and sandstone.

3.5.1 A-A’ Model

In the 3D gravity model cross-section A - A', oriented west-east, it intersects the Burni Waihlup fumarole in the study area with a depth of more than 2200 meters. In the A-A' modeling, the red-yellow layer at the top is suspected to be the Cap Rock or capping rock layer with a depth of more than 0 - 300 meters. This clay cap is believed to consist of the Pusat Kembar formation, including andesite, dacite, basalt, and pyroclastic rocks rich in clay minerals with a density of about 2.545 - 2.565 g/cm3. The green-blue layer, with a depth of 300 - 1400 meters from the surface, is considered the reservoir system containing alluvium rocks from the Kutacane graben, which are rich in fractures and permeable, having a density of 2.525 - 2.505 g/cm3.

Meanwhile, below the reservoir, at a depth of 1500 – 2200 meters, is suspected to be the Ketambe intrusion formation consisting of granite rocks with a density of 2.545 - 2.565 g/cm3, serving as the heat source for the reservoir above as well as water from the faults in the study area.

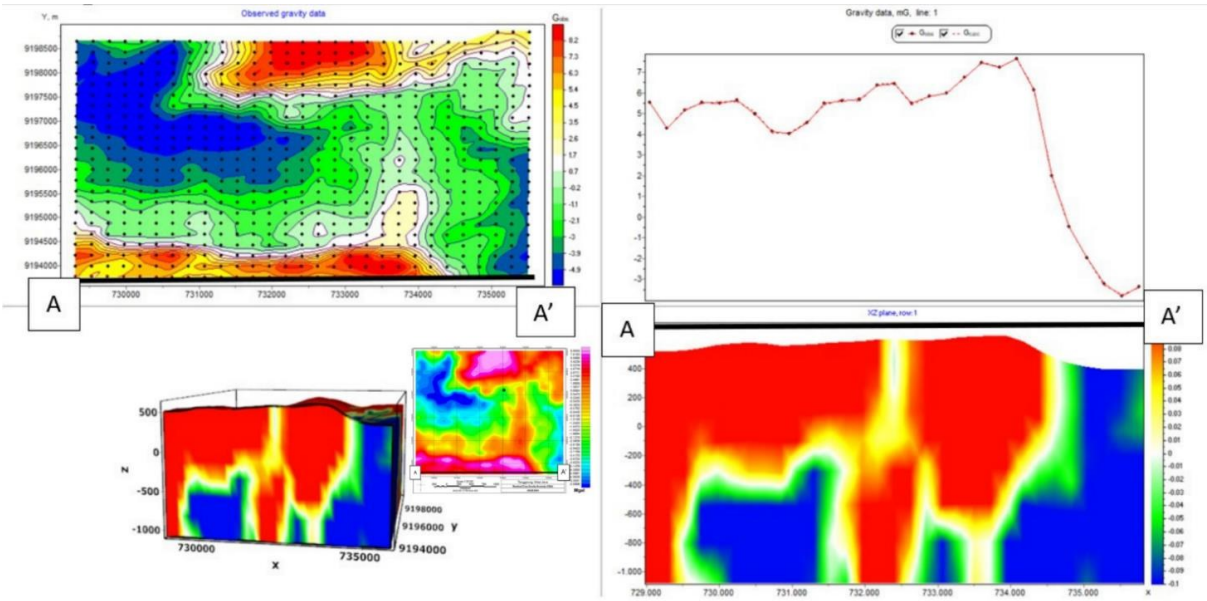

Figure 10: 3D Model Cross-Section A-A’.

3.5.2 B-B’ Model

In the 3D gravity model cross-section B - B', oriented west-east, it is located north of the Burni Waihlup fumarole in the study area with a depth of more than 2200 meters. In the B-B' modeling, the red-yellow layer at the top is suspected to be the Cap Rock or capping rock layer with a depth of more than 0 – 600 meters. This clay cap is believed to consist of the Pusat Kembar formation, including andesite, dacite, basalt, and pyroclastic rocks rich in clay minerals with a density of about 2.545 - 2.565 g/cm³. The green-blue layer, with a depth of 600 - 1000 meters from the surface, is considered the reservoir system containing alluvium rocks from the Kutacane graben, which are rich in fractures and permeable, having a density of 2.525 - 2.505 g/cm³.

Below the reservoir, at a depth of 1000 – 2200 meters, is suspected to be the Ketambe intrusion formation consisting of granite rocks with a density of 2.545 - 2.565 g/cm³, serving as the heat source for the reservoir rocks above as well as water from the faults in the study area.

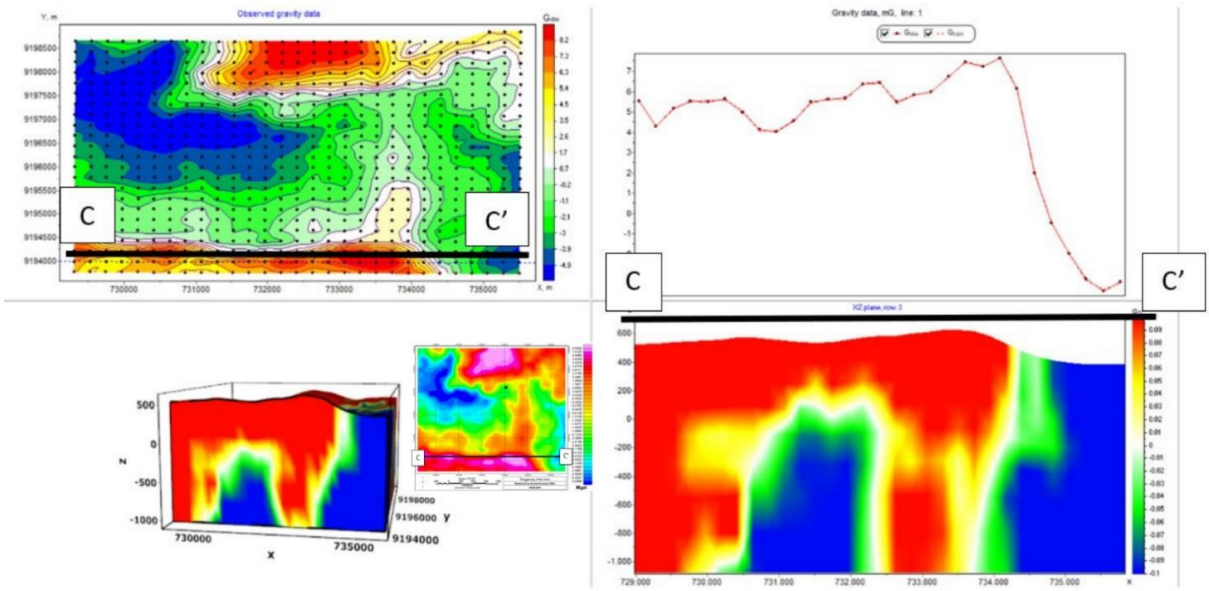

Figure 11: 3D Model Cross-Section B-B'.

3.5.3 C-C' Model

The gravity 3D model cross-section C - C' is a vertical section running north-south, cutting directly through the "Leuwilutung" hot spring in the northern part of the study area, with a depth of over 1400 meters.

In the C-C' model, the red-yellow layer on top is presumed to be the cap rock or sealing layer, with a depth of 0 to 500 meters. This clay cap is thought to consist of breccia, tuff, and andesite lava from Patuha Mount, with a density of 2.45 to 2.5 g/cm³. However, in the northern part of this vertical slice, a blue area can be seen, which may represent the Leuwilutung manifestation in the Tanggeung area.

Below this, the white to green layer indicates the reservoir rock, with a density of 2.4 to 2.3 g/cm³ and an average depth of 600 to 1400 meters. This reservoir rock is interpreted as tuff and sandstone.

The selection of the slicing is based on the absence of significant geothermal structures in the central and northern parts of the study area. The images below show that the central and northern regions are dominated by sedimentary rock deposits, such as tuff and sandstone. This is also interpreted as sediment deposits from rivers, as the study area includes numerous rivers, leading to abundant sediment deposits in the central and northern parts of the study area.

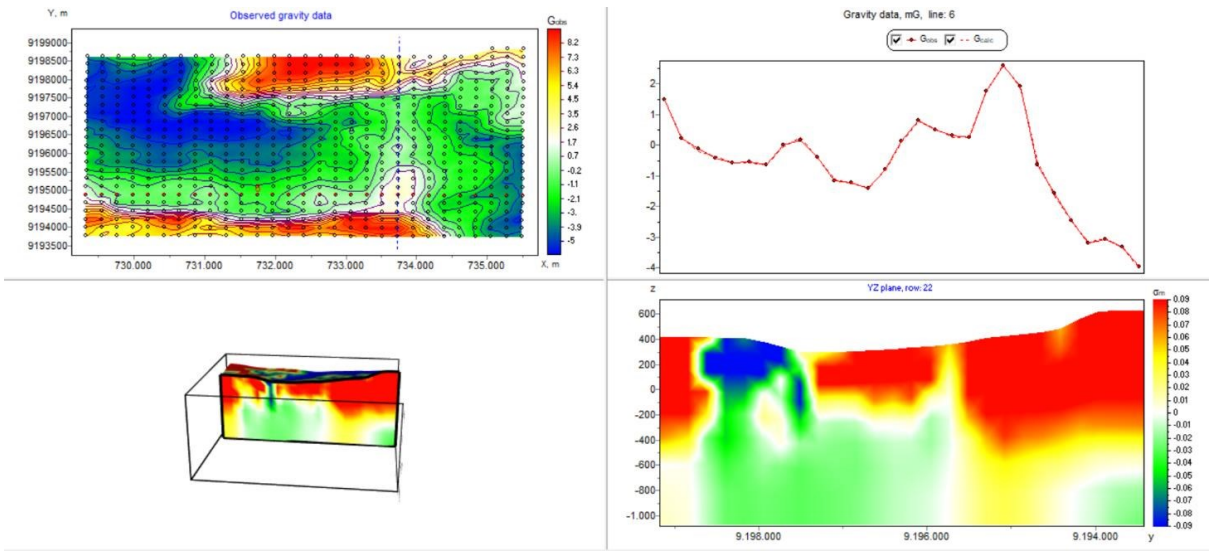

Figure 12: 3D Model Cross-Section C-C'.

3.6 Volumetric Calculation

The 3D inverse modelling of the designated are shown large thickness of breccia stone with density around 2.4-2.7 g/cc that is potential for geothermal storage. Volume of breccia stone on the area is predicted around 9.422-11.215 km3. The model's outcome (Fig X) provides initial insights into the concept of estimated capacity for geothermal storage.

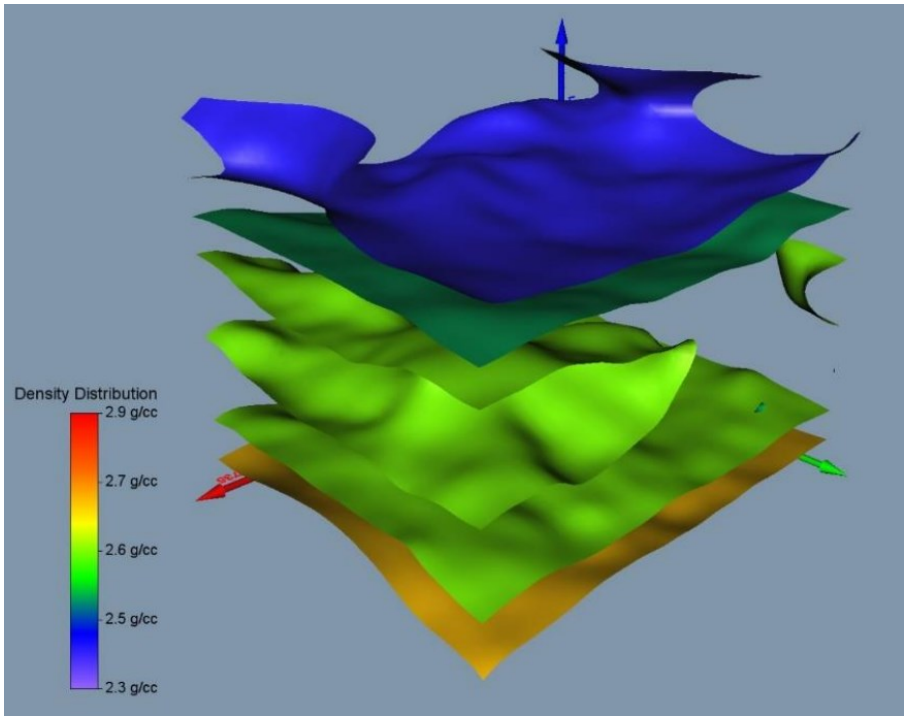

Figure 14: Distribution of Breccia Stone in the Area (Blue = 2.4 g/cc, Light Green = 2.5 g/cc, Light Green – 2.59 g/cc, Yellow = 2.7 g/cc)

4. CONCLUSION

This study shows that the Tanggeung area has significant geothermal potential, as indicated by geothermal manifestations in Leuwilutung, which serve as an outflow from the upflow in the southern part of the study area. Geophysical methods such as resistivity, magnetic, gravity, and electromagnetic have proven effective in identifying geological structures and geothermal potential. Geophysical data analysis reveals high gravity anomalies in the south and southwest, interpreted as the Upper Jampang Formation with rocks such as breccia tuff, tuff, and andesite lava, and low gravity anomalies in the north, interpreted as alluvial deposits and sandstone. A 3D model based on gravity anomaly data shows a clay cap with an average depth of 0 to 700 meters and a reservoir rock of tuff and sandy deposits from the Cibuni River with a density of 2.4 – 2.3 g/cm³ and depths of 700 to 1500 meters. The reservoir volume is estimated to be 9–11 cubic kilometers. These findings can serve as a basis for developing clean and sustainable geothermal energy in the Tanggeung area.

Keywords: Reservoir rock, lateral permeability, breccia, Lumut Balai

ABSTRACT

This study examines the physical properties, composition, dimension, and distribution of the reservoir rock of the Lumut Balai (LMB) geothermal system in Sumatra Indonesia, an extensive geothermal area within a 10 km wide volcanic-hosted caldera. Rock sample and drilling data were analyzed for this study through binocular and petrographic observation, porosity and permeability measurements, and borehole images identification.

The LMB reservoir rock demonstrates favorable grain permeability from the fragment – matrix contact rim in the tuff breccia. This formation permeability contributes significantly to the productive feed points discovered at elevation of 200 to -200 meters. Additionally, the temperature distribution shows close correlation with the tuff breccia and feed point zone, suggesting a vast lateral distribution permeability throughout the caldera.

1. INTRODUCTION

The Lumut Balai (LMB) geothermal system is situated in the active tectonic zone of the Great Sumatran Fault, characterized by tensional faults, horst and depression forming, pull-a-part basins, and series of quaternary volcanic activity. The geothermal system is well-developed within the Old-Lumut Caldera. Quaternary volcanic products dominate the surface rock inside the caldera with andesitic to basaltic composition. The tertiary sediment was marked as the basement formation of the system (Figure 1).

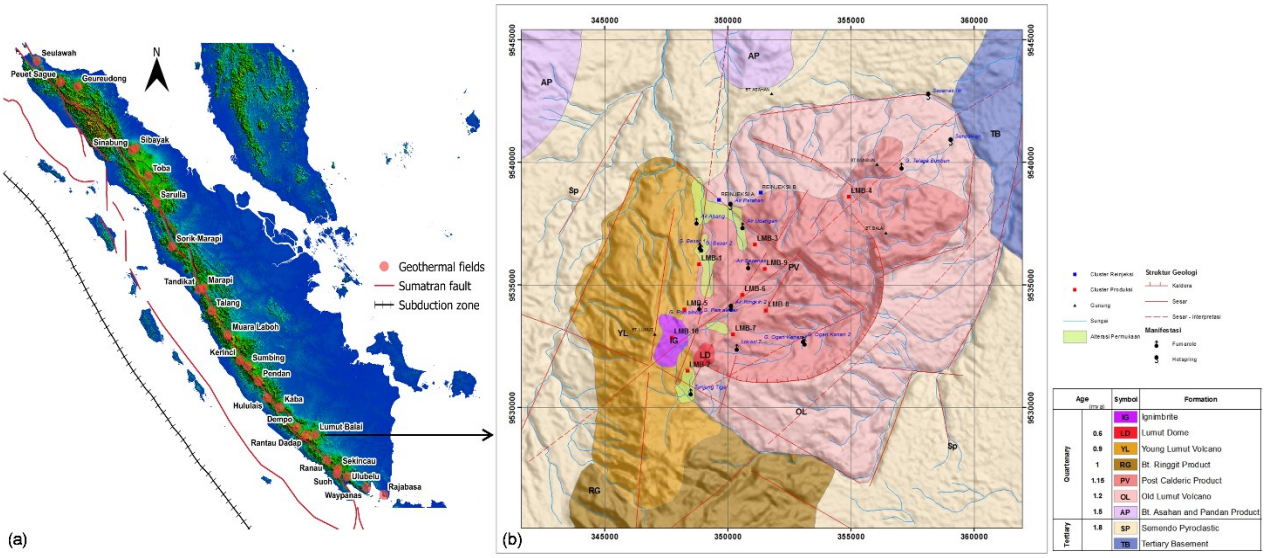

Figure 1: Location of geothermal prospect area along the Great Sumatran Fault (a) and surface geological map of the Lumut Balai Geothermal system (b).

The geothermal system of LMB features a neutral water-dominated reservoir with temperatures ranging from 230 to 260 °C. Productive feed points were discovered near sea level elevation (Yanto, 2021). The reservoir rock associated with feed points, high temperature, and propylitic zone is identified as tuff breccia from the Pre-Old-Lumut Formation product of Old-Lumut Volcano. This favorable volcanic breccia is hydrothermally altered by secondary quartz, calcite, chlorite, epidote, adularia, wairakite, actinolite, and adularia.

2. THE LUMUT BALAI RESERVOIR ROCK

2.1 Physical properties and borehole log

The reservoir rock in LMB is identified as tuff breccia. The rock matrix consists of volcanic glass, tuff, and lapilli, and coarse-sized angular fragments of andesite and basaltic lava act as lithic grains. The poorly-sorted breccia is highly altered with high-temperature secondary mineral assemblage deposition, particularly in between fragments – matrix contact boundaries (Figure 2).

Petrographic observations reveal that intensive secondary mineral deposition occurred in the micro vein network in between grain to grain, grain to matrix, and open vesicles. Secondary quartz, calcite, epidote, and chlorite are the most common minerals found in rock veins. Furthermore, the matrix is altered by scattered fine-grained crystals of chlorite, sericite, epidote, and opaque minerals (Figure 2a and 2b).

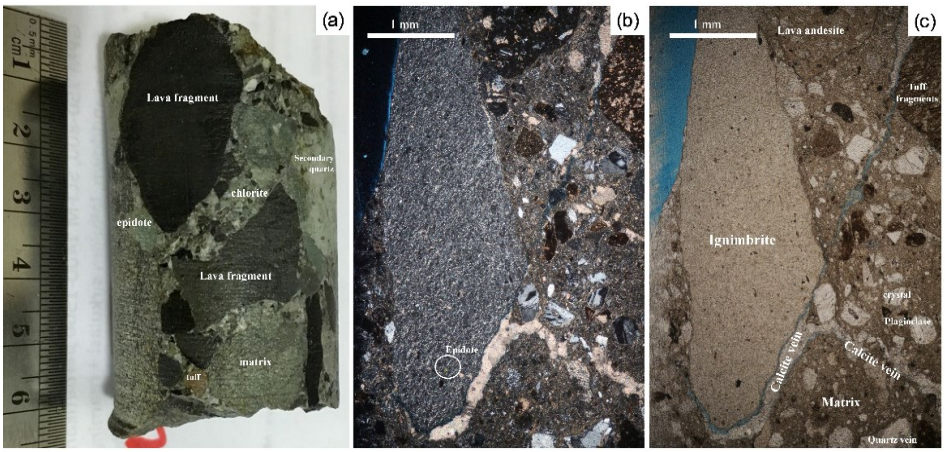

Figure 2: Core sample retrieved from the reservoir zone of LMB system shows fragmental texture in breccia; hand specimen photograph (a), thin section under crossed in polarized view (b), and plane polarized view (c).

Figure 3 illustrates the most prevalent data trend observed in the productive borehole of LMB geothermal system. The tuff breccia is identified as the reservoir rock, due to its strong correlation with the high-temperature alteration zone, measured feed points, and the convective temperature trend in the reservoir.

In a fault-controlled reservoir, the feed points are typically indicated by an immediate high loss rate during steady injection, as seen in the Hululais geothermal field (Arifin, 2020). However, the main feed points in the LMB are found under medium loss conditions (0 to 7 barrel per minute), as demonstrated by Feed Point A (Figure 3). This indicates that Feed Point A is likely associated with an excellent primary permeability of the reservoir rock rather than faulted zone.

Feed Point A, located near sea level, contributes up to 95% of the well's production rate, as confirmed by the production spinner log measurement. Furthermore, the convective temperature trend, indicative of the reservoir zone, is observed at this depth, with temperature reaches 234 °C (Figure 3). On top of that, this borehole successfully generates 6.4 MW of electricity.

2.2 Borehole image

In this study, we cross-validated borehole image data with injectivity/production spinner tests and core samples. Our findings indicate that the typical reservoir rock formation at feed points is strongly associated with fragmental rock, specifically identified as tuff breccia from the core samples.

The tuff breccia interval is characterized by a fine matrix with some conductive, rounded patches, which are interpreted as vesicular structures. These conductive features are believed to represent open spaces filled with conductive minerals, such as clay, or reservoir fluids (Figure 4). Furthermore, spinner test results that this tuff breccia zone contributes for more than 40% of the total injection capacity during the well test. This shows the important role of tuff breccia as a permeable reservoir rock.

2.3 Distribution

The tuff breccia is encountered at relatively similar depths within the caldera, approximately between 200 to -200 meters elevation. Accordingly, all contributive feed points are discovered within the tuff breccia layer. Temperature distribution follows the formation bed and caldera basin, indicating that the reservoir hydrology is controlled by the lateral permeability distribution of tuff breccia in relatively uniform depth (Figure 5).

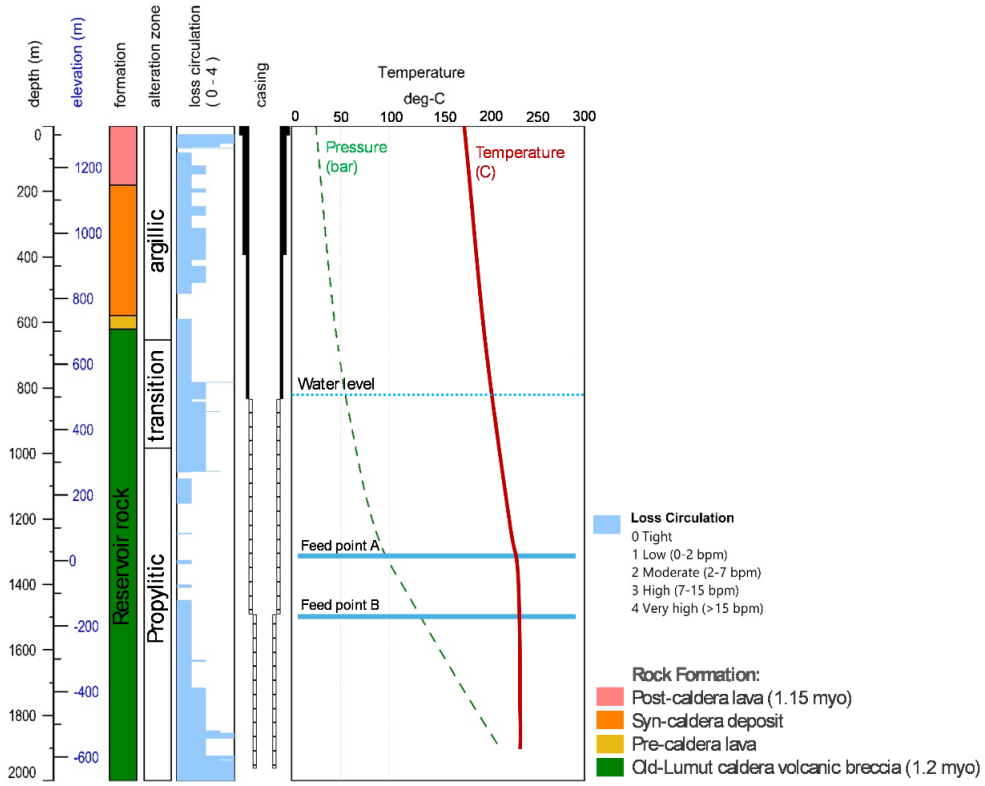

Figure 3: An example of borehole log from producer wells in Lumut Balai geothermal system shows typical association of the feed points with high temperature reservoir zone.

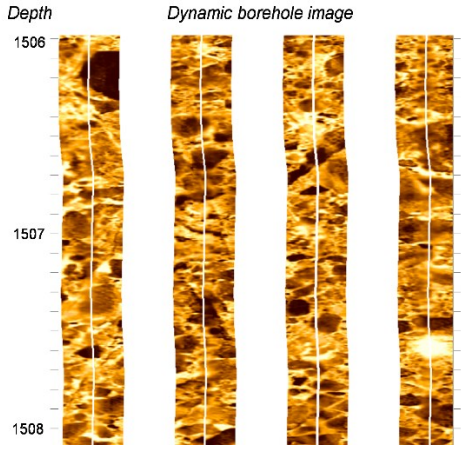

Figure 4: Borehole image of the reservoir rock in Lumut Balai which is associated with the production zone.

3. COMPARISON STUDY

The tuff breccia in LMB is interestingly comparable to the Ulubelu (UBL) reservoir rock. Both fields exhibit a depression-fill mechanism with volcanoclastic deposits; in the case of UBL, the reservoir rock is identified as lapilli tuff (Nusantara, 2021). The reservoir rock is restricted by the caldera rim in LMB, meanwhile it is strongly controlled by the pull a-part basin morphology in UBL. Correspondingly, UBL reservoir rock also shows a favorable lateral primary permeability in its feed points distribution.

We observed and plotted the composition of LMB and UBL core samples into the pyroclastic classification (After Fischer, 1966). Despite sharing a similar fragmental texture, UBL reservoir rock has finer grain size and better sortation than LMB (Figure 6). Nonetheless, both lithologies are effectively contributing to the well's production capacity rate.

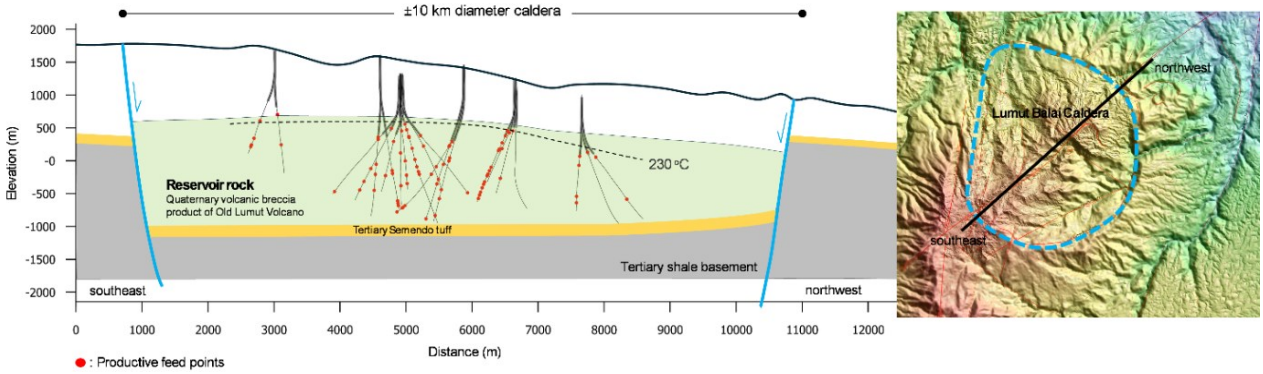

Figure 5: The northeast – southwest profile shows distribution of reservoir rock influences the feed points and temperature lateral extent.

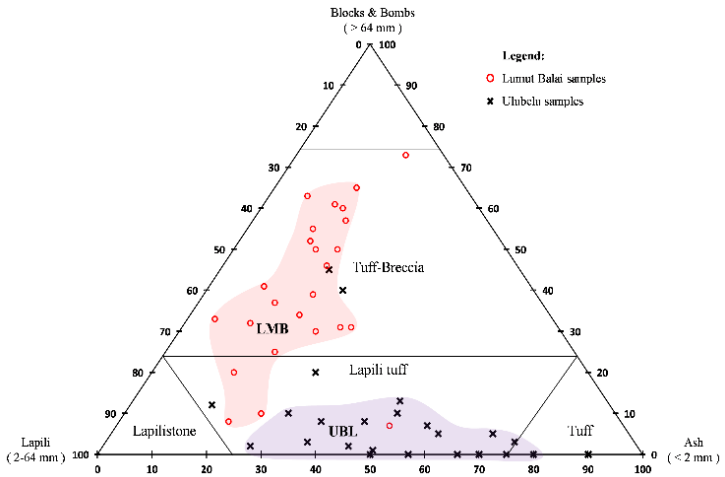

Figure 6: Characterization of reservoir rock in LMB compared to the reservoir rock in UBL geothermal system suggesting a different type of volcanoclastic facies. LMB is composed of tuff breccia and UBL is dominated by lapilli tuff.

Primary permeability and porosity measurements from core samples indicate sufficient initial formation capacity to convey hydrothermal fluid through the lithology layer. Average permeability and porosity measured are 0.37 mD and 4.0 % for LMB, and 0.36 mD and 8.8 % for UBL, respectively. The higher porosity in UBL is attributed to its higher vesicles/ gas escape pores properties in its rock component.

4. CONCLUSION

The LMB geothermal system is influenced by tensional activity inside the caldera that is strongly associated with active volcanism. This combined activity results in the development of tuff breccia as the reservoir rock in LMB geothermal system. The distinctive fragmental texture of LMB reservoir rock promotes significant primary permeability with an extensive lateral distribution, as confirmed by numerous successful boreholes. Consequently, the elevation and thickness of this reservoir rock are crucial factors in well-targeting strategies within this field.

ABSTRACT

Laboratory analysis plays a vital role in advancing our understanding of geothermal systems, optimizing resource utilization, and mitigating operational risks. By employing state of-the-art analytical techniques and adhering to rigorous quality standards, researchers and engineers can extract valuable information from geothermal samples to support sustainable and efficient energy production. PGElabs are the pioneer with over 40 years of excellence in geothermal laboratory. Supported by technical experts, advanced instruments, and also guided by ISO/IEC 17025:2017 based laboratory management system, we have developed various methods and standards in terms of sampling, fluid and rock analysis and other special methods so that we contribute to maintaining operational reliability and reservoir sustainability. This paper examines the journey of PGELabs from its initial stage to present condition and also to indicate the pivotal milestone where PT Pertamina Geothermal Energy Tbk (PGE) launched the PGELab to become a commercial geothermal laboratory which is part of PGE's growth story as a center of excellence.

1. INTRODUCTION

PGELabs established in 1983 concurrently with Commercial on Date Unit 1 PT PGE Area Kamojang. PGELabs is a specialized geothermal laboratory which can carry out sampling, chemical analysis of geothermal fluids and rocks/ solids which is equipped with the latest analytical equipment and has been accredited ISO/IEC 17025:2017. Geothermal energy often face challenges associated with resource uncertainty. Successful geothermal production relies heavily on accurate and comprehensive data provided by specialized geothermal laboratories. Through detailed subsurface data and analysis, we can better understand reservoir properties, optimize drilling strategies, and mitigate exploration risks.

PGELabs equipped with advanced geological and geochemical analysis tools will significantly aid in resource assessment and characterization in geothermal energy. As stakeholders deeply involved in the geothermal energy, we wish to underscore the critical importance of geothermal laboratory.

PGELabs, a pioneer with over 40 years of excellence in geothermal laboratory services, offers critical services including Laboratory Analysis, Tracer Tests, and Geothermal Sampling. The laboratory continually develops various methods and standards for sampling, fluid and rock analysis, and other specialized techniques to enhance operational reliability and reservoir sustainability. In 2024, leveraging its extensive experience and international acclaim, PGELabs is set to advance as a commercial entity, marking a significant new phase in its development.

2. OUR SERVICES

PGELabs offers key services such as Laboratory Analysis, Tracer Tests, and Geothermal Sampling. As a specialized geothermal laboratory, PGELabs is equipped with the latest analytical equipment and is accredited to ISO/IEC 17025:2017. This accreditation ensures that we can carry out precise sampling and chemical analysis of geothermal fluids and rocks/solids with the highest level of accuracy and reliability.

2.1 Laboratory Analysis

Laboratory analysis plays a vital role in advancing our understanding of geothermal systems, optimizing resource utilization, and mitigating operational risks. By employing state-of-the-art analytical techniques and adhering to rigorous quality standards, researchers and engineers can extract valuable information from geothermal samples to support sustainable and efficient energy production. Supported by highly qualified and experienced personnel, reliable advanced equipment, and an integrated laboratory management system, PGE laboratories are committed to delivering excellence in every aspect of their work.

Our Expertise:

Fluid analysis

- Geothermal water analysis
- Geothermal gas analysis

Rock Analysis

- Petrography,
- Mineral & scale analysis,
- Fluid inclusion analysis

(a)

(b)

Figure 1: (a) Fluid analysis, (b) Rock analysis.

Figure 2: Tracer test equipment.

2.2 Tracer Test

Tracer tests play a crucial role in advancing our understanding of geothermal systems and optimizing the development and management of geothermal resources for sustainable energy production. Laboratory analysis of tracer samples is essential for elucidating reservoir characteristics, fluid flow dynamics, and heat transfer

processes within geothermal reservoirs. By providing valuable insights into reservoir behavior, tracer test analysis significantly contributes to optimizing reservoir management strategies and enhancing the efficiency and sustainability of geothermal energy production.

Our Expertise:

- Reservoir tracer testing, sampling & analysis
- Chemical tracer flow testing, sampling & analysis

2.3 Geothermal Sampling

Sampling is essential for understanding the composition, temperature, pressure, and other parameters of geothermal reservoirs, which is crucial for assessing the potential for geothermal energy production. PGELabs experienced in conducting geothermal sampling across diverse conditions and locations, we ensure thorough validation and interpretation of sampling data by qualified experts. This expertise and rigorous approach enable us to provide accurate and reliable insights into geothermal resources.

Our Expertise:

- Exploration Geothermal Sampling
- Well Testing Geochemistry Sampling
- Production & Monitoring Sampling

Figure 3: Geothermal sampling activity.

3. OUR TRANSFORMATIONS

PGElabs are the pioneer with over 40 years of excellence in geothermal laboratory. We are always transforming and developing various methods and standards in terms of sampling, fluid and rock analysis and other special methods so that we contribute to maintaining operational reliability and reservoir sustainability.

3.1 Steam Wetness Measurement (2012)

Improving Quality of Steam Wetness Measurement Using Portable Isokinetic and Throttling Calorimeter.

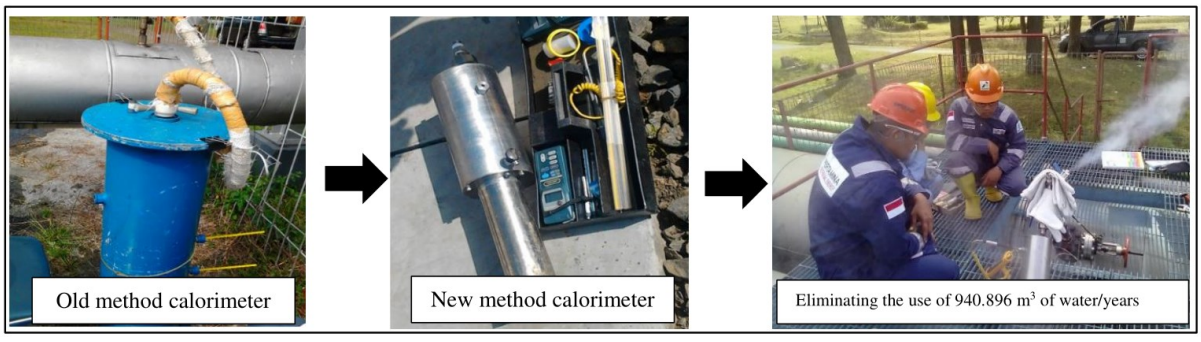

Figure 4: Improving Quality of Steam Wetness Measurement Using Portable Isokinetic and Throttling Calorimeter.

3.2 Superheat Measurement (2012)

Measurement of Superheat Degree in Production Wells Using Mini Probe for Reservoir Monitoring and Evaluation.

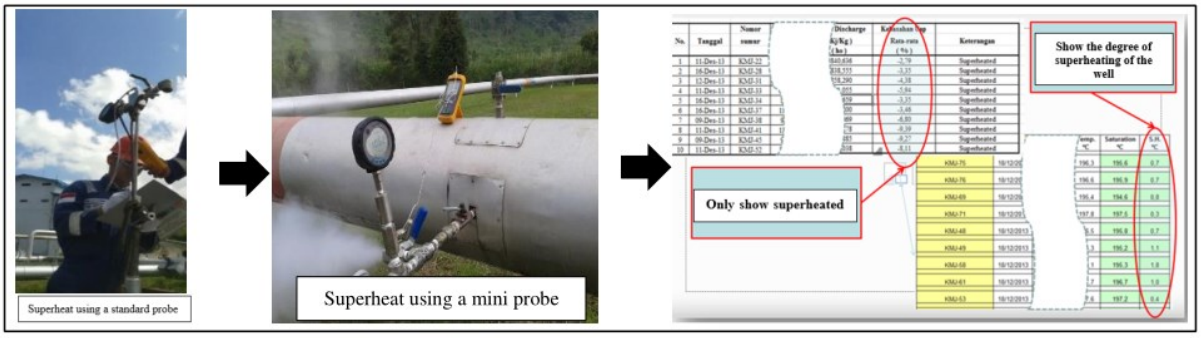

Figure 5: Measurement of Superheat Degree in Production Wells Using Mini Probe for Reservoir Monitoring and Evaluation.

3.3 Fluid Cation Analysis (2013)

Advancing Cation Analysis in Geothermal Fluid: Transition from Conventional Method to ICP-0ES (Inductively Coupled Plasma - Optical Emission Spectroscopy).

PGElabs transitioned from conventional method to ICP-OES (Inductively Coupled Plasma – Optical Emission Spectroscopy) for cation analysis (Na, K, Ca, Mg, Si, Fe, Li, B) in geothermal fluid samples significantly enhances testing quality by delivering more accurate, faster, and consistent results. Unlike manual method, which relies on large quantities of chemical reagents, ICP-OES uses plasma technology to detect cation elements with high sensitivity, even at low concentrations. In addition to improving accuracy, this method also reduces the production of hazardous and toxic waste (B3), supporting more environmentally friendly operations and lowering waste management costs, making it a more efficient and sustainable solution.

Figure 6: ICP-OES (Inductively Coupled Plasma – Optical Emission Spectroscopy).

3.3 Fluid Anion Analysis (2013)

Advancing Anion Analysis in Geothermal Fluid: Transition from Conventional Method to Ion Chromatography.

PGELabs transitioned from conventional method to Ion Chromatography (IC) for anion analysis (F, Cl, SO4) in geothermal fluid samples enhances testing quality by providing more accurate, faster, and consistent results. Unlike manual method, which requires large quantities of chemical reagents, Ion Chromatography uses ion separation technology to detect anion elements with high sensitivity, even in small amounts. In addition to improving accuracy, this method also reduces the production of hazardous and toxic waste (B3), supporting more environmentally friendly operations and lowering waste management costs, making it a more efficient and sustainable solution.

Figure 7: IC (Ion Chromatography).

3.4 Total NCG (Non-Condensable Gas) Measurement (2014)

The Portable total NCG Super Fast at PT PGE for Accelerate the Total NCG Measurement Process.

PGELabs has developed a straightforward tool designed to measure the total amount of Non-Condensable Gases (NCGs) in geothermal steam. The device operates by optimizing the condensation process in a dedicated condenser, where steam is condensed into a container. By measuring the total vapor volume, condensate gas pressure, and condensate volume, it enables precise calculations of the NCG volume. This tool offers several advantages including faster measurement, high accuracy, low cost, portability, ease of handling, simple installation, and being chemical-free and environmentally friendly.

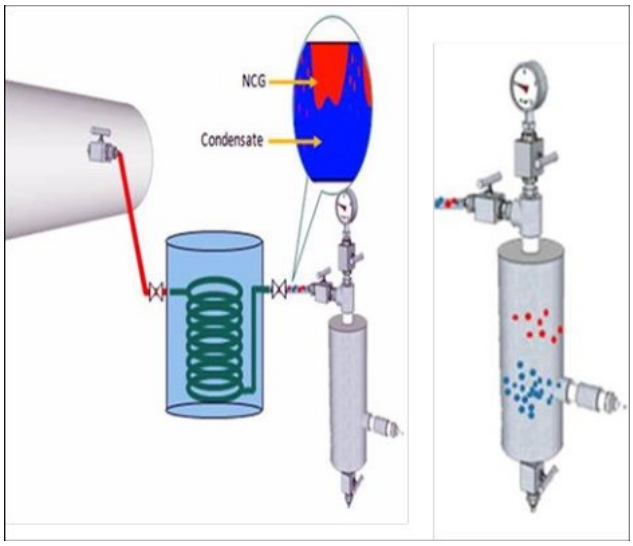

Figure 8: Portable NCG (Non-Condensable Gas).

3.5 Accreditation & Certification ISO/IEC 17025:2017 (2019)

PGElabs is certified and accredited to ISO 17025:2017, reflecting our commitment to transforming and enhancing the quality of our analyses. By adhering to the highest international standards for testing and calibration, we deliver trustworthy and precise results. This accreditation ensures that our laboratory provides reliable and accurate results for a range of tested parameters, including:

- Geothermal condensate (pH , Conductivity, TDS, TSS, Na, K, Ca, Mg, Li, Fe, SiO2, B, NH4, F, Cl)
- Geothermal water (pH, Conductivity, TDS, TSS, Na, K, Ca, Mg, Li, Fe, SiO2, B, NH4, F, Cl, SO4)
- Geothermal gas (steam) (H2, Ar, O2, N2, CH4, CO2, H2S, NH3)
- Geothermal rock
- Geothermal scale.

3.6 Advanced CO2 Gas Analyzer (2020)

Improving the Quality and Quantity of CO2 Testing in Geothermal Steam Samples using the ACID CONVERSION (ACONV) Method.

PGELabs transitioned from conventional acid-base titration to the use of a CO2 Analyzer for analyzing CO2 in Non-Condensable Gas (NCG) samples from geothermal steam has significantly improved the quality of test results by providing more accurate and faster data. The CO2 Analyzer operates automatically with high precision, reducing reliance on operator skill and minimizing the potential for manual errors commonly associated with the traditional method. Additionally, the CO2 Analyzer can process smaller sample volumes more efficiently, allowing for quicker analyses and more consistent, repeatable testing. This enhances overall testing efficiency and supports more effective monitoring of geothermal operations.

Figure 9: Accreditation & Certification ISO/IEC 17025:2017.

Figure 10: CO2 Gas Analyzer.

3.7 Optimization of Anion Sample Preservation (2023)

Improving the Quality of Sulfate Testing in Geothermal Fluid Samples Using the PZACR (Preservetive Zinc Acetate & Conditioning Reagent) PZACR Method (Preservative Zinc Acetate & Conditioning Reagent.

PGELabs has innovated and transformed its processes by incorporating the addition of Zn Acetate for field preservation of samples, which precipitates dissolved H2S, and implementing reagent conditioning during spectroscopic analysis to reduce HCO3 interference. These improvements optimize sulfate testing for brine and injection samples. The PZACR method has extended the holding time for geothermal water samples from 7 days to 43 days. This advancement not only ensures high-quality analysis results but also leads to operational cost

savings, accelerates data delivery, reduces the risk of H2S exposure for analysts, and enhances confidence in the performance of laboratory analysts.

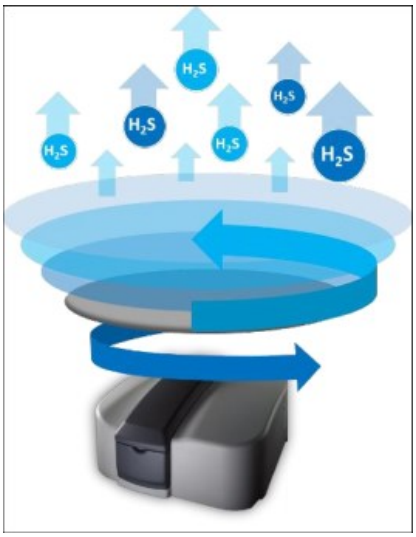

Figure 11: PZACR Method.

Figure 12: Govast (Gas Geothermal Vacuum System).

3.8 NCG (Non-Condensable Gas) Measurement (2023)

Increasing the Effectiveness of Geothermal Gas Sample Testing Preparation Using GOVAST method (Gas Geothermal Vacuum System).

PGELabs has innovated the analysis of geothermal samples by addressing the inefficiencies of direct gas chromatography for concentrations above 100ppb at pressures below 10 kPa. By implementing the GOVAST Gas Geothermal Vacuum System, the laboratory enhanced sample preparation, improving testing precision to an average %RPD of 4.912% and reducing cycle time from 44.58 to 17.34 minutes. This advancement led to substantial cost savings, including reduced external service fees and GC (Gas Chromatography) spare part expenses, a decrease in sample reanalysis from 47.05% to 1.56%, and a reduction in handling hazards.

3.9 NCG (Non-Condensable Gas) Reference Standards (2024)

Production of NCGs Reference Material as a Reference Standard for Geothermal Gas Samples in the Laboratory of PT PGE.

In preparation for its 2024 transition to a commercial laboratory, PGE Laboratory innovated by developing NCGS reference materials to meet ISO/IEC 17025 accreditation requirements. This innovation addresses the lack of available proficiency testing services by creating a unique process for generating reference standards. The procedure involves creating liquid standards for NH3 and CO2, vacuum-sealing them in Giggenbach bottles to prevent contamination, and then injecting these standards into a pre-treatment system for distribution. This advancement has positively impacted the laboratory's performance in quality, cost, delivery, severity, and morale, ultimately leading to successful ISO/IEC 17025 accreditation.

Figure 13: Pre-treatment Reference Standard for Geothermal Gas Samples.

4. CONCLUSION

PGELabs, a pioneer with over 40 years of excellence in geothermal laboratory services, leverages a team of technical experts and advanced instruments to develop a wide array of methods and standards for sampling, fluid, and rock analysis. This expertise ensures the operational reliability of Steamfield Above Ground Systems (SAGS) and power plants, contributing significantly to the sustainable development of geothermal energy in Indonesia. Equipped with the latest sophisticated technology, PGELabs delivers high accuracy and precision in data production, offering comprehensive services throughout all stages of geothermal development. This approach effectively addresses subsurface uncertainty and supports exceptional production quality, fostering the effective and sustainable management of geothermal resources.

PGELabs has received international recognition through ISO 17025:2017 certification, which underscores our commitment to quality assurance in laboratory analysis and sampling. We continuously innovate and transform our processes to enhance the effectiveness and efficiency of our analytical and sampling methods. This dedication to improvement ensures that our results meet the highest standards of quality and precision, reinforcing our role in advancing geothermal energy development with reliable and accurate data.

PGELabs will embark on a new phase of commercialization in 2024, building on its extensive experience and global recognition. This transition represents a significant advancement for the laboratory as it evolves into a commercial entity, leveraging its established expertise and international acclaim to enhance its market presence and expand its service offerings.

Preliminary Assessment of Critically Stressed Fracture in Lumut Balai and its Effect on Permeability of the Field

Muhammad Tajul Arifin, Sapto Trianggo Nurseto, and Mulyanto

PT Pertamina Geothermal Energy Tbk

muhammad.tajul@pertamina.com

Keywords: Lumut Balai, fracture, permeability

ABSTRACT

Unlike other geothermal fields in Sumatra, which are mostly located near the Great Sumatran Fault, Lumut Balai is situated approximately thirty to forty kilometres away from the fault. This unique location means that the geological structures in Lumut Balai are not directly affected by the movement of the Great Sumatra Fault. However, this situation complicates the assessment of permeable structures in Lumut Balai due to the presence of numerous major geological structures within the field.

To determine which structures direction is permeable, a preliminary slip tendency analysis was conducted. The goal was to identify critically stressed fractures that could serve as easier pathways for fluid flow compared to other fractures. The assessment utilized borehole data from six wells, pressure data and field-wide joint inverted gravity data. Additionally, interpreted feed zone depth data were used to understand the influence of critically stressed fractures on permeability in each well.

The study revealed that critically stressed fractures in Lumut Balai predominantly align with a north-northeast direction, coinciding with several major geological structures in the field. This directional consistency also explains why the hydrology of Lumut Balai flows in specific directions. Furthermore, the assessment found that most of the feed zones with significant contributions are influenced by the occurrence of critically stressed fractures.

By understanding the direction of these fractures from data collected across several wells and integrating it with the field's conceptual model, the assessment could guide decisions on which geological structures to target for future well prognosis.

1. INTRODUCTION

Not all fractures in geothermal fields are permeable, some fractures with certain directions might be more permeable than others, and some of them also could be filled with minerals and block the fluids from passing through the fracture. The permeability provided by fractures is one of the favorable for well targeting, thus efforts on identifying permeable fractures are important work.

Many works have been done in analyzing fractures and their effects on the permeability of a geothermal field, especially in Sumatra, such as in Rantau Dadap & Muara Laboh (Wallis, et al., 2020; Wallis, et al., 2023), Bukit Daun (Ikhwan, et al., 2020), Ulubelu (Nurseto, et al., 2015 and Arifin, et al., 2020), Hululais (Nurseto, et al., 2023, Arifin, et al., 2020), Sorik Marapi (Sanjaya, et al., 2023), Lumut Balai (Nurseteo, et al., 2020, and Kamah, et al., 2010). In general, these publications agree that fault and fractures are one of the main contributors to accommodating fluid flux into the borehole from the reservoir.

The study focuses on Lumut Balai geothermal field which is situated differently compared to the other geothermal fields in Sumatra where most of them are in the proximity of the Great Sumatran Fault. Meanwhile, Lumut Balai geothermal field is located as far as forty kilometers away to the north of Kumering Segment, the closest segment between Lumut Balai and the Great Sumatran Fault (Figure 1.a and 1.b). The geologic structures in Lumut Balai might not be directly influenced by the dextral strike-slip movement of the Great Sumatran Fault, thus complicating the determination of which geologic structures direction are potentially more permeable than the others. To answer this problem, assessment of critically stressed fractures in Lumut Balai is important as these fractures are expected to be hydraulically active due to situated at the appropriate angle to the current stress field, to be mechanically active (Zoback, 2007).

There are 2 publications discussing fractures and permeability as Nurseto, et al., (2020) discussed field-wide productive geological structures and Kamah, et al., (2010) discussed the evaluation of fracture and injectivity in 3 Lumut Balai wells, yet none discusses critically stressed fracture and its effect on permeability.

Thus, the latter sections of this paper cover the data and methodology in determining the critically stressed fracture from 6 wells (Figure 1.c), the analysis of identified critically stressed fracture in wells that is responsible for the permeability of the well, and to some extent its influence on hydrogeology of the Lumut Balai geothermal field.

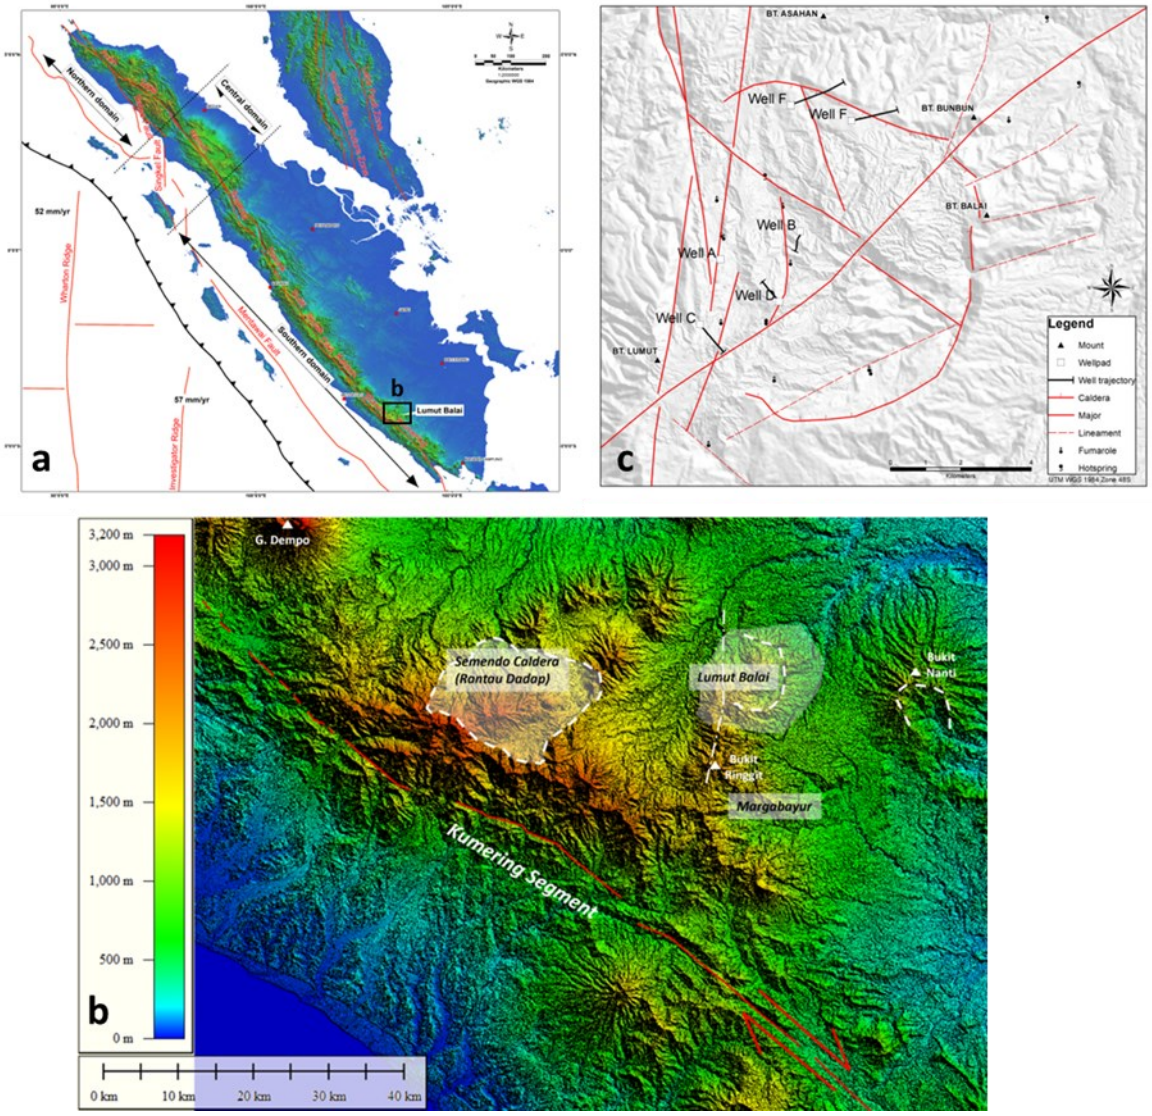

Figure 1: (a & b) Location of Lumut Balai geothermal fields overlain with DEMNAS, regional tectonic setting, Sumatran Faults, and related features (Sieh & Natawidjaja, 2001; Pour, et al., 2016), subdivision of geothermal system in Sumatra (Sutrisno, et.al., 2020). (c) Structural map of Lumut Balai and 6 well distribution used in the study.

2. METHODOLOGY

To analyze which fractures that tend to slip with the direction and magnitude of current the stress field, or critically stressed fractures, the approaches are based on the methods thoroughly explained by Zoback (2007), Wallis et al. (2020), and Ikhwan et al. (2022). The general data and workflow to identify critically stressed fracture are shown in Figure 2, where the datasets that are utilized for preliminary assessment of critically stressed fracture in this study are:

1. Fracture data interpreted on borehole image (micro resistivity or sonic) from 6 wells distributed in the southwest, center, and northern part of the Lumut Balai Caldera (Figure 1.c). Fracture data based on borehole image data is used to analyze the fracture geometry, type, and distribution at depth along the well. As the data used in this study is a micro-resistivity borehole image, the fracture type utilized in the subsequent processes is only the conductive fracture type. This is a generalized type covering all possible conductive fractures such as fault and conductive fracture whether it is continuous or discontinuous. Its conductive nature is interpreted to be filled with water or conductive minerals such as clay, nevertheless,

this feature is the most likely to be permeable. Resistive fracture is not utilized in the analysis due to its being filled and blocked by resistive minerals such as calcite or quartz.

2. Well-test data: pressure and temperature logs. Pressure data is utilized to define the pore pressure around the borehole which is assumed at hydrostatic conditions.
3. Surface gravity data acquisition that has been processed to 3D gravity-MT joint inversion and then converted to density. Density data is utilized to calculate Sv (vertical stress) or overburden.

Maximum horizontal stress orientation is determined based on the average orientation of the drilling-induced tensile fracture (DITF) found in the borehole image data. In a vertical well, the maximum horizontal stress (SHmax) axis could be determined directly by using the strike of drilling-induced tensile fracture when both borehole breakouts and drilling-induced tensile fracture are observed in the well. The DITF is parallel to the SHmax axis, while the borehole breakout is parallel to the direction of minimum horizontal stress (SHmin). Although 1 of 6 of the wells is vertical and has DITF orientation at N 10 E to N 20 E, to honor the sparse distribution of the wells used in this analysis, the average SHmax orientation from 6 wells is at around N 30 E direction which is still reasonable compared to the DITF direction in a vertical well.

The stress regime of Lumut Balai in this study is interpreted to be controlled by a normal stress regime, where the vertical stress is σ1, maximum horizontal stress = σ2, and minimum horizontal stress is σ3. The stress regime determination for this preliminary assessment is based on the condition that Lumut Balai is heavily influenced by its local regime of normal faulting due to the formation of a 9-10 km wide caldera.

After analyzing the fracture distribution at depth, the 1D geomechanics assessment (Sv/Shmin/Shmax calculation in the borehole), and stress regime determination then Fractoolbox (2023) is utilized to calculate slip tendency analysis, convert and plot the fractures with its normal effective stress and the shear stress on 3D Mohr circle. Slip tendency analysis on a 3D Mohr circle utilized $\mu > 0.5$ (shear to stress ratio), where the shear stress acts at the fractures are greater than the normal stress. Fractures that are more likely to be permeable and hydraulically active are the ones with more susceptibility to shearing, hence the current state of shear stress > normal stress at the fractures plane must be met. In convective and high-temperature geothermal systems, the shearing and repeated failures provide a mechanism to prevent the deposition of hydrothermal minerals and maintain the permeability of the fractures (Wallis, et al., 2020, and Ikhwan, et al., 2022).

Lastly, the identified critically stressed fractures at those 6 wells are evaluated against the distribution and magnitude of feed zone data derived from pressure-temperature-spinner (PTS) logs during injection or production. The evaluation demonstrates the influence of critically stressed fractures on the permeability of the well.

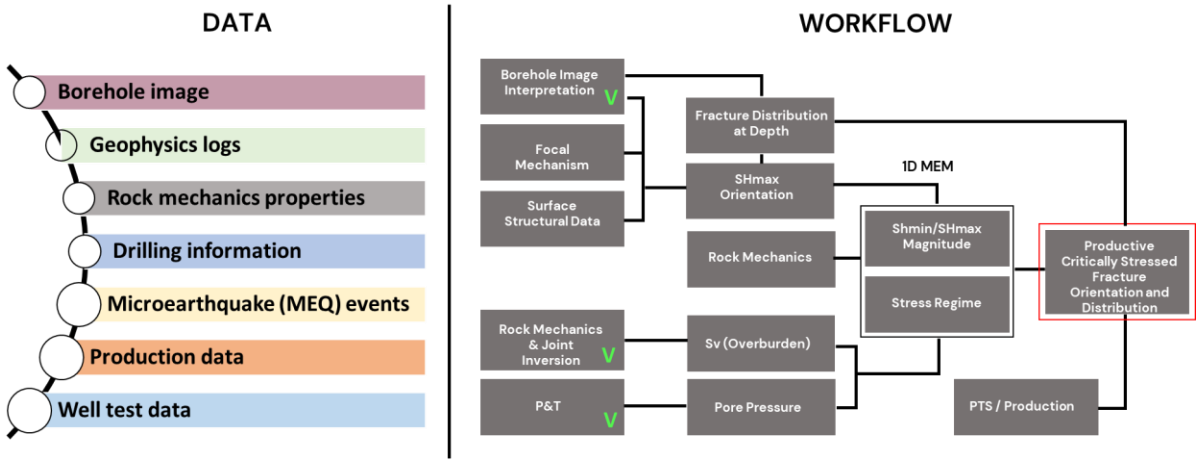

Figure 2: The 1D geomechanics model workflow to identify the critically stressed fracture from the image log data (Ikhwan, et al., 2022). Green marks are the data used in the study.

3. RESULT AND DISCUSSION

The borehole image data acquisition was conducted within the perforated liner sections reflecting the well sections that cover the reservoir zone. Nevertheless, not all the 6 wells reservoir section is covered completely by borehole images, such as the perforated liner 8-5/8" section in Well D and Well E. In addition, some part of the reservoir section in the perforated liner 10-3/4" in Well F is not covered by borehole image data due to wash-out borehole (Figure 3).

The general strike direction of the observed conductive fractures and faults in 5 of 6 wells is dominated by 195-240° (NE-SW) direction with a predominantly high dip angle of 60-80° and a minor relative N-S strike direction

found in Well A (Figure 3). The NNW-SSE strike direction is only observed in Well F as the well is intersected by the relative NNW-SSE direction fault.

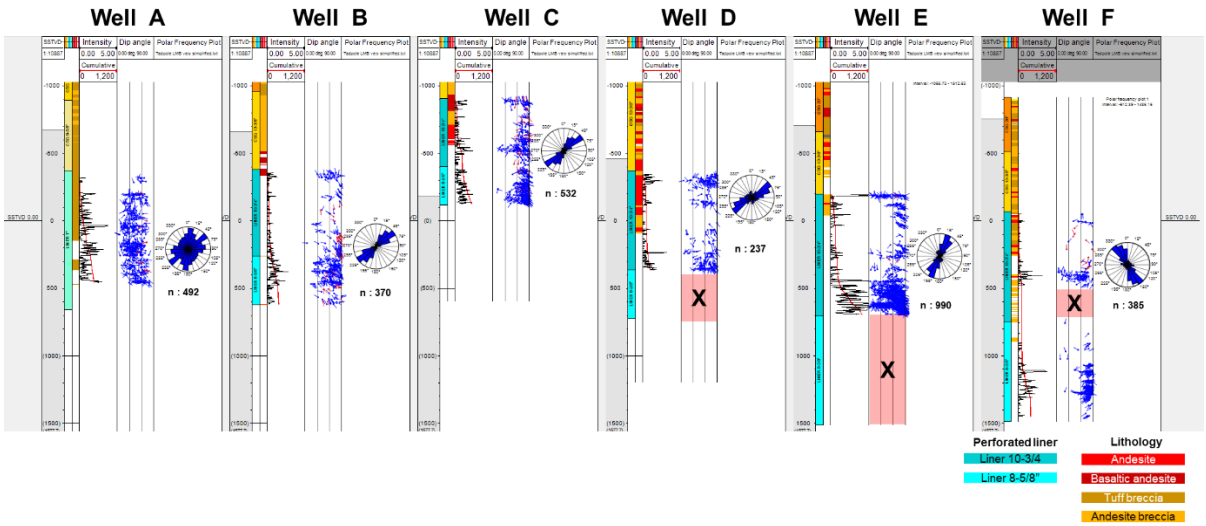

Figure 3: Section of the 6 wells shown in elevation (first column), well sections (second column), lithology (third column), tadpoles and stereonet of the identified conductive fractures (fourth and fifth column). 'X' marks are not covered by the image log.

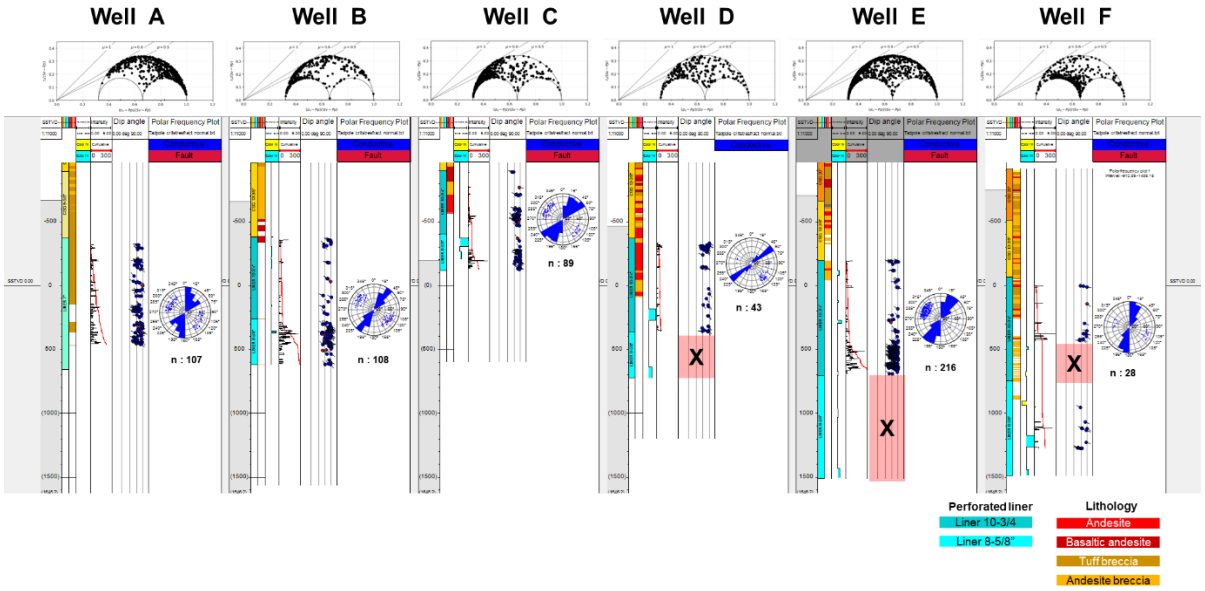

Figure 4: Below the well name is the conductive fractures plotted in 3D Mohr circle. Below the 3D Mohr circle is section of 6 wells shown in elevation (first column), well sections (second column), lithology (third column), tadpoles and stereonet of the identified critically stressed fractures (fourth and fifth column). 'X' marks are not covered by the image log.

After conducting the slip tendency analysis using the above conductive fractures distribution and orientation, there are 591 identified critically stressed fractures from 6 wells which are interpreted to be potentially permeable (Figure 4). These critically stressed fractures are the conductive fractures that are located above the μ 0.5 line within the 3D Mohr circle, reflecting the tendency to slip is greater than the effective normal stress influence. The 3D Mohr circle depicts the conductive fractures with its projected stresses (normal effective stress and the shear stress). The critically stressed fractures observed in these 6 wells have strike direction dominated by 195-225°(NNE-SSW) and dominated by a high dip angle range of 60-80°, mean 62°.

It is noticeable that the fractures population between the conductive fractures and critically stressed fractures are not directly correlated as evidenced in the Well A and Well F. In Well A, the population of conductive fractures in quadrant 2 (NW) and quadrant 4 (SE) are not characterized as critically stressed fractures. Moreover, although

Well F is predominantly comprised of NW-SE conductive fractures, the critically stressed fracture in Well F is dominated by the NNE-SSW direction.

3.1 Influence of critically stressed fractures to the permeability of the well

It is observed that feed zone intervals (third column, after lithology column) coincide with the occurrence of critically stressed fractures in most of the wells, excluding Well A which does not have any PTS data to evaluate the relationship between the observed critically stressed fracture and fluid flux to the well (PTS during production) or to the formation (PTS during injection). More importantly, the major contributor feed zone intervals (light blue bars) in 5 wells are directly influenced by the occurrence of critically stressed fractures cut by the well (Figure 4).

3.1.1 Well B

Out of 532 conductive fractures plotted in the 3D Mohr circle, around 108 fractures are located above the $\mu > 0.5$, which is categorized as critically stressed fractures. The identified critically stressed fracture in Well B formed an NE-SW strike direction (30-45 NE) and has a dip direction facing both NW and SE directions almost equally. Along the borehole depth, in general, the conductive fractures are more intense below the 1300 mTVD along with the 58% fluids injected into the formation.

There are 7 feed zone intervals identified by PTS logs during injection, where the major contributors (>10%) are observed in the 3 intervals. The shallowest major feed zone interval (22%) is not covered by the borehole image data, and thus could not be evaluated control on the permeability at this interval. The other 2 major feed zone intervals (10% and 49% contributions), depicted by numbers 2 and 4, are fracture controlled, suspected heavily influenced by the wide aperture fracture, and coincide with the population of critically stressed fractures around that interval. It is also observed that the 49% feed zone interval is heavily populated with fractures compared to the 10% contributor.

The other 4 minor feed zone intervals (<10% contribution) are interpreted to be more controlled by matrix permeability rather than the fractures. It is also supported by the minimum distribution of the conductive fractures and critically stressed fractures around the 4 minor intervals, as shown by numbers 1 and 3 in Figure 5.

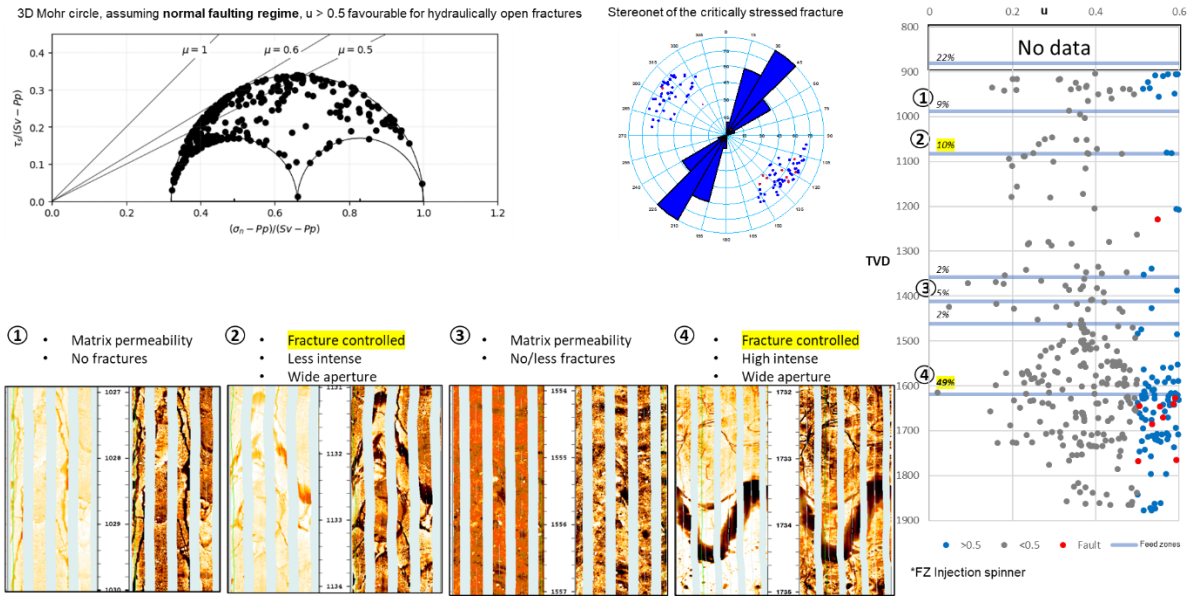

Figure 5: The occurrence of critically stressed fractures with wide aperture and less intensity in Well B contribute heavily to the permeability of the feed zones (highlighted by yellow). Meanwhile the minor feed zones (<10%) are controlled more by matrix permeability. The distribution of the conductive fractures in 3D Mohr circle and stereonet of the critically stressed fractures in Well B. The right chart showed the conductive fractures that have shear to stress ratio < 0.5 are shown by grey points while the critically stressed fractures and faults (> 0.5) are shown in blue and red points. The feed zone intervals are highlighted by light blue rectangular within the same chart and represented by numbers in the fracture distribution chart and in the image log.

3.1.2 Well C

There are 89 out of 532 conductive fractures that are identified as critically stressed fractures in Well C. These critically stressed fractures in Well C are predominantly composed of the 195-240 NE strike fractures (NE-SW) with NW dip direction and much of the fractures are more populated at 1100 to 1600 mTVD depth.

Based on the PTS during injection data, there are only 2 feed zone intervals with 86% (major feed zone) and 14% (minor feed zone) contribution, as shown by numbers 1 and 2 in Figure 6. Both feed zones are interpreted to be controlled by critically stressed fractures identified within each feed zone interval. In the first major feed zone at a depth around 1360 mTVD (86%, number 1), it is interpreted to be heavily influenced by the occurrence of three wide aperture fractures one of them is critically stressed fractured, although fractures population around that interval has less intensity. The latter minor feed zone (14%, number 2) is also influenced by the occurrence of wide aperture conductive fracture that is identified as critically stressed fracture and supported by critically stressed fractures observed around the interval as shown in the borehole image number 2 in Figure 6.

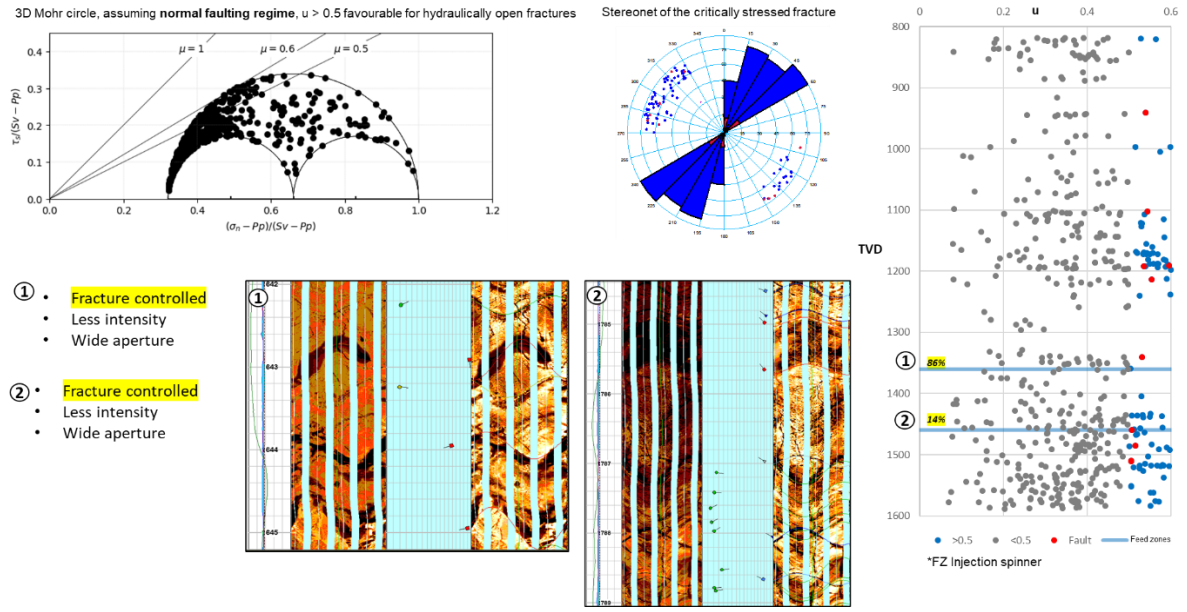

Figure 6: The occurrence of critically stressed fractures with wide aperture and less intensity in Well C contribute heavily to the permeability of the 2 feed zones (highlighted by yellow). The distribution of the conductive fractures in 3D Mohr circle and stereonet of the critically stressed fractures in Well B. The right chart showed the conductive fractures that have shear to stress ratio < 0.5 are shown by grey points while the critically stressed fractures and faults (> 0.5) are shown in blue and red points. The feed zone intervals are highlighted by light blue rectangular within the same chart and represented by numbers in the fracture distribution chart and in the image log.

3.1.3 Well E

This well has PTS log during production and is only covered by borehole image data in the perforated section 10-3/4" (800 to 1800 mTVD) which contains abundant 990 conductive fractures and is mostly located in the interval between 1500 to 1800 mTVD. Only 216 of these conductive fractures are identified as critically stressed fractures that are highly dominated by 195-225 NE strike fractures with their NW dip direction, and only a few fractures have a dip direction at SE (Figure 6).

There are 4 feed zone intervals identified and measured by PTS log during production in the section that is covered by borehole image data, as shown in feed zones number 1 to 4 in Figure 7. Only 1 feed zone interval does not coincide with the occurrence of critically stressed fracture (number 2, with 10% contribution). This feed zone interval is interpreted to be greatly affected by matrix and contact permeability as this interval comprises volcanic breccia with very few fractures.

On the other hand, the other 3 feed zone intervals are interpreted to be not only controlled by fractures (number 1, 3, and 4) but also by matrix/contact permeability (1, and 3). The smaller 6% contribution in the deeper part of the section comprises numerous fractures within the lava andesite (number 4). Around this feed zone interval, there are many of the fractures identified yet do not have any contribution of fluid flux to the well. This interval might comprise fractures that have shallow continuity to the formation. The lithological units within feed zone number 1 with a 17% contribution are almost identical to the feed zone interval number 2. The difference between

the 2 feed zone intervals is the occurrence of critically stressed fractures in feed zone 1 that add more permeability contribution to the fluid flux into the well. The combination of fractures and matrix/contact permeability is also observed in feed zone number 3 with a 41% contribution. This interval coincides with the critically stressed fractures and also many layers of tuff and tuff lapilli which in total greatly contributes to the fluid flux into the well.

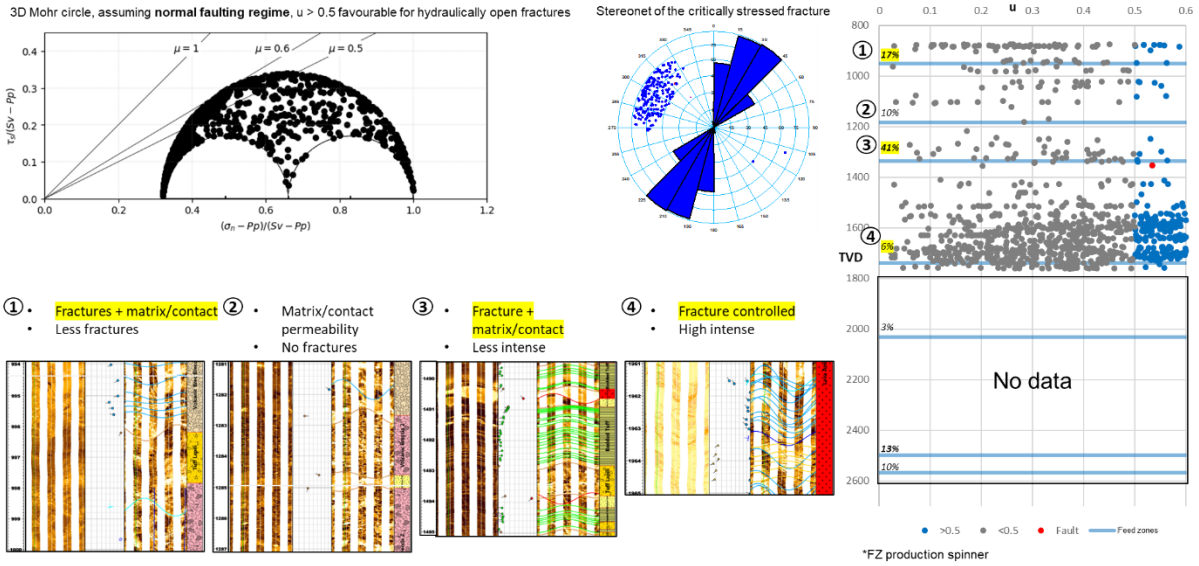

Figure 7: The occurrence of critically stressed fractures with the combination of matrix/contact with less fractures in Well E contribute heavily to the permeability of the number 1 & 3 feed zones while the number 4 is fracture controlled (highlighted by yellow). The distribution of the conductive fractures in 3D Mohr circle and stereonet of the critically stressed fractures in Well B. The right chart showed the conductive fractures that have shear to stress ratio < 0.5 are shown by grey points while the critically stressed fractures and faults (> 0.5) are shown in blue and red points. The feed zone intervals are highlighted by light blue rectangular within the same chart and represented by numbers in the fracture distribution chart and in the image log.

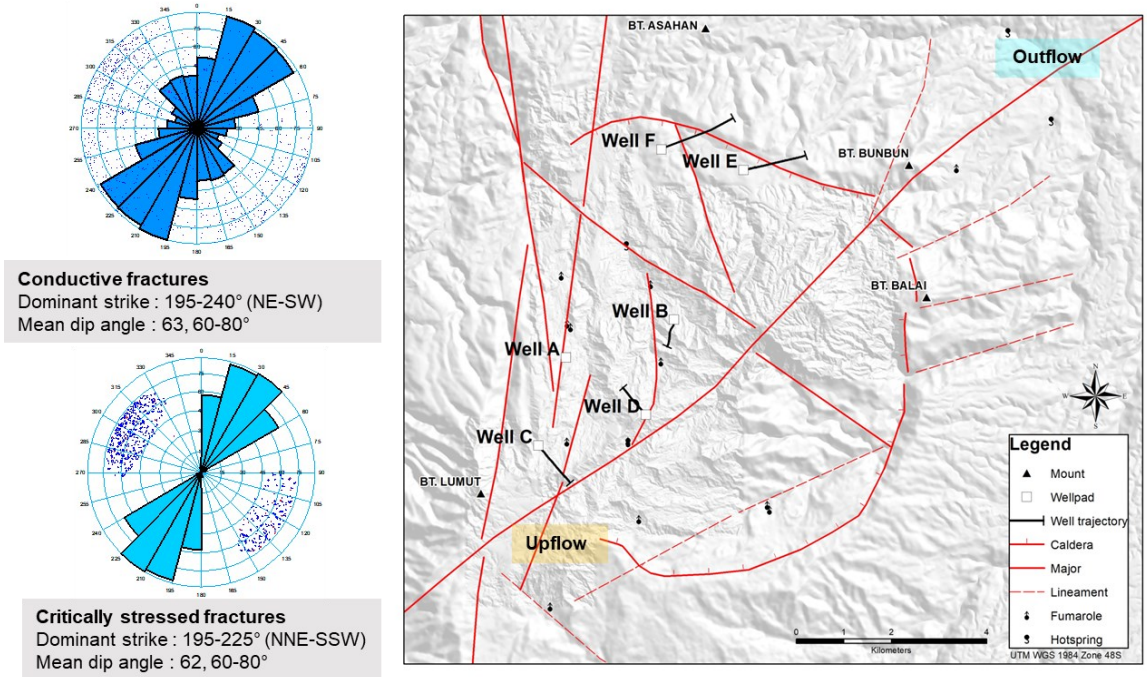

Figure 8: Compilation of conductive fractures and critically stressed fractures depicted in stereonets and its polar demonstrates the domination of NNE-SSW fractures that might influence the hydrology of the fluids from upflow to the outflow in Lumut Balai.

3.2 Field wide permeability contribution

Based on the compilation of conductive fractures from 6 wells, Figure 8 depicted that although the dominant strike of the conductive fractures is NE-SW at around 195-240 NE the other direction of conductive fractures such as N-S, or even the NW-SE are still observed. It is thought that these conductive fractures are the product from the field-wide geological structures that is intersected by the 6 wells. Nevertheless, based on the evaluation above, not all these strike directions contribute to the permeability of each well.

The conductive fractures that have been analysed to be critically stressed fractures are dominated by strike direction of NNE-SSW at around 195 – 225 NE. These are the fractures that responsible to control the permeability at the major feed zone intervals and supported by the primary permeability from the respective lithological units, such as tuff, breccia andesite or lavas or contacts between the lithological boundaries.

The dominant NNE-SSW strike direction of permeable critically stressed fractures support the interpretation of how the fluids move laterally and updip under the caprock from the upflow at the southern end of the Lumut Balai Caldera to the NE outside the Caldera. The outflow area is characterized by chloride hotsprings in Sendawan Ilir, while the upflow area is supported by the evidence of highest temperature well around the upflow area.

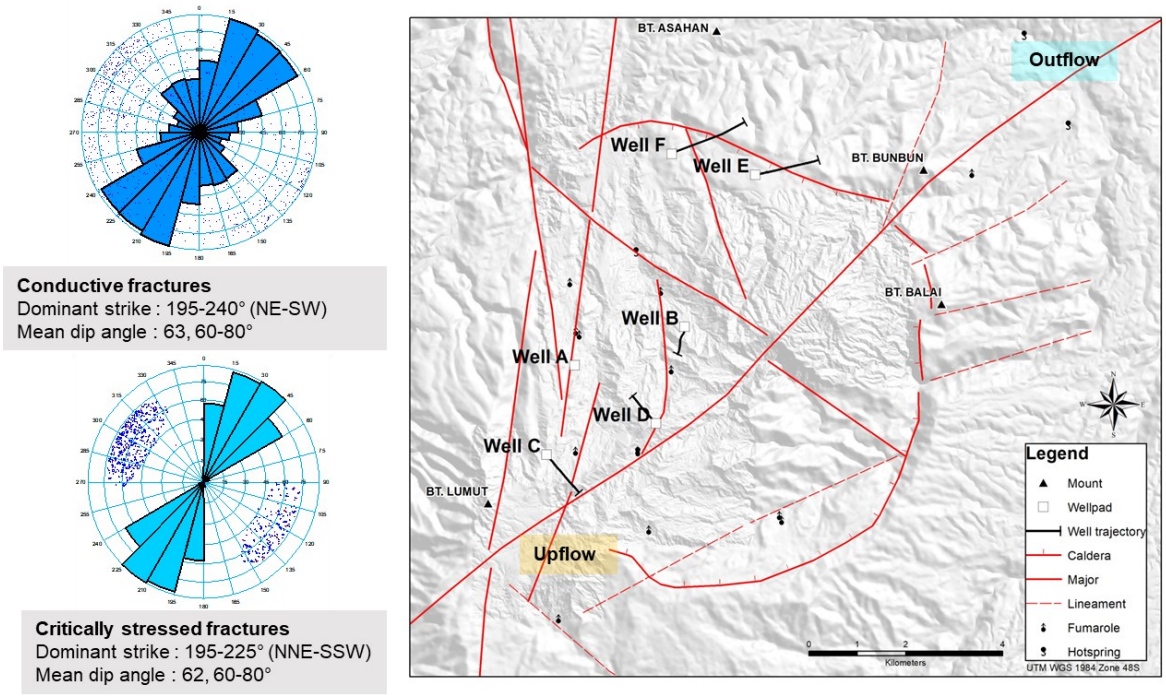

Figure 8: Compilation of conductive fractures and critically stressed fractures depicted in stereonets and its polar demonstrates the domination of NNE-SSW fractures that might influence the hydrology of the fluids from upflow to the outflow in Lumut Balai.

4. CONCLUSION

Identifying potentially permeable geological structures is an important task for geoscientists in the geothermal industry. One way to identify such structures is by analyzing critically stressed fractures using slip tendency analysis

The slip tendency analysis results indicate that critically stressed fractures predominantly strike in the 195°–225° NE (NNE-SSW) direction, which significantly affects the permeability of the feed zone. A feed zone controlled by critically stressed fractures contributes significantly to permeability compared to permeability from lithology or lithological contacts. Moreover, combining critically stressed fractures with other permeability factors further enhances the permeability of the feed zone. The dominant orientation of critically stressed fractures also influences the hydrology from upflow to outflow in Lumut Balai.

Identifying critically stressed fractures and their orientations can assist in well targeting, increasing the possibility of achieving the desired permeability output from a specific geological structure. Additionally, it implies that geological structures with strike directions orthogonal to the critically stressed fractures might be lower permeability. Furthermore, couple of basic data such as focal mechanisms from micro-earthquake events, rock

mechanics measured from petrophysics analysis of the cores and density logging data (if available) could be integrated to measure better Shmin/SHmax magnitude and more precise stress regime determination.

ABSTRACT

Fractures play an important role at the Salak geothermal field. Previous studies have shown that the majority of permeable entries in Salak are associated with fractures, which are classified as Effective Fractures (EFs). These geological features are responsible for fluid flow in and out of the wellbore. Lithologic contacts have a very limited role in hosting permeable entries. To understand the characteristics of the fractures, borehole image interpretation was conducted on 18 wells, with 12 wells located inside the commercial area and 6 located outside. Subsequently, 3 fracture main parameters were evaluated and compared between inside and outside reservoir, namely, fracture orientation, density, and aperture. The comparison aimed at determining whether fractures outside the reservoir are similar to producing EFs inside the reservoir, or whether they represent a different fracture. Analyses show that some fracture parameters have similar characteristics while others have significant distinctions. Geologic setting and process may cause differences in fracture characteristics. Ultimately, this study is expected to improve well targeting and planning during the drilling of makeup wells and become an input for both static and numerical model.

1. INTRODUCTION

Salak Geothermal Field (also known as Awibengkok) is located in West Java and it is situated 70 km south of Jakarta, the capital of Indonesia (Figure 1; A). It is Indonesia's largest-producing geothermal field with a recent total installed capacity of 381 MWe using six power plants. It consists of 180 MWe from PLN Units 1, 2 & 3, and is mostly provided by two-phase wells located in West Salak area. Star Energy Geothermal Salak supplies the steam to, operates, and produces electricity (201 Mwe) from Units 4, 5 & 6, and mostly using steam cap wells located in East Salak Area (Golla et al, 2020). The Salak geothermal system is a high-temperature water-dominated reservoir with benign chemistry and low-to-moderate NCG content (Acuña et al., 1997). The highest reservoir temperature measured is more than 325 °C, located in the western portion of the production area, and it is interpreted as the main system's upflow. Based on Stimac (2008), the field can be divided into four sectors with distinctive temperatures, fluid chemical signatures, and tracer return patterns. The four sectors have been termed the Western, Central, Eastern, and Far Eastern Cells Conceptual model of the field shows that geothermal fluids generally flow towards the northeast and east-southeast and outflow in the surface thermal manifestations, which are mostly located near the eastern and northern margins of the drilled reservoir (Figure 1B).

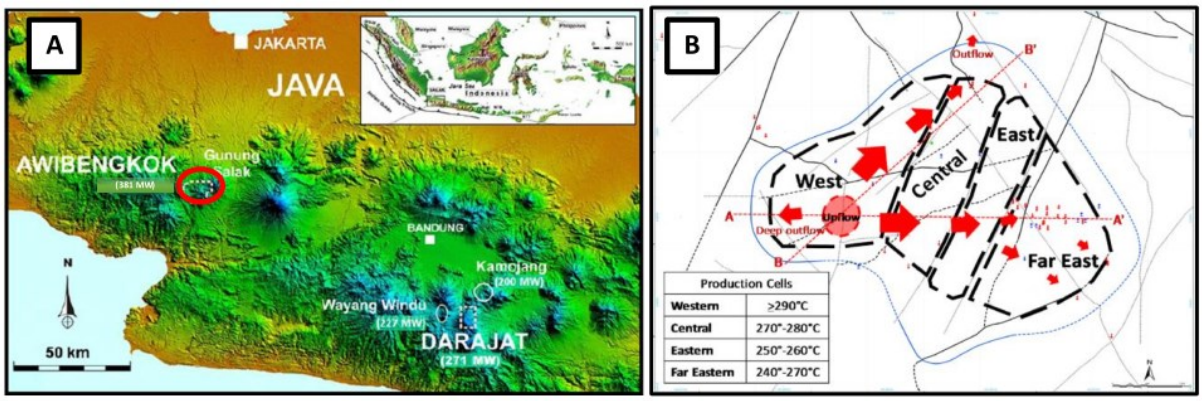

Figure 1: (A) Left: Map of West Java showing major cities and volcanic centers. It is also shown the location of the Salak geothermal field with other geothermal fields in West Java (modified Aprilina et al, 2017); (B) Right: Map showing the conceptual model and the general flow (arrows) of geothermal fluids at the Salak geothermal system under natural-state (pre-exploitation) conditions (Golla et al, 2020).

In past interpretations of fractures from borehole image logs, the stereonet and rose diagram plots that were normally shown depict the general strike and dip orientations of all the discernible open fractures encountered by the well. This paper will deliver more characteristics of the fractures and its comparison between the inside and outside reservoir area. The deliverables of this objective will be used to improve well targeting and input for both static and numerical model parameters.

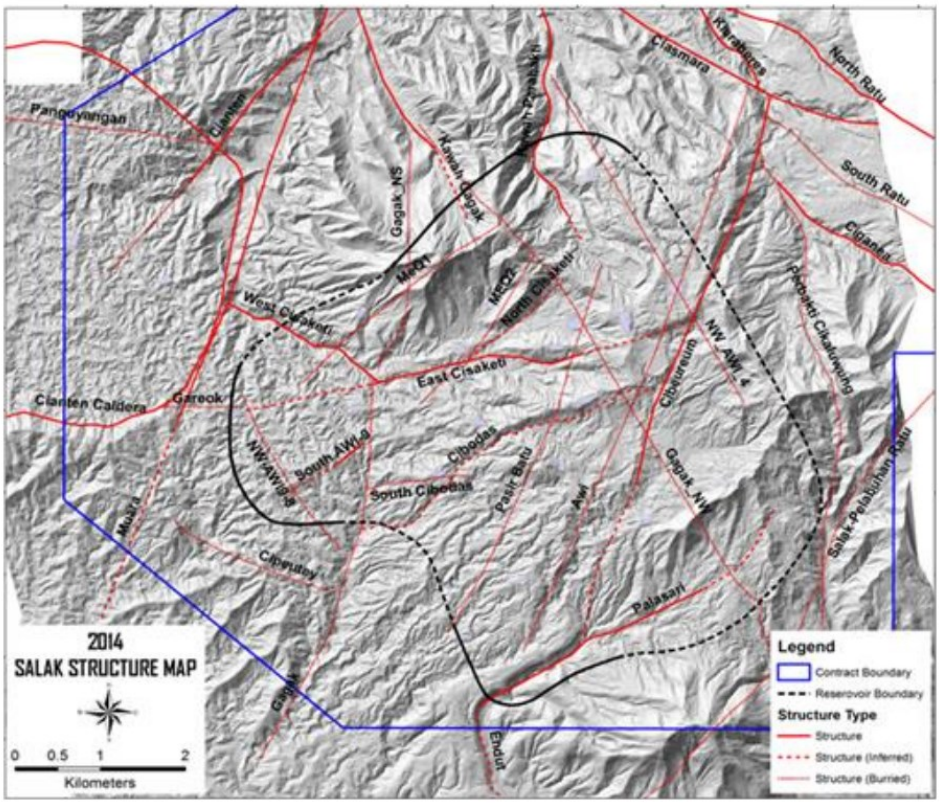

Figure 2: 2014 Salak structural map (Golla et al 2014).

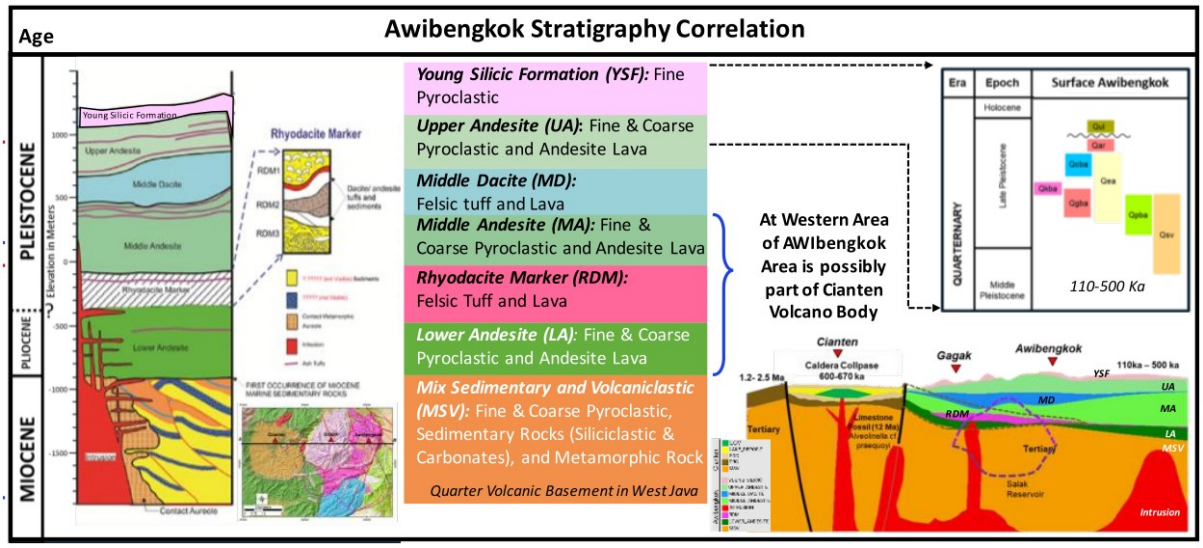

Figure 3: Subsurface stratigraphic section, rock composition and cross section of Awibengkok/Salak Geothermal Field. (modified from Stimac et al, 2007).

2. GEOLOGY OF SALAK GEOTHERMAL FIELD

As typical of most geothermal fields in Indonesia, Salak Geothermal Field is located in the mountains, and it is part of the Taman Nasional Gunung Halimun-Salak with elevations varying between 950-1,500 m above sea level (ASL). The Salak geothermal system is situated in a mountain range comprised of inactive andesitic volcanoes,

with the highest peaks are Gunung Salak, Gagak, Perbakti, and Endut, which lie along the main trend of the Sunda Volcanic Arc which extends from Sumatra to Flores (Hamilton, 1979; Hutchinson, 1989). These peaks border the geothermal field in the east, northwest, southeast, and south, respectively, and give way to lower hilly countries in the north and south (at 600-950 m ASL). The Cianten Caldera, a collapsed andesitic stratocone, lies further to the west with a floor at ~850-950 m ASL (Figures 2 and 3).

Initially, Salak structural map was mainly developed from lineaments interpreted by different workers from aerial photos and satellite imageries and, when possible, augmented with surface field mapping. Unless measured at the surface, most of the structures in the fault model were assumed to dip vertically. Not all these structures (or lineaments) extend deep into the reservoir, and, consequently, affect reservoir permeability and processes. This data subsequently incorporated interpretations from geophysics, geology, geochemistry, and reservoir engineering data. Later on, structural map refinement and validation were conducted by data conditioning to highlight structural relief in the RDM horizon and temperature from well data. Figure 2 below are the result of 2014 Salak structural map refinement (Golla et al ,2014). Salak structure is dominated with NE-SW trend, and it is believed was controlled by West Java the regional stress in West Java (SHmax at N10°E; Tingay et al., 2009). This trend is similar to the general direction of Salak Shmax ($\approx$N24ºE) assuming that the stress regime is extensional (Sugiaman, 2003). This study is corroborated by recent drilling-induced tensile fracture (DTIF) evaluation from borehole image log data denotes that Salak DTIF mostly has NNE-SSW trend. In addition, fault criteria were developed to consistently represent the mapped structures at the surface.

The Salak structures were classified into three general categories, namely:

- **Confirmed**: Structures that were identified at both the surface and confirmed with subsurface data. These structures will be drawn as solid lines and will have a high degree of confidence.
- **Inferred**: Structures that were defined from lineaments from LiDAR or other remote sensing data only. If confirmed by field measurements, these structures will be drawn with solid lines in the structural map but with dashed lines if based on lineaments only.
- **Buried**: Structures that have subsurface evidence/s only and do not correlate with surface lineaments. These structures are drawn as dotted lines and have low degree of confidence.

In term of Stratigraphy, the subsurface rocks at Salak Field are composed of andesitic, basaltic lava, breccia, tuff, and lahar that comprise several long-lived volcanic centers underlying the south-western margin of Gunung Salak Hulen and Lutz (1999; Stimac and Sugiaman (2000). Stimac et al. (2008) divided the subsurface rocks at Salak into four major formations that are thought to represent discrete episodes in the evolution of the western Java segment of the Sunda Volcanic Arc. The “formation” terminology here is used to refer to distinctive time-bounded rock sequences that have not been formally correlated with documented formations on a regional basis. The four major formations, from oldest to youngest, are the (1) Lower Volcanic Formation that consists of Marine Sediments and Volcaniclastics (MSV) and Lower Andesite; (2) Rhyodacite Marker or RDM; (3) Middle Volcanic Formation; and (4) Upper Volcanic Formation. Both the Middle and Upper Volcanic Formations consist of a series of dacitic (at their base) and andesitic rocks overlying each other (Aprilina et al., 2017). In addition, multiple intrusions are spread all over Salak/Awibengkok geothermal field. Figure 3 discerns Awibengkok stratigraphy section.

3. TERMINOLOGY

As in the past, fractures encountered in the borehole image logs were interpreted with the main objective of identifying the fractures that correlate with the permeable entries, evaluating trends exhibited by these fractures, and applying the trends to better understand of geothermal reservoir. Examples of terminology used in Star Energy during the fracture identification are classified as follows (Intani et.al, 2017):

- **Effective Fractures**: These are geologic features that correlate with the PTS-based permeable zones. Normally, these will be high-confidence fractures where the conductive feature is present in all the image log tool pads (i.e., 360° around the borehole). Figure 4 shows a schematic for picking EFs in image log data.
- **Conductive (or Open) Fractures**: These are high-confidence fractures where the electrically conductive fracture trace is present in all the image log tool pads or 360° around the borehole.
- **Partial Open Fractures**: These are fractures where the conductive feature is not found on all the image tool’s pads. The authors tried to follow the 75% (or about 270° around the borehole).

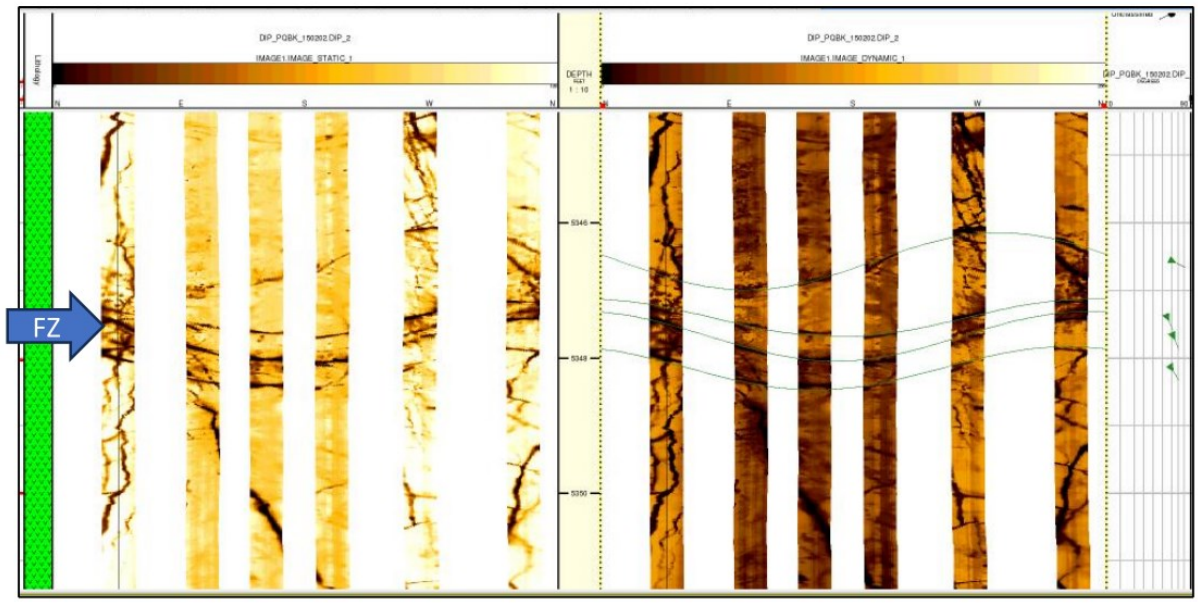

Figure 4: Schematic discerns effective fractures (EFs) picking depend on the location of entry/feedzone (blue arrow). These open/conductive fractures subsequently will be classified as effective fracture (EFs).

4. FRACTURE CHARACTERIZATION INSIDE AND OUTSIDE GEOTHERMAL RESERVOIRS

This section discusses fracture characterization from borehole image interpretation. As mentioned earlier, there is a fracture categorized as Effective Fracture (EFs) because it correlates with a permeable zone, where fluid enters or out from this zone. In some cases, picking the EFs was quite easy because a single, large-aperture fracture stood out at the depth of the production zone. However, there are many cases where no prominent fracture appeared to correspond with the permeable entry. If a single prominent fracture was not present, all fractures within ~10 m of the permeable entry were selected as EFs. Aside from EFs, open (or high-confidence conductive) fractures were also identified from the borehole image logs. Note that the majority of the EFs is composed of "Groups of Fractures" where a certain cluster of fractures was picked to represent the permeable entry because there was no single prominent fracture identified, i.e., the actual % of producing EFs may be lower than shown in figure 5. In Salak commercial area, 82% of permeable entries correlate with EFs composed of a group of fractures, 15% correspond to single fractures, while only 2 permeable zones are related to lithology boundary (figure 5).

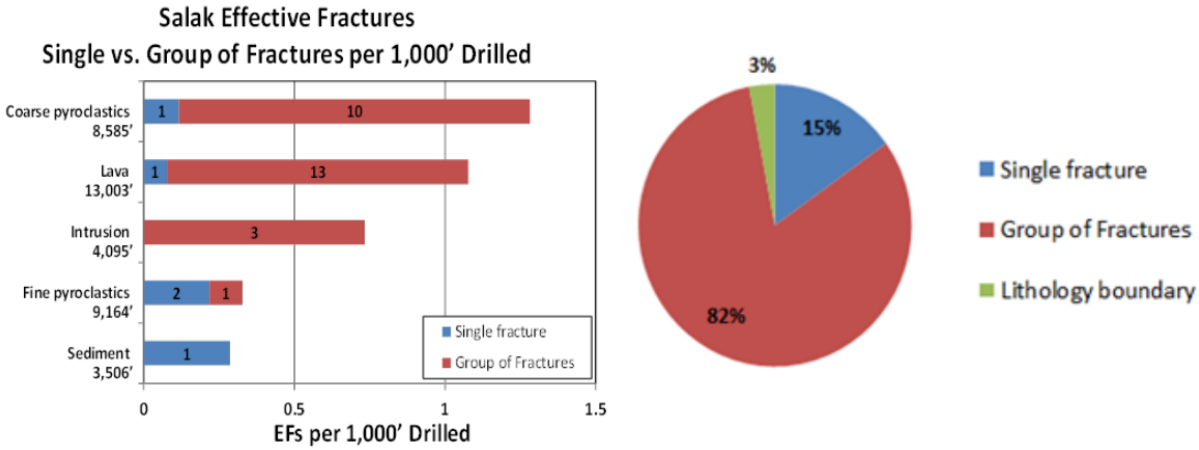

Figure 5: (Right) Pie chart showing the distribution of permeable entries composition: correlate group of fractures (82%), single fractures (15%), lithology boundary (2%). (Left) Chart showing the number of EFs, either as single fracture or group of fractures, in various lithologies. Numbers inside the bars denote the number of EFs/permeable zones.

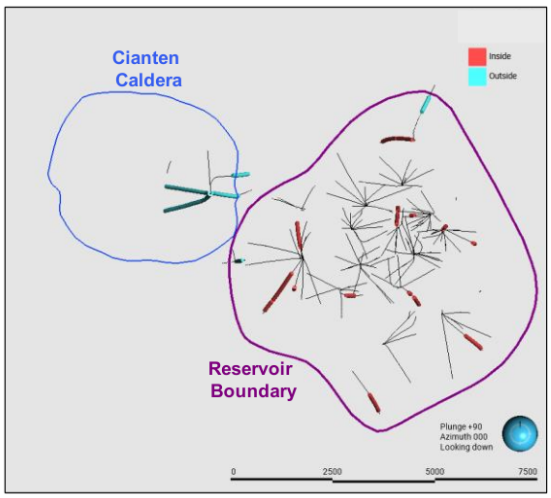
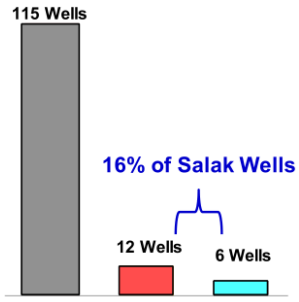
In Salak fields, there are 18 out of 115 wells with borehole image data. Although only 16% of all Salak wells have image log data, their locations are distributed around the entire Salak main production area (Figure 6). In terms of

location, 12 image log wells are located inside the commercial area, and 6 are located outside. About 50 permeable entries were intersected by these 12 wells, with 31,500 ft /~9600 m (cumulative) of reservoir logged. There are 68% (34 feedzones) of these permeable entries have good-quality image logs that can be interpreted. The remaining 16 permeable zones have no image logs. In the case of Salak, step-out drilling in the Cianten Caldera in the west and at the edge of the commercial reservoir provided the opportunity to collect borehole image data (Figure 6). Effective fractures (EFs) have been identified in some edge wells in the Cianten area. Thus, a one-to-one analysis of Efs inside and outside the Salak reservoir can be conducted. Analysis of these image logs (inside and outside reservoir) revealed about 8,100 open and partial open fractures and only 2% or 141 fractures correlated with permeable zone (EFs). This suggests that only a small percentage of the fractures are produced from the network of open fractures in the geothermal reservoir.



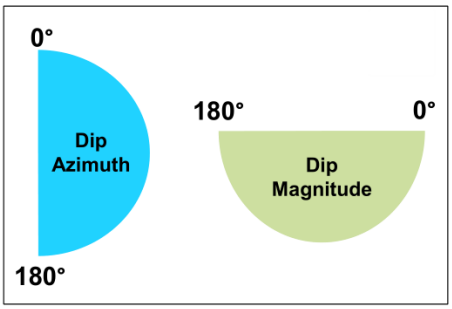


Region	Borehole Image Interval, ft	No. of Open Fractures	No. of Partial Open	No EFs	% of EF from All Open Fractures
Inside Reservoir	~ 31,500	978	3,743	100	10
Outside Reservoir	~23, 400	702	2,674	41	6

Figure 6: (Left) Map showing the location of wells with borehole image logs at Salak. Although only 12 wells (16% of total. wells) are located inside the commercial production area, they are spread out within the production area. The purplepolygon represents the Salak reservoir area. (Right) table shows the numbers of open and EFS inside and outside reservoir.

4.1 Fracture Orientation

Fracture dip azimuth and magnitude scatter plots were generated to determine the general distribution and trends of fractures inside and outside the Salak reservoirs. To remove bias in the plotting, both dip azimuth and magnitude were calibrated to a 0-180° range (Figure 7). If fractures outside the reservoir have dip azimuth >180°, they were normalized/converted to a value between 0° to 180°. Normally, the maximum dip value is 90°; however, fractures that have dip azimuth >180° will have dip magnitudes >90°. For example, a fracture with dip azimuth of 220° and a dip magnitude of 65° will be represented as a fracture with dip magnitude 135° to remove bias. Thus, a dip magnitude of 110° (70°) is steeper than a dip magnitude of 170° (10°). Figure 7 illustrates the normalization of dip azimuth and magnitude into the 0-180° range.



- If measured Dip Azimuth is 210°, the normalized Azimuth = 210°-180° = 30°
- If a fracture has a measured Dip Azimuth >180° and a Dip Magnitude of 70°, the normalized Dip Magnitude = 180°-70° = 110°

Figure 7: Schematic showing the normalization of dip azimuth and magnitude.

At Salak, both open fractures and EFs inside the reservoir have dip azimuth ranging from 50° to 180° with dip magnitude of 60°-120° (figure 8). In terms of dip azimuth, the open fractures and EFs inside the Salak reservoir have an average strike orientation about N22° E and it is very close to the SHmax direction (≈N24° E). For the outside reservoir, both the open fractures and EFs appear to have different dip azimuth ranges with the inside

reservoir (45° to150°), although their dip magnitude range is similar with the fractures inside the reservoir at 70°-120° (figure 8). Other charts used to evaluate the distribution of fractures both inside and outside the Salak are the histogram plots shown in Figures 9 and 10 (dip azimuth and magnitude histogram). In all groups of fractures at Salak, a random (or background; blue highlight) and a dominant set (yellow highlight) of fractures are shown by the histogram charts. The histogram of the dip azimuth of fractures inside the Salak reservoir shows a concentrated population of fractures with an average dip azimuth of 112° or N22° E a strike orientation. This population is very close to the SHmax direction (≈N24° E) or dip azimuth N114°E (top chart: Figure 9). Meanwhile, the concentrated population of fractures outside the Salak reservoir has an average dip azimuth of 90° or a N-S strike orientation (2nd chart in Figure 9) and has wider range (yellow highlight in figure 9 below). A random population of fracture dip magnitude was also identified at Salak inside and outside reservoir (Figure 10). At Salak, the dominant groups of fractures inside and outside the reservoir have very similar average dip magnitudes of 92° and 90°, respectively (Figure 10).

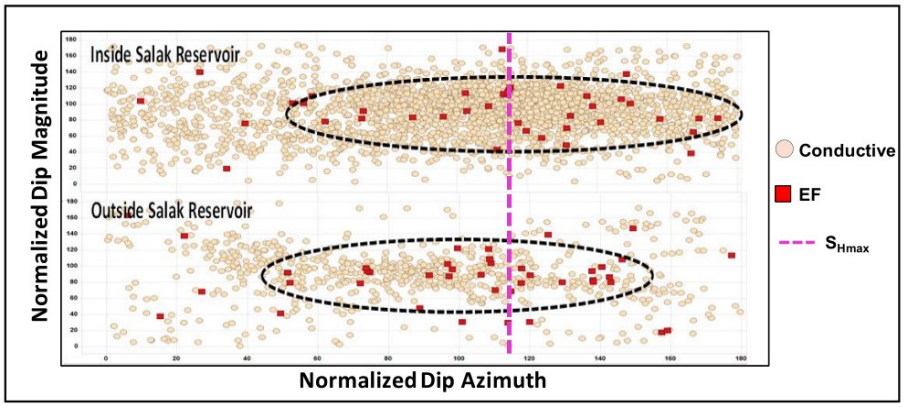


Figure 8: Charts showing scatter plot for the distribution of Conductive (Open) and Effective Fractures inside and outside Salak reservoirs. The strike orientation of the fractures is perpendicular to the dip azimuths shown above.

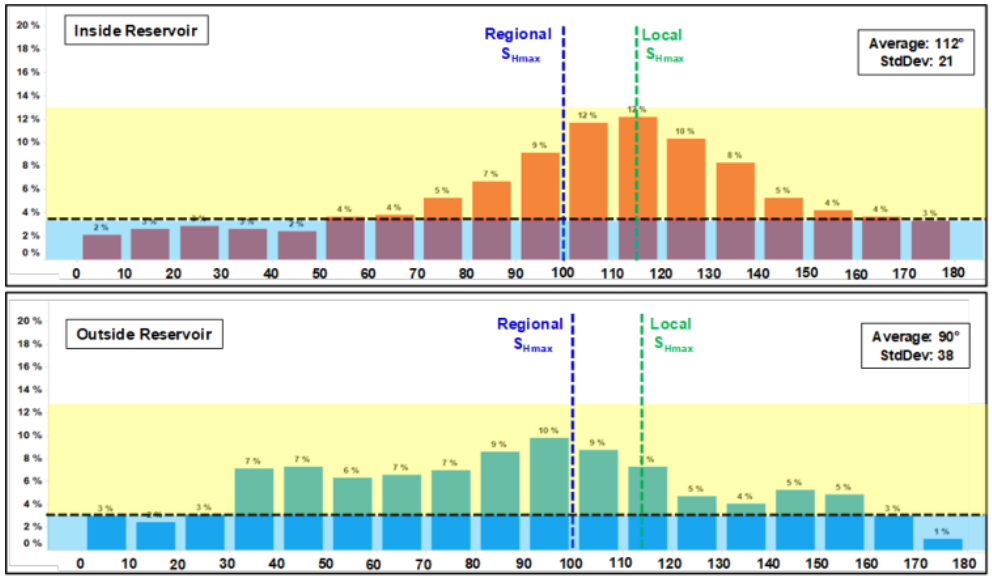

Figure 9: Histograms showing the distribution of dip azimuth of open fractures and EFs inside and outside the Salak reservoirs. The Y-axis denotes the percentage of fractures in one bin divided by all the data. The vertical black dashed lines indicate the SHmax direction in each field while the horizontal black dashed lines are the arbitrarily picked boundary between the random/background and dominant sets of fractures. The strike orientation of the fractures is perpendicular to the dip azimuths shown above.

Besides qualitatively, Salak's aerial distribution of EFs orientation was also evaluated and it can be seen in Figure 11 (Golla et al, 2017). A similar observation is evident at Salak where, cumulatively, the EFs strike mostly within the NE-SW quadrant. The core of the production area (or the Central and East Cells) have slightly more NNE-SSW predominant orientations, while in the West Cell, the EFs exhibit a slightly more ENE-WSW strike

orientation. There may also be slightly more orientational variation in the Far East Cell, although this variation is mostly due to the orientation of fractures associated with the single feed zone logged. The slightly more diverse orientation of the EFs near the eastern edge of the Salak production area. Some factors for the diverse EFs at the edge of the field may be local stresses (Satya and Golla, 2014), presence of nearby eruptive centers etc. Compared to other sectors in reservoir area, outside of reservoir has more variation of EFs orientation.

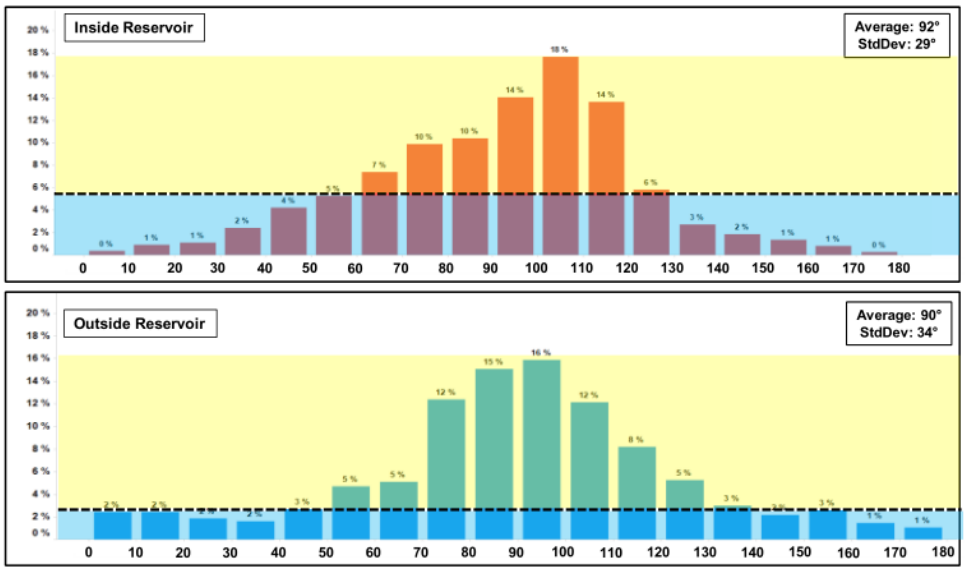

Figure 10: Histograms showing the distribution of dip magnitude of open fractures and EFs inside and outside the Salak reservoirs. The Y-axis denotes the percentage of fractures in one bin divided by all the data. The horizontal black dashed lines are the arbitrarily picked boundary between the random/background and dominant sets of fractures.

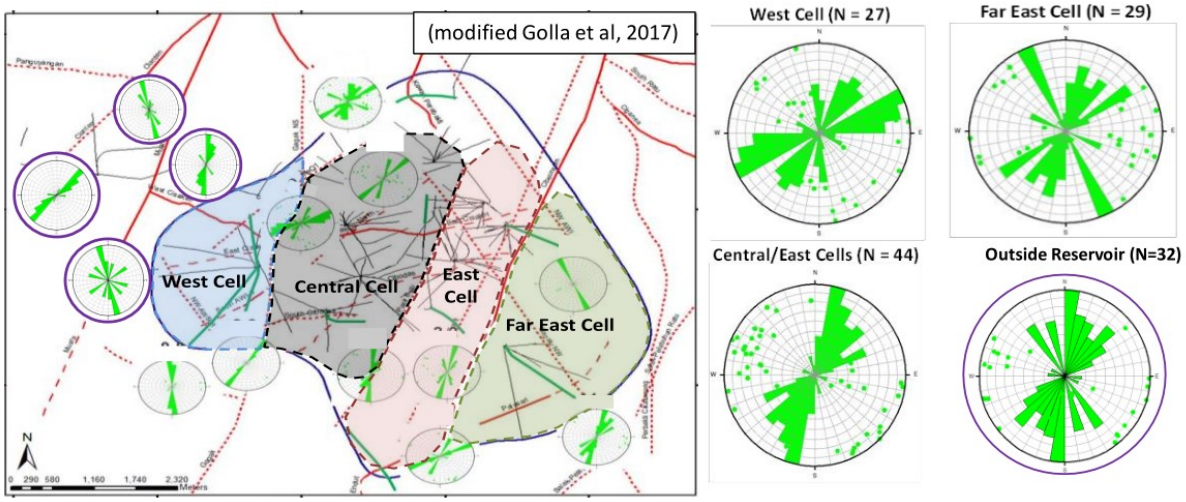

Figure 11: (Left) Map showing the aerial distribution of EFs orientation. (Right) Stereo nets showing the strike orientation, dip azimuth and magnitude (circles) of EFs in each sector of Salak reservoir. Note that outside reservoir stereonet indicates with purple rim color.

4.2 Fracture Density

The next analysis is to evaluate the distribution of fracture density in the different rock types located inside and outside the reservoir, then, test the theory that relatively brittle rocks host more fractures. An apparent increasing trend of open and EFs with depth inside Salak reservoir is demonstrated. The shallower formations have almost similar densities of open and EFs while the deeper Lower Andesite (LA) and MSV Formations host more than half to double the number of fractures (Figure 12). This increasing trend is not demonstrated by the fractures outside the reservoir. The brittle intrusions and andesite lava flows host more open and effective fractures compared with the relatively softer pyroclastic and sedimentary rocks, especially inside the reservoir (Figure 12; left).

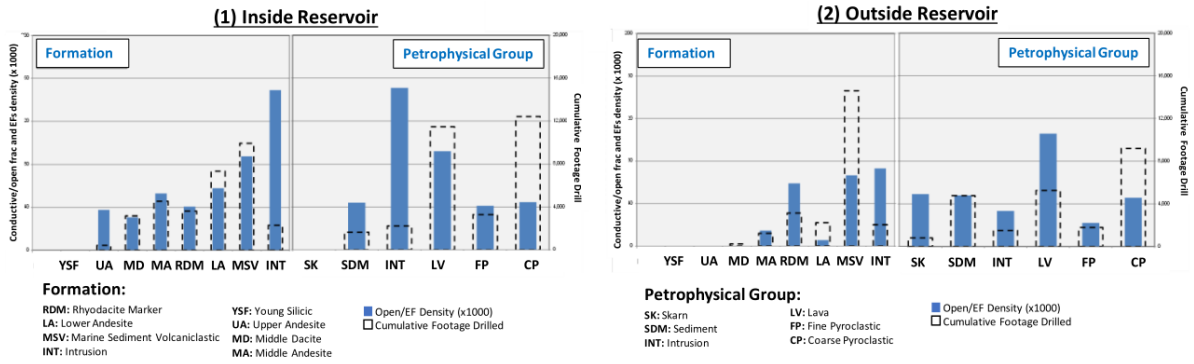

Figure 12: Charts showing the distribution of both Conductive (Open) and Effective Fractures in different formations and petrophysical groups (rock types) located: (1) inside and (2) outside the Salak reservoir. Note that formation, from oldest to youngest, is left to right (YSF to MSV).

Table 1: Fracture Density inside and outside the reservoir.

Area	Borehole Image Logged Interval, ft	Open Fractures Only	Fracture Density Open + Effective Fractures	Effective Fractures Only
Inside Reservoir	31,534	0.064	0.068	0.0027[A]
Outside Reservoir	23,393	0.056	0.057	0.0008[B]

A Excludes borehole image logged interval that did not encounter permeable entries (25,956' only)
B Excludes borehole image logged interval that did not encounter permeable entries (21,417' only)

In general, fracture density for both open and effective fractures inside and outside the Salak reservoir is almost similar (Table 1). If only the Effective Fractures are considered, their density inside the reservoir is about 3 times higher than outside the reservoir. These data show that there are more open fractures inside compared to outside the Salak geothermal reservoirs and this is probably due to the dynamic conditions in the reservoir. The circulating geothermal fluids continuously precipitate and dissolve existing rock minerals which do not happen in static conditions or outside the reservoir. Most of the outside wells in Salak were drilled in the Cianten Caldera where there was once a geothermal system that has since died; thus, this area is possibly now static without active fluid circulation.

4.3 Fracture Aperture

By simple definition, an aperture is an opening, a hole, or a gap in solid materials; therefore, a fracture aperture is the open space in the rock that is occupied by the interpreted fracture. There are some approaches used to estimate fracture aperture. One method that is mostly used to estimate fracture aperture is the calculation by a well-established equation, relating the fracture width to the excess current measured by the imaging tool (Luthi and Souhaité, 1990). Due to the limitation of log data, the aperture of EFs in this study is measured manually by subtracting the depth of the bottom from the top EF surface (Figure 13; left). We acknowledge that this method may yield less accuracy compared to a more general approach. Nevertheless, our goal in employing these techniques is to determine the relative aperture differences both inside and outside the reservoir. The initial measurement generates the apparent aperture because the EF is still influenced by borehole inclination and the EF dip orientation. To get the true aperture, the apparent aperture had to be corrected using β, the angle between the borehole and EF (Figure 13; right).

The table in figure 14 shows the summary of the EF aperture measurement inside and outside of the Salak reservoir. The injection wells drilled outside the Salak reservoir have injecting PTS data; thus, permeable entries and EFs were identified, and EF aperture was measured. S-curves in comparing the distribution of EFs inside and outside the reservoir show significant differences in aperture size (Figure 14; left). It can be discerned by distinct differences of population distribution between the inside and outside reservoir in S-curve. The average aperture of EFs in Salak inside reservoir is about 13 mm and it is almost twice bigger than outside reservoir. Even, the EF apertures in East Salak, mostly steam cap well, is still larger than EF aperture outside the reservoir by almost 20%. In addition, there is an obvious difference in average EF aperture at West and East Salak. The EFs in West Salak have a larger average aperture (>2x) than the EFs in East Salak, and this is probably because brine (in West Salak) will require a larger fracture opening for it to flow out of the matrix. A counterargument to this may be the lower number EFs in West Salak which could bias the average aperture results. The table below in Figure 14 is a tabulation of the comparison of fracture characteristics inside and outside the Salak reservoirs.

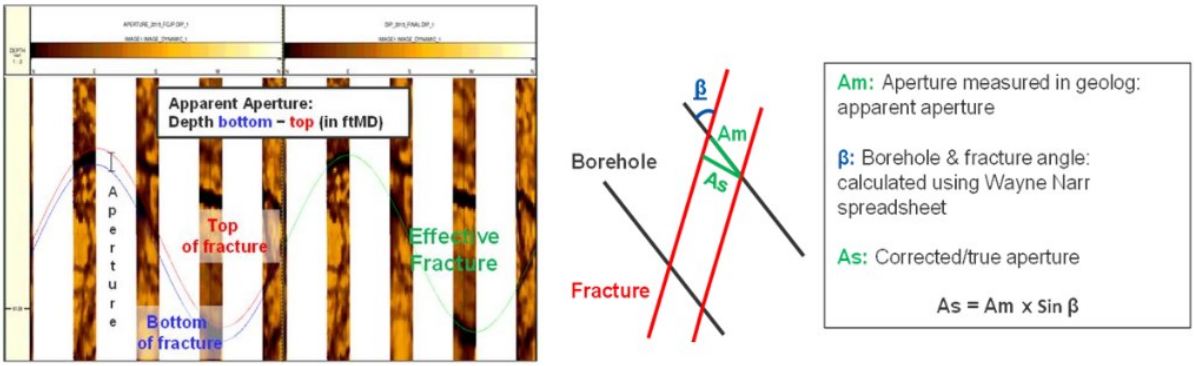

Figure 13: (Left) Borehole image showing the delineated EF and its top and bottom surfaces which were used to manuallymeasure the EF aperture. (Right)Schematic showing β and the formula used to compute for the true aperture.

	No. of Data	Min	Average	Max	Std. Dev.
Inside Reservoir	92	1.6	**13.3**	61.8	10.1
East	60	1.6	**9.4**	24.2	4.4
West	32	8.5	**20.6**	61.8	13.2
Outside Reservoir	36	3.1	**7.4**	15.5	3

Figure 14: (Left) S-curve distribution. (Right) Summary table of EF aperture measurement comparison (right).

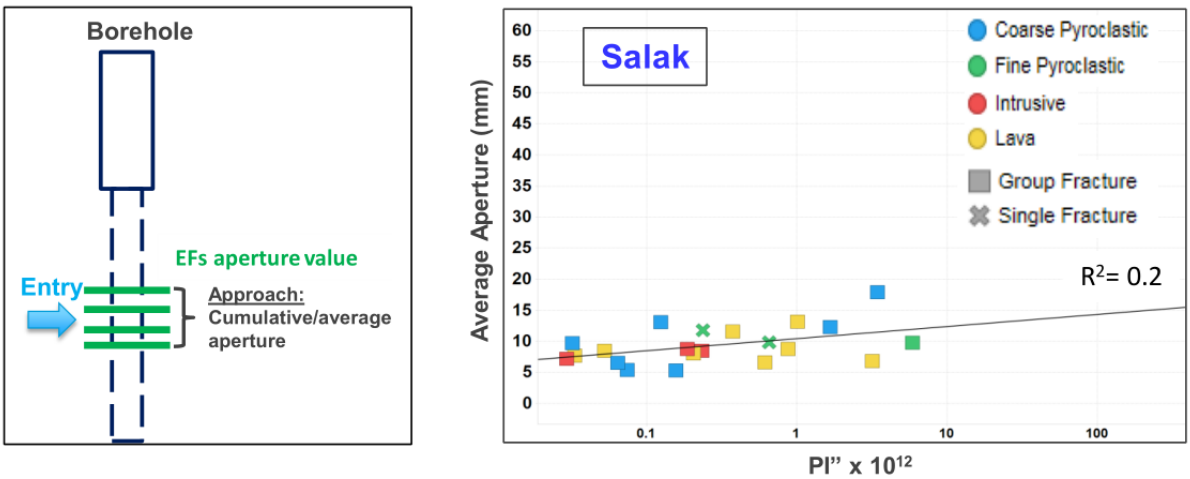

Figure 15: (Left) Illustration of method in evaluating aperture of EFs with permeability. (Right) Cross-plot between average aperture vs permeability (represented by PI').

A working hypothesis that was initially tested was that EF aperture is correlated with permeability, i.e., highly permeable feed zones have larger apertures. In this evaluation, permeability is represented by the productivity index prime value (PI'). There are two ways to use aperture value (cumulative or average aperture value) during aperture vs permeability analysis, as illustrated in Figure 15 (left). As the majority of the permeable zones consist

of Groups of Fractures, the initial analysis considered the cumulative aperture of the Group of Fractures versus the PI' of that particular permeable zone. This approach assumes that all the fractures in the group are producing (which is uncertain). The alternative way of looking at EF aperture is that only one of the fractures in the group is producing; in this case, the average aperture of the group was correlated with the PI' of the permeable zone. The alternative approach was used in this study as it spreads the uncertainty of exactly which fracture is produced in many groups of fractures. The cross-plots between PI and EF aperture at Salak can be looked at in Figure 15 (right). In summary, these cross-plots do not show any strong, direct correlation between the measured EF aperture and PI' as shown by the low R2 (20%). Thus, it seems that permeability is not only controlled by fracture aperture; other influences are fracture connectivity, roughness, etc. Lastly, 5 mm appears to be the smallest EF aperture that can be measured using current software in this current method; there are probably fractures with smaller apertures, but these seem to be not discernible in the software used.

5. DISCUSSION

The general alignment in fracture orientation both inside and outside the Salak geothermal reservoir suggests the presence of a major control on how these fractures were created. It is generally believed that the regional maximum horizontal stress (SHmax) orientation controls the propagation of fractures. In the vicinity of Salak, the general direction of SHmax is ≈N24ºE assuming that the stress regime is extensional (Sugiaman, 2003). The average orientations of fracture dip strike orientation at Salak are generally aligned with the SHmax direction. This interpretation is similar to the results of the analyses of borehole image-derived fractures in other geothermal fields, such as, Dixie Valley, NV (Hickman et al., 1997), Valles Caldera, NM (Nielson et al., 1998), and Wairakei, New Zealand (McLean and McNamara, 2011; McNamara et al., 2016).

In terms of fracture development, local stresses related with volcanism, local faulting, and intrusions may generate a supplementary population to the initial fracture system that is aligned with the regional stress in West Java. Another local control on fracture development appears to be the specific reservoir lithology. This study shows that there are more fractures in the brittle lava flows and intrusive rocks at Salak. Note that these rocks tend to form cooling joints both parallel and perpendicular to their axis of placement; thus, some of the interpreted fractures in borehole image logs are probably inherent. Salak is probably in a transtensional region where both extensional and transtensional shearing are occurring (Fauzi et al., 2015). Transtensional regions are characterized by the presence of both extensional (i.e., normal faults, grabens) and wrench structures (or strike-slip faults); Salak is characterized by both normal and strike-slip structures and lineaments at the surface. This transtensional state is probably responsible for the steeply dipping (>60°) fractures at Salak Fields (Figures 8 and 10). There are no significant differences observed in the fracture dip magnitude inside and outside Salak reservoir, where, both areas have vertical to sub-vertical dips (>60°). The difference is discerned in the fracture orientation/azimuth. Fracture inside reservoir has NNE-SSW trend (N22ºE in average) and it is a similar orientation to Shmax regional (N24ºE), however, some fracture at the edge of the field has diverse orientation and it is inferred due to local stresses, e.g., nearby intrusion (Figure 16A and 16B).

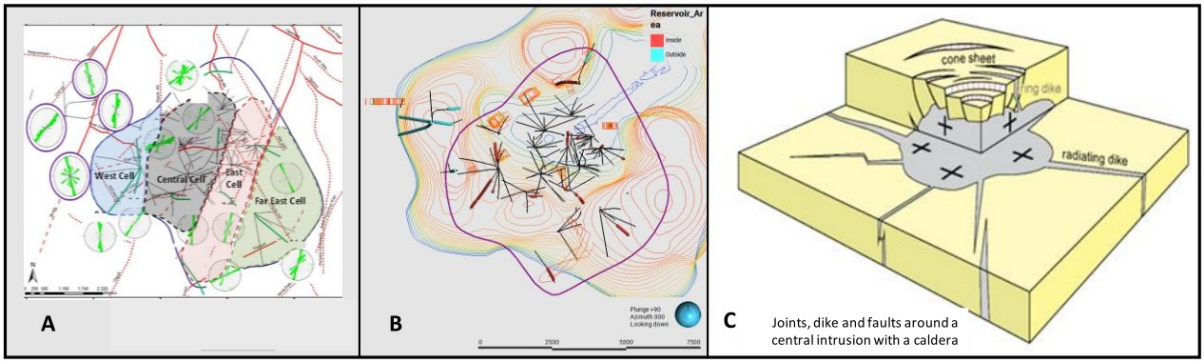

Figure 16: (A)EFs Salak aerial distribution. Note that EFs is mostly has similar orientation with SHmax (NNW-SSW), however, there is diverse of EFs orientation at the edge o the field; (B) Contour line represent of Salak intrusion model. Note that intrusion mostly located in the boundary of Salak Field; (C) Illustration of fracturing inside a caldera (from Burg, 2016). Note that most structures have vertical to sub-vertical dip magnitudes, but the strike azimuth or orientation varies depending on the location within the caldera.

For the outside reservoir, fracture orientation has a wider dominant range and has an average concentration in N-S trend (figure 9). The difference of orientation that occurred in the fracture outside reservoir is inferred due to the location. Most of outside reservoir data comes from well located at the Cianten Caldera, and Caldera geologic setting may generate more variation of fracture orientation with sub-vertical dip as illustrated in Figure 16C. This

figure shows a schematic of the typical fractures (joints) formed in a caldera. Note that the dip magnitude of the fractures is almost similar (or vertical to sub-vertical) but the dip azimuth varies depending on the location within the caldera. Some wells were drilled towards the caldera ring structure, while others were drilled towards the interior of the caldera (Figure 6).

Based on aperture measurement evaluation, aperture EFs inside the Salak reservoir is about twice as larger than effective fractures outside (Figure 14). There are probably many factors that control the fracture aperture size; some obvious mechanisms are (1) compressive stress strength of the general area, (2) fracture azimuth orientation, (3) rock strength, and (4) hydrothermal alteration process. The first mechanism is related to the compressive stress strength difference. Because of the lack of data, it is believed that compressive stress strength is generally the same inside and outside the Salak reservoir. However, brittle rocks will probably break or fracture more than softer rocks as shown by the higher density of fractures in lava flows and intrusion compared with softer pyroclastics and sedimentary rocks. The next mechanism is related to the fracture orientation relative to the regional stress direction. Theoretically, open fractures will be generated if maximum stress (σ1) is parallel to the fracture azimuth (Figure 17). As previously described, the majority of the measured fracture dip azimuth inside the reservoir is parallel with the SHmax orientation; thus, the lower compressive stress inside the reservoir will theoretically generate larger apertures. However, this mechanism does not support actual data which depicts no distinct correlation between aperture size and fracture azimuth (Figure 17). Large fracture aperture should be observed in fractures with 100°-130° azimuth; however, the data shows no distinct patterns in fracture aperture with fracture azimuth.

The last mechanism is hydrothermal alteration and is probably the preferred model to explain the larger effective fracture aperture inside the Salak reservoir. Although the reaction of the circulating geothermal fluids and reservoir rocks may both precipitate and dissolve minerals, it appears that there is more dissolution in rocks with propylitic alteration. Stimac et al. (2004) showed analogues result in Scanning Electron Microscope (SEM) images of the Mat-25 core which indicate that the observed porosity is generated through the destruction of primary porosity and formation of secondary porosity by the hydrothermal system itself as circulating fluids dissolve primary minerals. At Tiwi (Philippines Geothermal Field), total porosity correlates with the abundance of open fractures (Stimac et al., 2004). Furthermore, overburden compaction appears to be likely more extreme for clay-rich formations and poorly consolidated fragmental rocks than for dense lavas. Dense lava flows and intrusive rocks were encountered inside the Salak reservoirs while softer pyroclastics are dominant outside both reservoirs. In addition, mineral precipitation (in particular, silicification) occurs more outside the reservoir and this can reduce fracture aperture. Rock cuttings from the Cianten Caldera wells show abundant secondary silica probably from the cooling geothermal system at Cianten Caldera; also, there was rarely lost mud circulation during the drilling of these wells suggesting fewer open fractures.

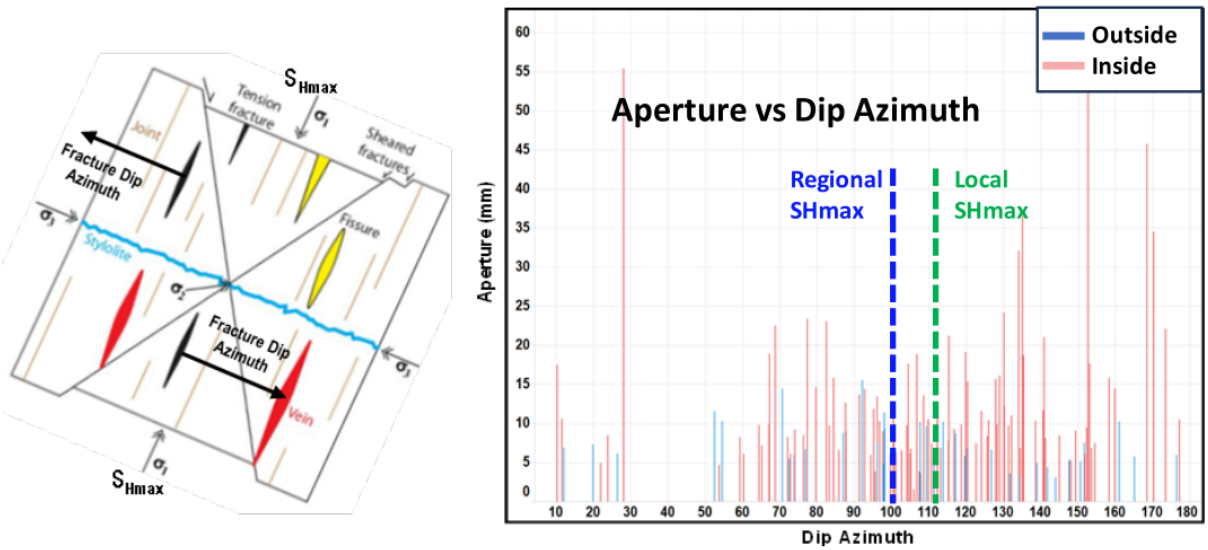

Figure 18: (Left) Schematic showing the illustration of a shear fracture model (modified from Fossen, 2010). Joint, fissure and vein commonly form where σ1 is parallel with fracture plane while stylolites occur where σ1 is perpendicular with the fracture plane. (Right) Chart shows aperture vs. dip azimuth of EFs inside (red) and outside (blue) the Salak reservoir.

In terms of fracture density, conductive/open fracture density is similar between the inside and outside reservoir, where relatively brittle rocks (i.e., lava flows and intrusions) host more fractures than the "softer" pyroclastics and sedimentary rocks. Interestingly, effective fracture (EFs) density discerns that inside reservoir is significantly

higher than outside(~3x). EFs aperture denote that inside reservoir has bigger aperture(~2x) than outside reservoir. According to this evaluation, the inside reservoir has more permeable fractures (i.e., higher EFs density) with larger aperture compared to the outside reservoir, thus, it suggests that fracture connection inside the reservoir is higher than outside.

Based on several observations mentioned in the previous section, there are both similarities and differences in the characteristics of fractures inside and outside the geothermal reservoir. Some of the similar characteristics include the following:

- Two populations of fractures are evident inside and outside the reservoir in terms of fracture orientation (or azimuth), namely, a randomly distributed fracture set and a group that is generally aligned with the SHmax direction.
- Fractures both inside and outside reservoir have vertical to sub-vertical dips (>60°);
- Fracture density discerns that both inside and outside have similar numbers and brittle rocks relatively (i.e., lava flows and intrusions) host more fractures than the "softer" pyroclastics and sedimentary rocks.

Conversely, below are some of the differences in fracture characteristics inside and outside the reservoir:

- Fracture orientation inside reservoir exhibit a narrow range, while fracture outside reservoir has a more varied orientation.
- There are more permeable fractures (i.e., higher EFs density) inside the reservoir.
- EFs inside the Salak reservoir have bigger aperture than those outside.

The differences in geological setting and reservoir process between inside and outside reservoir is apparently cause the differences in fracture characteristics. Table 2 is a summary of characteristics of fracture inside and outside reservoir.

Table 2: The summary of characteristic of fracture inside and outside reservoir.

Parameter		Salak (SHmax N24°E)	
		Inside	Outside
Fracture Orientation	Dip Azimuth	2 populations	2 populations
		Average strike orientation (N22°E) is parallel to SHmax (-2°)	Average strike orientation (N-S) is shifted left of SHmax
		Narrow range	Wider range
	Dip Magnitude	2 populations	2 populations
		Average ~92°	Average ~90°
Fracture Density	Conductive/Open Frac	0.064 (14% more than outside)	0.056
	Open+Effective Frac	0.068 (14% more than outside)	0.057
	Effective Frac	0.0027 (~3x higher than outside)	0.0008
Effective Fracture Aperture, mm		13.3 (~2x bigger than outside)	7.4

Eventually, the result of fracture characterization will be utilized to improve well targeting and planning during the drilling of makeup wells and become an input for the numerical model. Evaluation of open and EFs orientation inside the reservoir is very useful input during developing well trajectory for new Make-up Wells. To optimize well intersection with fracture, well plan trajectory will be generated as much as perpendicular of fracture, thus it is expected to get a higher chance to encounter EFs. In modeling, fracture orientation information will be used to orient the grid in the 3D static model. Also, the evaluation results of fracture density will be used to develop a 3D fracture spacing model. Fracture spacing, an important property, will be used in numerical models to estimate production rates and provide pressure support.

ACKNOWLEDGMENT

The authors would like to thank the management of Star Energy Geothermal Salak Ltd. (SEGS) for supporting this study and granting permission to publish this paper. Massive thanks to SEGS olleagues who contributed to reviewing and improving its contents.

ABSTRACT

The Wayang Windu Geothermal Field (WWGF) has been operating for over 20 years and is committed to increase the capacity of the power plant should the resource support. Based on the resource assessment, the development needs to cover a larger and deeper area to have sustainable production. The westernmost section has been identified as a promising resource area and approached by the latest drilling campaign in 2021. Pad I, the latest pad in this section, exhibits unique characteristics compared to others. A dry-steam well drilled on this pad, namely I1 produced ~11 kg/s of steam, which is more moderate compared to other dry-steam wells in adjacent pads that produce over 20 kg/s of steam. Concerns have arisen about whether this indicates the well is close to the reservoir's margin, despite a good connectivity to adjacent high-performing wells like D5, D7, and Q6, as observed by chemistry monitoring during drilling. Regular chemistry monitoring sequences, including gas, steam condensate, and stable isotope analysis were conducted to characterize the well. Gas analysis showed NCG levels at 0.8 – 1.0 wt.% in steam, slightly higher than adjacent wells but within the range of the northern reservoir section. In addition, stable isotope analysis indicated enriched composition and positioned close to the surrounding upflow zone. Other findings, such as PT data were consistent, the top of reservoir depth is similar to the adjacent wells, with the presence of a water dead-leg. However, the TFT analysis confronted these results with an enthalpy of around 2786 kJ/kg. Additional analysis using the downhole liquid sample confirmed that the water composition was consistent with the remnant of condensate injectate fluid. Furthermore, a comprehensive saturation model of vapor to liquid (Sv/Sl) was generated to understand the reservoir process occurring in this well which suggested that boiling activity occurs in the reservoir. Based on these indicators, it can be deduced that well I1 is still within the same cell as the northern vapor zone and not located on the reservoir's margin. The current low productivity in this well might be associated with a distinct localized reservoir area associated with the prompter pressure drop than the surrounding wells (Pentury, 2024), which leads to a slower boiling process. Future development strategy still recommends exploring the surrounding areas of Pad I and remaining resources, aligned with frequent surveillance monitoring and comprehensive resource assessment.

1. INTRODUCTION

The Wayang Windu Geothermal Field (WWGF) has been operating for over 20 years with current total installed capacity of 230.5 MWe. Currently, 80% of Wayang Windu production relies on the steam wells, while only 20% comes from the two-phase wells. Based on the resources assessments, the development needs to cover a larger and deeper area to have sustainable production and support WW expansion project. With the success of two big two-phase producers in the 2020-2021 drilling campaign, vertical extension to the reservoir brine is achievable and the two-phase well ratio will keep improving in the future. As for the lateral extension, the westernmost section has been identified as a promising resource area and approached by the latest drilling campaign in 2021.

A new well pad, codenamed I, was constructed in 2020 to cover this area. The result of the drilling in this pad exhibits unique characteristics compared to others. A dry-steam well drilled on this pad, namely I1 produced ~11 kg/s of steam, which is more moderate compared to other dry-steam wells in adjacent pads that produce over 20 kg/s of steam. Concerns have arisen about whether this indicates the well is close to the reservoir's margin, despite a good connectivity to adjacent high-performing wells like D5, D7, and Q6, as observed during drilling activity monitoring. Routine geochemistry fluid monitoring and reservoir data are combined to determine the reservoir characteristic, leading to a recommendation for further development in the area.

2. WELL CHARACTERIZATION

I1 as a dry steam production well monitored through regular chemistry monitoring sequences, including gas, steam condensate, and stable isotope analysis. Gas data is essential in characterizing the well and conceptually locating the area in the geothermal system, whether this area in the productive zones or it is already closer to the margin.

Not only chemistry data, subsurface pressure and temperature data are also vital to understand the reservoir in this western area.

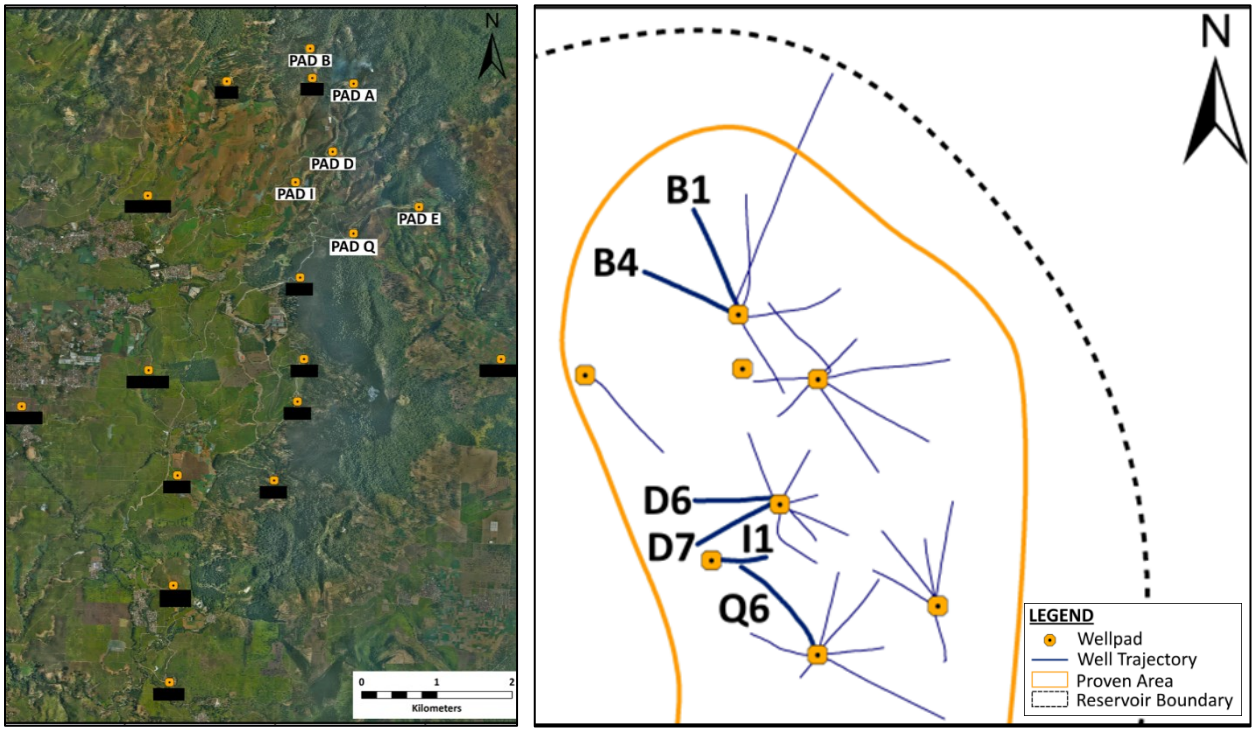

Figure 1: Left: Map of All wellpads in Wayang Windu. Right: Northern area of Wayang Windu with the new I1 well.

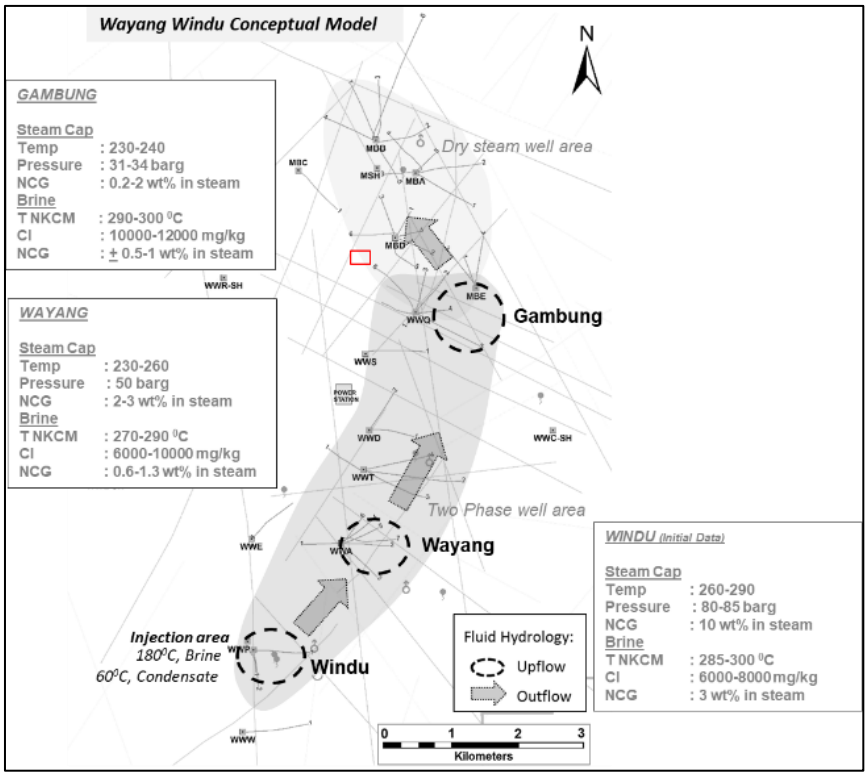

Figure 2: Current Conceptual Model of Wayang Windu Geothermal Field and sector information. There are three uplow areas: Gambung (north), Wayang (central), and Windu (south). Pad I located at the red box (modified from Malik, 2020).

The conceptual model of Wayang Windu has consistently identified three reservoir cells, called Gambung, Wayang, and Windu. The recent model (Figure 2) has shown its sectoral information and the major flow paths. The new pad I was aligned with the current model where it fed by the Gambung reservoir and far from the margin area. However, the analysis on gas and stable isotope composition might be the key parameters in identifying the pad I characteristics and defined the future strategy.

2.1 Gas Analysis

The gas composition analyzed monthly ever since the well started online in mid-2022, including the total Non-Condensable Gas (NCG) and other single gas parameters. The analysis of total NCG will evaluate the general well characteristic in correlation with the recent conceptual model. Considering that this new pad is located further west and semi-exploration, it is expected that the well will be produced from the lateral extension of the Gambung steam cap. The initial prognosis was that the NCG levels would be similar with the closest wells at 0.4-0.6 wt%, however, it had a higher average NCG (as seen in Figure 3) with a stable trend although the value is quite far below the wells that are identified as close-to-margin.

Evaluating the steam composition in the new area is important to involve the behavior of different gas solubility or commonly expressed as the gas ratio. The gas ratio (less soluble gas/ more soluble gas) such as CO_2/H_2S (Figure 3) shows that I1 has a fluctuating trend, which the normal trend of continuous steam formation should follow with decreased CO_2/H_2S as the proportion of the more soluble gas will increase relative to the less-soluble gas (Nicholson, 1993). The observation interprets that pad I has a unique steam formation pattern that shows intermittent pressure changes or even localized permeability, thus making the gas distribution erratic.

Further gas analysis are using CO_2/Ar-H_2/Ar gas ratio grid and FT-CO_2 geothermometer grid. Both cross plots use two geothermometer equations to identify reservoir temperature and the fraction of equilibrium vapor in the sample. Result of the cross plots showing higher temperature on I1 well compared to the surrounding wells. Although in both analyses, the data positioned lower than equilibrated liquid line, which might indicate immature/not fully equilibrated condition (Giggenbach and Goguel, 1989). One possible explanation is continuous extraction on small volume of reservoir section due to localized permeability, limiting contact with the rock in the shallow reservoir section thus not giving the time for equilibration.

2.2 Stable Isotope Analysis

The analysis of stable isotope of ^{18}O and Deuterium has been widely used both for exploration and exploitation. Its implementation on mature vapor-dominated fields, such as the Geysers and Larderello, are observed for its ^{18}O spatial variation (Arnorrsson, 2000). ^{18}O value for deep reservoir fluid is enriched, meanwhile shallow meteoric water has depleted value. This distinctive characteristic helps to identify mixing process between reservoir fluid and meteoric water, which generally interpreted as the relative distance of fluid travelled from deep reservoir feed (upflow) to the meteoric recharge area (outflow).

Stable isotope analyzed from the condensates that are sampled routinely twice a year to characterize the well. Besides, the condensate composition also sampled routinely along with the gas. Result of chemistry analysis on the routine condensate showed no significant mixture of external fluid influx to the wellbore, which implies that the fluid chemistry is the result of reservoir process. Stable isotope analysis also agrees with this observation as all data showed enriched composition and positioned close to the upflow zone, refusing the idea that this well is close to margin as shown by B pad that positioned closer to meteoric water line (Figure 5).

2.3 Pressure Temperature Analysis

Based on PTS data, the top of reservoir depth is similar to the adjacent wells, indicating a connecting and similar system with area in pad D and Q. Initial temperature showed up to 230^{o}C with up to 30 bar pressure. Further analysis interpreted three feed zones in the wellbore, located in around 990, 906, and 880 mASL. This well is a shallow dry steam well with a total depth (TD) that does not exceed the average liquid level of the field, which is approximately 400 meters above sea level (mASL). Therefore, the presence of liquid below approximately 800 mASL in the 2021 PT profile (Figure 6) has been verified as a water dead leg or an accumulation of cooler injected fluid that does not flash, due to the lack of productive fracture zones beneath that depth. This also corresponds to the evidence of the PT spinner profile that shows the increase in RPS only occur on the top of ~800 mASL Chemistry analysis using the downhole liquid sample also confirmed that the water composition was consistent with remnant of condensate injectate fluid. Follow-through tracer flow test (TFT) analysis confirming the water is not producing to the surface, with the results of an enthalpy around 2786 kJ/kg.

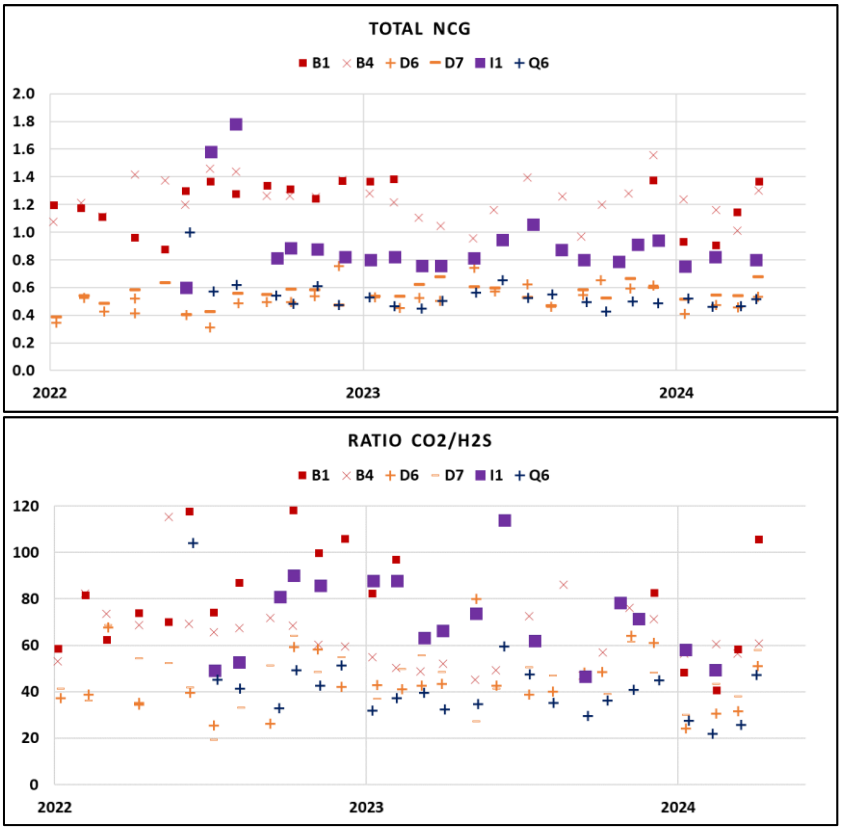

Figure 3: NCG levels at 0.8 – 1.0 wt.% in steam, slightly higher than adjacent wells (Q6, D6, D7) but within the range of the northern reservoir section and not as high as close-to-margin wells (B1, B4).

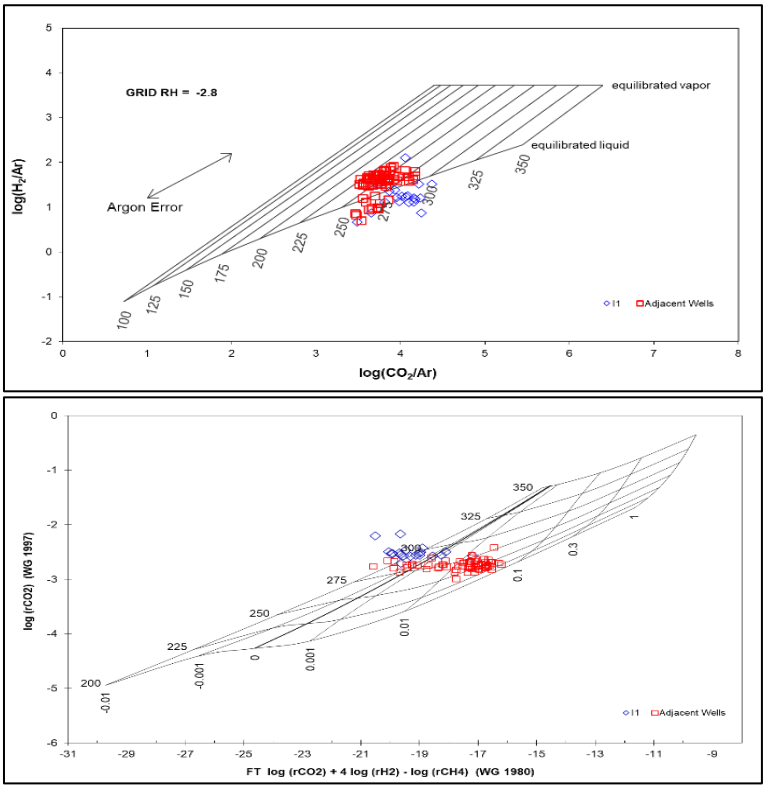

Figure 4: CAR-HAR and FT-CO2 diagram show I1 have higher average temperature than the surrounding wells.

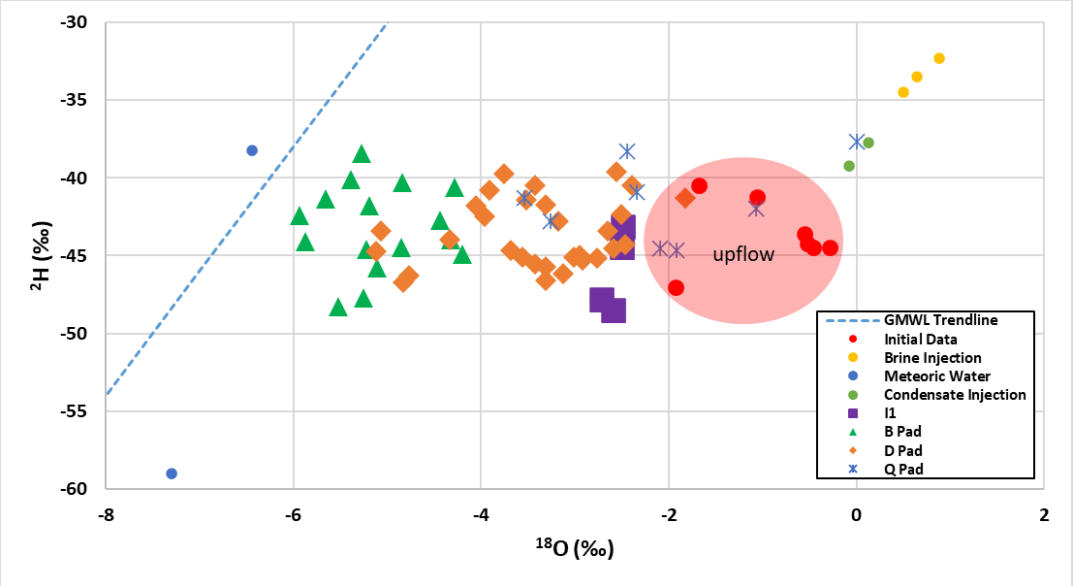

Figure 5: Stable isotope analysis of I1 condensate shows enriched composition.

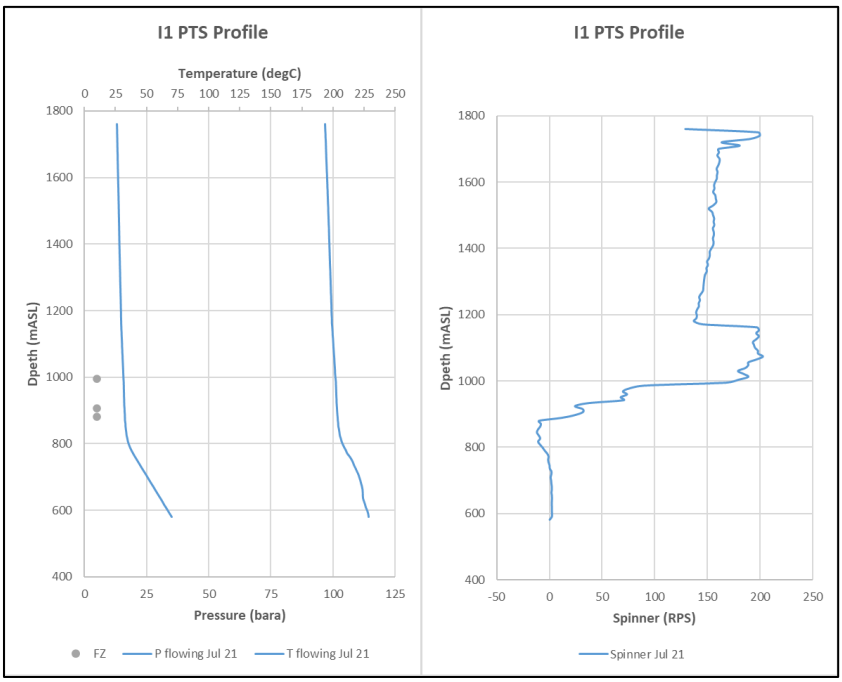

Figure 6: PTS data of I1 well.

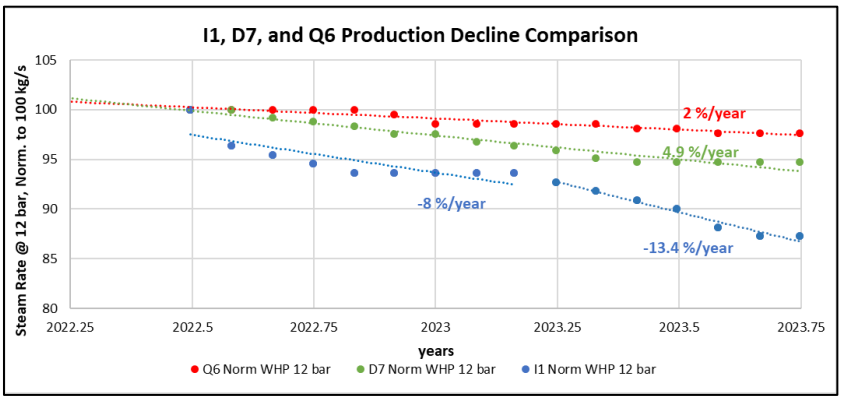

Figure 7: Production decline of well I1 compared to the adjacent wells.

Performance of this well monitored through production and reservoir (steam cap) pressure. I1 well had moderate production in the initial discharge, however it is underperforming in the terms of decline rate. Compared to the adjacent wells that are older and bigger producers, the decline rate of this well is still higher. It has 8% decline in the first year of production and accelerated to 13% per year afterwards, while the surrounding wells Q6 and D7 have only 2% and 5% respectively. Figure 7 show the comparison with normalized 12 bar pressure and 100 kg/s initial steam rate. Similar observation also applies for the reservoir pressure, although initially it has similar magnitude, I1 well have larger pressure decline although producing less than the adjacent wells (Figure 8).

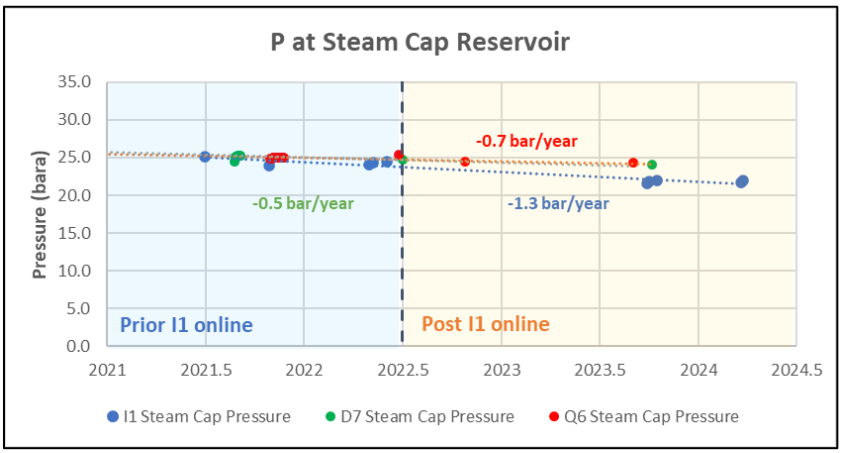

Figure 8: Pressure declines of well I1 compared to the adjacent wells.

Pad A	0.9
Pad D	1.08
Pad I	0.16
Pad E	1.56

Figure 9: Saturation model of well pad I compared to the other pads.

2.4 Saturation Model

To further assess the well conceptual resources, a comprehensive saturation model of vapor to liquid (S_v/S_l) from the gas grid reaction generated to understand the reservoir process occurring in the northern part of Wayang Windu. When it monitored continuously including other observation such as volatiles carryover (B, SiO_2, Cl), gas/steam ratio, steam flow, and stable isotope, it gives the benefit to understand vapor dominated wells behavior and a hint to steam reservoir management (D'Amore, 1995). This method also implied in mature vapor dominated field like The Geysers and Larderello.

Application of the vapor/liquid in matrix proportion discussed in this paper is the method to understand the deep process of how gas elements changes reflected by the steam separation process, most importantly in a new pad I. A simple illustration to show the correlation of liquid saturation to physical phenomena in the northern part of Wayang Windu presented in the Figure 9. The fact that B pad is the lowest pressure area, having the most intense boiling means maximum fluid intake into the steam phase, but limited remaining deep recharge, thus increasing degree of superheat and highest Sv/Sl. In contrary, the lowest S_v/S_l ratio reflects the least boiling process in this new pad I. The average value of S_v/S_l (~1) were located in pad A and D where mostly having low superheat and operate at the higher pressure. Those pads are mostly constant high steam suppliers. The pads support the 'balance' characteristic by maintaining the least pressure drop or maintained silica solubility. The physical phenomena reflected by the saturation that pad I has the highest liquid saturation but cannot support the vapor saturation are possibly correlate some parameters affecting the rock matrix, such as local permeability occurring in pad I.

However, the remaining liquid saturation below pad I is still high compared to others, so focusing the production in that area will possibly enhance the boiling area.

3. CONCLUSION

Based on indicators from the data presented above, all evidence narrowed down the interpretation into well I1 is still within the same cell as the northern vapor zone and not located on the reservoir's margin. Resources in this area are confirmed, proven by high temperature in this area. Several geothermometers calculated that I1 even has higher temperature than the adjacent wells. Measured data from PT survey shows temperature of up to 230^{o}C and 30 bar pressure which is reasonable for a dry steam producer. Some notes are that this well has higher pressure drop compared to the adjacent wells. Moderate productivity in this area compared to the adjacent wells might be associated with a distinct localized reservoir area associated with the prompter pressure drop than the surrounding wells (Pentury, 2024), which leads to a slower boiling process. As for the future development strategy, we still recommend exploring the surrounding areas of Pad I, focusing on avoiding the localized permeability around Pad I, going after big permeability potential and maximizing production, along with fit-for-purpose surveillance for comprehensive resource assessment and reservoir characterization.

Keywords: Magnetotelluric, volcanic geothermal systems, deep conductors

ABSTRACT

Elevated temperatures in volcanic geothermal systems result from high heat flow caused by shallow intrusion of magma. Magmatic intrusion acts as the major heat source of the system and drives hydrothermal convection. Understanding the nature and location of magmatic heat sources is therefore relevant for characterizing the geothermal system. Magnetotelluric studies around the world have revealed numerous occurrences of deep electrical conductors below volcanic geothermal prospects. Interpretations of such deep conductors often invoke the presence of magmatic melt and magma derived fluids thereby arguing in favor of interpreting deep conductors as related to the magmatic heat source. However, the architecture of magmatic systems is rather complex and strongly depends on the degree of solidification, residual melt, and volatile content. Electrical resistivity alone does not provide conclusive evidence about the nature of deep conductors. We describe a selection of scenarios and their impact on geothermal reservoir formation: Under favorable conditions magmatic mush reservoirs in the upper crust can remain stable over long geological timescales thereby providing a constant heat supply for a geothermal system. Undesirable situations are encountered when H_2S from degassing magma combines with water to form sulfuric acid brine, a fluid with exceptional high electrical conductivities. Such acidic hydrothermal plumes can form above largely cooled intrusions and make geothermal drilling unattractive. In cases where volcanic eruption happened through sedimentary overburden, deep conductors may also represent buried fluid-bearing sediments, hence being unrelated to magmatic systems and potential heat sources. Therefore, conclusive interpretations of deep conductors require a comprehensive geoscientific approach. First, a detailed understanding of the geological setting, eruptive history and magma evolution is required and, second, integration of various types of geophysical observables is key to understand the internal structure and fundamental petrophysical properties of deep electrical conductors under volcanic geothermal prospects. Here we present case studies from geothermal prospects around the world and provide a classification or grouping for deep conductors based on their geological setting, volcanic history and available well data.

1. INTRODUCTION

Since the beginnings of industrial-scale development of geothermal resources, electrical sounding methods have played an important role in geothermal exploration and for siting drilling targets (Wright et al., 1985). It was recognized early that high-temperature volcanic geothermal reservoirs are often overlain by a pronounced low resistivity layer that is composed of electrically conducting clay minerals, which are produced through hydrothermal alteration (Moskowitz and Norton, 1977). Subsequently, electrical resistivity methods took an important role in geothermal exploration due to their capability to identify and map the extent of the electrically conductive clay “cap”. The clay cap is not only a product of hydrothermal processes and hence a strong indicator for geothermal activity, but it also seals the reservoir top, due to the properties of clays, which swell when in contact with water and form an impermeable layer (Gunderson et al., 2000).

Amongst a variety of active and passive geophysical electromagnetic (EM) sounding techniques, the magnetotelluric (MT) method established itself as a widely used tool in geothermal exploration. MT relies on natural electric and magnetic field variations that originate from global lightning activity and the interaction of the Earth’s geomagnetic field with the solar wind (e.g. Vozoff, 1991). The EM source fields are always present, allowing a short deployment time of measurements systems in the field, and MT easily covers penetration depths relevant for clay cap imaging, reservoir characterization and beyond (e.g. Berktold, 1983; Cumming, 2009; Muñoz, 2013).

In early applications of the MT method in geothermal exploration MT data were generally interpreted using 1D modeling and focused on delineating the clay cap atop the geothermal reservoir (Pellerin et al. 1992, Anderson et al., 2000). 1D imaging of the clay cap is an established application and remains a common method (e.g. Árnason et al. 2010) even after 3D interpretations became feasible with increasing computational capacities. The reason why 1D modelling of MT responses to image the clay cap produces valuable models can be attributed to the strong electrical conductivity signature of the clay cap, which is essentially 1D. Therefore, cross-sections stitched from 1D inversions of the MT responses are still common in geothermal exploration and often used as an initial quality assurance check. Anderson et al. (2000) pointed out that clay cap topography delineated by 1D MT modelling enables the reliable location of geothermal reservoirs, which are encountered under regions of clay cap updoming. 1D models of geothermal areas and prospects often imaged deep electrical conductors below the clay that typically extend from below the clay cap and the geothermal reservoir to greater depths. These deep conductors have been found as early as in studies by Hermance et al. (1976), who interpreted a deep low-resistivity zone beneath Icelandic volcanic prospects as small fractions of basaltic melt. However, quantitative interpretations of deep conductors were hampered by limitations of 1D interpretations of MT data, which provide only a valid approximation for the shallow part near the surface of a volcanic geothermal system. Only in rare cases do MT data obey 1D or even 2D conditions down to larger depths. Owing to their geological nature, volcanic geothermal prospects exhibit strong 3D features that extend from the surface to the lower crust. Deep seated magmatic melt sources feed vertically extensive magmatic pathways that crosscut geological strata and feed shallow melt reservoirs that drive localized hydrothermal fluid flow often hidden under heavily faulted terrain with strong surface topography and steep slopes.

The 3D nature of volcanic geothermal prospects became apparent when 3D MT interpretations of volcanic geothermal prospects provided full-featured 3D images that revealed lateral resistivity variations below the clay cap with vertically extensive transcrustal anomalies raising question about their nature (e.g. Newman et al. 2008, Heise et al. 2015, Hill et al. 2015).

2. METHODS

The MT method is an inductive EM sounding technique especially sensitive to electrical conductors (e.g. Vozoff, 1992). MT relies on measuring time series of the natural electric (**E**) and magnetic (**H**) field variations at a specific location (**r**) at the Earth's surface. In the frequency domain (ω) the electric and magnetic field are related through a complex-valued second-rank tensor Z:

$$\boldsymbol{E}(\boldsymbol{r},\omega) = \begin{pmatrix} C_{11}(\boldsymbol{r}) & C_{12}(\boldsymbol{r}) \\ C_{21}(\boldsymbol{r}) & C_{22}(\boldsymbol{r}) \end{pmatrix} \begin{pmatrix} Z_{xx}(\boldsymbol{r},\omega) & Z_{xy}(\boldsymbol{r},\omega) \\ Z_{yx}(\boldsymbol{r},\omega) & Z_{yy}(\boldsymbol{r},\omega) \end{pmatrix} \boldsymbol{H}(\boldsymbol{r},\omega) \quad (1)$$

Z contains the full 3D information about the electrical resistivity distribution of the subsurface, where lateral information comes from the location (r) and depth information from the frequency (ω). MT electric field data are commonly subject to frequency-independent amplitude changes known as galvanic distortions (e.g. Jiracek, 1990). Distortion is described by a real-valued frequency-independent distortion matrix C. In the ideal case of no distortion present C has the form of the identity matrix and can be omitted from eq. (1).

3D interpretation of MT data requires 3D inverse modelling of the full impedance tensor. In contrast, 1D interpretations of the impedance tensors typically interpret a rotationally invariant of the tensor such as the determinant (Berdichevsky, 1999). For 2D interpretations the impedance tensor is rotated into the direction of geoelectrical strike and only the two modes TE (Zxy) and TM (Zyx) are interpreted. The impedance tensor (eq. 1) can also be affected by galvanic and inductive distortions, which are either caused by small-scale near surface electrical scatterers below the resolution of the data, by pronounced topography (Stark et al., 2013; Käufl et al. 2018), or by a superimposition of both. Concepts to correct for distortions exist for underlying 1D and 2D assumptions (Groom and Bailey, 1989), however, they are strictly speaking not valid for 3D data.

3D inversions can be performed inverting simultaneously for 3D resistivity structure and distortion matrices, with a control parameter that suppresses deviations from the identity matrix, which represents the a priori condition of no distortion (Soyer, 2020). Topographic distortions are addressed by the accurate implementation of topography in the 3D resistivity model (Käufl et al. 2018; Soyer at al., 2019). Another method to bypass distortions is to invert for magnetotelluric phase tensors (e.g. Samrock et al. 2018), a quantity that is unaffected by distortions (Caldwell et al., 2004). 3D inversion of MT data and concepts to address distortion without simplifying assumptions have led to an increasing number of 3D electrical resistivity models of volcanic geothermal prospects that allow interpretations that are consistent with theoretical concepts of the architecture of volcanic geothermal systems and geological models. In the following we present a surface to depth hypothetical model of a volcanic hydrothermal system that builds upon existing models with a stronger focus on deep electrical conductors.

Besides geological causes for deep conductors, non-geological sources must be considered as a possible reason. Data distortion, noise and systematic bias in the MT dead band can lead to geological misinterpretations (Hennessy and Macnae, 2018).

3. COMPREHENSIVE HYPOTHETICAL MODEL OF VOLCANIC HIGH-TEMPERATURE GEOTHERMAL SYSTEMS

The main source of heat in a volcanic high-temperature geothermal system is magmatic activity. Magma is primarily generated through partial melting processes in the Earth's mantle (Grove and Till, 2015). Melt is generated through two main processes: First, by decompression melting at extensional settings such as continental rifts, in the backarc of subduction zones, at midoceanic ridges and by mantle plume activity. The second melt generation process is through a change of composition in the Earth's mantle so that the solidus of the new composition is lower than the present temperature. This process happens e.g. in subduction zones. Magmatic systems are dynamic transcrustal features (Cashman et al., 2017) with a highly complex architecture (Edmonds et al. 2019). Melt eventually reaches the Earth's surface where it erupts in volcanoes or is stored at mid-crustal depths in highly crystalline magmatic mush reservoirs.

Crystal mush reservoirs have relatively small melt fractions and can be in a rheologically locked-up rigid state forming ephemeral systems that undergo increasing solidification through fractional crystallization and degassing (Sparks et al. 2019). Re-melting of crystal mush can be initiated through emplacement of new magma from below at the base of the crystal mush reservoir (Huber at al. 2011). Magma storage in the upper crust drives hydrothermal convection ultimately leading to the formation of a high-temperature geothermal system (Scott et al. 2015). The architecture of such a system in shown in Figure 1. In the following we will describe the individual geological features and their electrical characteristics. The hypothetical model (Fig.1) builds up and expands work by Berktold (1983), Pellerin et al. (1992), Ussher et al. (2000), Andersson et al. (2000), Cumming (2009) and Samrock et al. (2023) amongst others.

Starting from the surface, the shallow depths of volcanic geothermal prospects are typically composed of fresh volcanic material including pumice, ash, and lava flows. This material is mostly dry and characterized by high resistivities. Going deeper, circulating geothermal fluids lead to the formation of the clay cap (feature 1 in Fig. 1). The clay cap forms through alteration along the flow paths of hot circulating fluids that hydrothermally alter the volcanic host rock producing clay minerals such as smectite (Ussher et al. 2000). These clays are characterized by very low electrical resistivities leading to a pronounced electrically conductive layer atop the geothermal reservoir. The clay cap has also a sealing function due to the tendency of clay minerals to hydrate and swell forming an impermeable layer when exposed to water. Hydrothermal alteration is temperature dependent and with increasing temperature clays produced in the argillic alteration regime become hydrothermally unstable. At higher temperatures propylitic alteration takes place with different alteration products such as chlorite and epidote. These minerals are characterized by much higher resistivities leading to an increase in bulk resistivity in the hotter propylitic alteration zone (feature 2 in Fig. 1) below the clay cap. Empirical evidence suggests that the clay cap bottom is marked by the 10Ωm isoline and temperatures of 250°C (Gíslason et al., 2015). Temperatures are hotter in the propylitic alteration zone and in upflow zones that form preferably along geological discontinuities such as faults (Wallis et al. 2017). Since the temperature pattern follows the upflow zones, temperature isosurfaces and hence the argillic alteration front are pushed closer to the land surface leading to the characteristic clay cap updoming above upflow zones (Fig.1; Anderson et al. 2000, Samrock et al. 2023). For a comprehensive database with petrophysical properties, including electrical resistivity, of rock from volcanic geothermal systems see e.g. Scott et al. (2023).

In the following, low resistivity features below the clay cap and the propylitic alteration zone are referred to as deep conductors. Deep conductors can have various origins of which several are described in the following. One reason can be the formation of an acidic hydrothermal plume and a high pyrite concentration. Hydrothermal acid plumes (feature 3 in Fig. 1) form through chemical reactions of sulfur-rich volcanic degassing and water (Byrdina et al. 2018). Byrdina et al. (2018) observed resistivities of acid fluids from Indonesian volcanoes below 0.1Ωm and decreasing resistivities with decreasing pH. Low pH environments also promote the formation of electrically conductive pyrite (FeS_2) by reaction between H_2S-rich fluids and Fe-rich volcanic rock (Levy et al. 2020).

Magma-derived fluids that are exsolved from crystallizing melt tend to migrate upwards due to buoyancy forces and may accumulate in the upper part of an active or cooled magmatic intrusion (feature 4 in Fig. 1). Such magmatic brine lenses can be composed of vapor and brine or even supercritical fluids. Watanabe et al. (2021) presented an empirical model to calculate the electrical conductivity of H_2O-NaCl fluids for pressures up to 200 MPa and temperatures up to 525°C. Their model shows that magmatic brine lenses have low electrical resistivities at the expected temperature and pressure conditions of a high-temperature geothermal system. Tseng et al. (2020) interpreted a deep conductor with resistivities less than 1Ωm below Kusatsu–Shirane volcano, Japan, as pressurized magmatic brine lens, the top of which is sealed by an impermeable layer of precipitated silica and

halite. Magmatic brine lenses are sourced from deeper magma reservoirs that may exist in form of crystal mush reservoirs. Crystal mushes have a crystal fraction of minimum 50 to 60 vol.% which is the mechanical threshold when crystals start touching each other and the melt crystal mixture cannot flow and erupt anymore (Bachmann and Bergantz, 2008). Samrock et al. (2021) coupled laboratory inferred melt electrical conductivity models and thermodynamic modelling of melt evolution and crystal fractionation to constrain electrical conductivities within crystal mush reservoirs. Their models provide interpretations of deep conductors under volcanic geothermal prospects in the Ethiopian rift that agree with thermodynamic equilibrium conditions and consider crystal mush reservoirs as three phase systems that consist of melt, crystals, and a fluid phase. Cordell et al. (2022) used a similar approach to interpret deep conductors and to constrain magma reservoir conditions by integrating thermodynamic petrological models and resistivities within deep conductors.

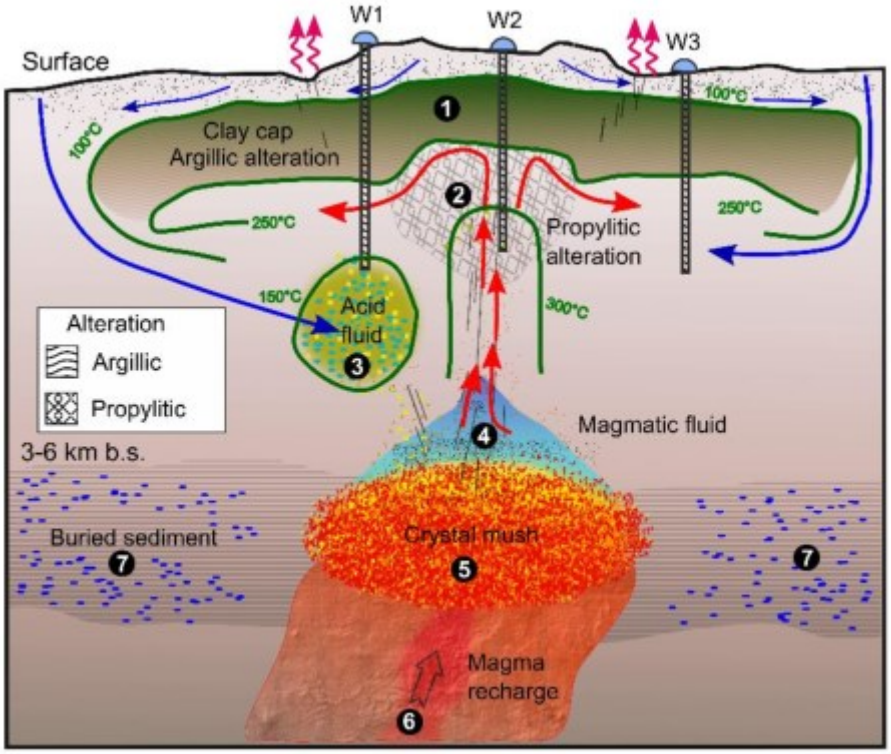

Figure 1: Surface to depth hypothetical model of a volcanic high-temperature geothermal system. The sketch shows the main features of a geothermal system and possible causes for conductive zones below the clay cap. 1) Clay cap: Argillic hydrothermal alteration zone with sealing function atop the reservoir. 2) Propylitic alteration zone below the clay cap, major target for drilling. 3) Acidic hydrothermal plume and formation of pyrite, both form through reaction of sulfur from magmatic degassing with fluids and host rock. 4) Liquid magmatic brine lens with high concentration of dissolved solids. 5) Magmatic reservoir with well interconnected partial melt fraction. 6) Magmatic recharge channel. 7) Buried sedimentary layer.

The upper crustal melt reservoir (feature 5 in Fig. 1) is fed from deeper parental melt sources. Recharge of melt might have ceased or is still ongoing if magmatic melt channels between the upper crustal melt reservoir and the deeper source region of the melt exist (feature 6 in Fig. 1). Active magmatic pathways will appear as deep routed conductors below the volcanic geothermal prospect. As an example, Dambly et al. (2023) presented a multiscale magnetotelluric model of a section in the Ethiopian Rift that shows melt generation and transport from the lower crust up to the near surface below the producing Aluto-Langano geothermal field. In cases where volcanic eruption happens through sedimentary layers, deep conductors can be related to fluid bearing sediments under volcanic cover having no volcanic origin (feature 7 in Fig. 1). This situation is encountered in Sumatra where Tertiary transgressive sediments are embedded between older Mesozoic volcanic units and younger Quaternary volcanic overburden (Barber et al., 2005; Mussofan et al., 2016). Despite not having a volcanic origin, deep sedimentary conductors might be falsely interpreted as magmatic heat source. However, if the geological context is known, sedimentary conductors under volcanic prospects might be target zones for drilling since they are often characterized by high permeabilities and provide good reservoir conditions (Ikhwan et al., 2023).

4. EXAMPLES OF DEEP CONDUCTORS IMAGED UNDER GEOTHERMAL PROSPECTS IN INDONESIA

In our long experience in the field of 3-D MT imaging of volcanic high-temperature geothermal systems, deep conductors appear under about half of volcanic geothermal prospects worldwide, whereas other geothermal fields show no indications for deep conductors (e.g. Soyer at al., 2018). In the following we present vertical sections of 3-D magnetotelluric models from volcanic geothermal fields in Indonesia, where deep conductors have been encountered. A detailed interpretation is beyond the task of this work; however, all three prospects have a long eruptive history and active geothermal surface manifestations. The conductor below Sibayak (Fig. 2) is clearly deep routed, which is indicative of an intrusive origin.

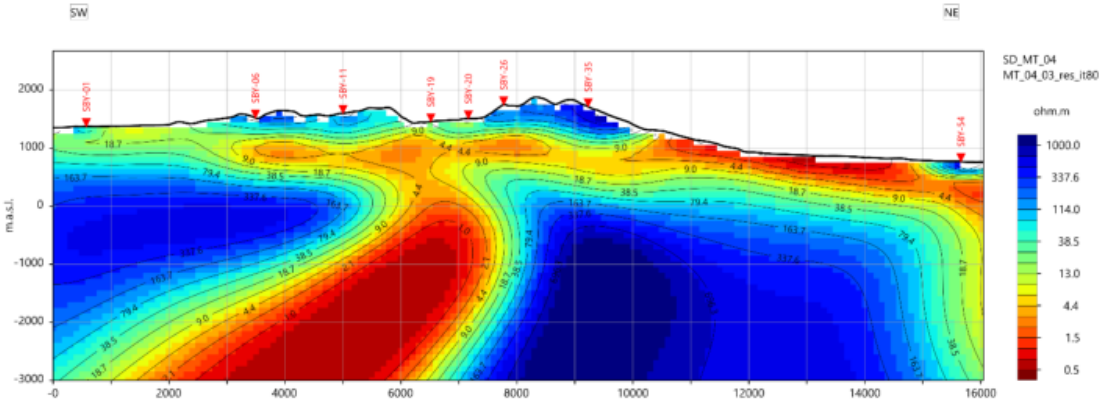

Figure 2: Deep conductor imaged below Sibayak, Indonesia.

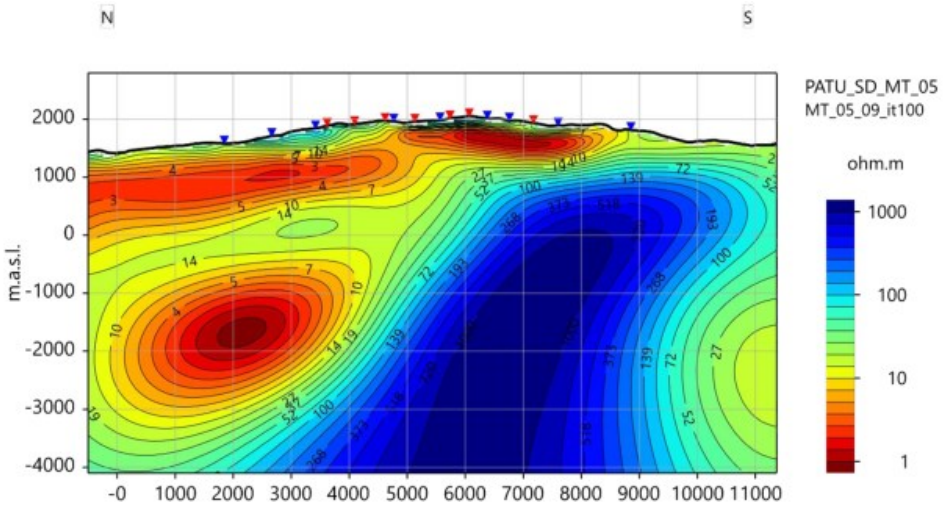

Figure 3: Deep conductor imaged below Patuha, Indonesia.

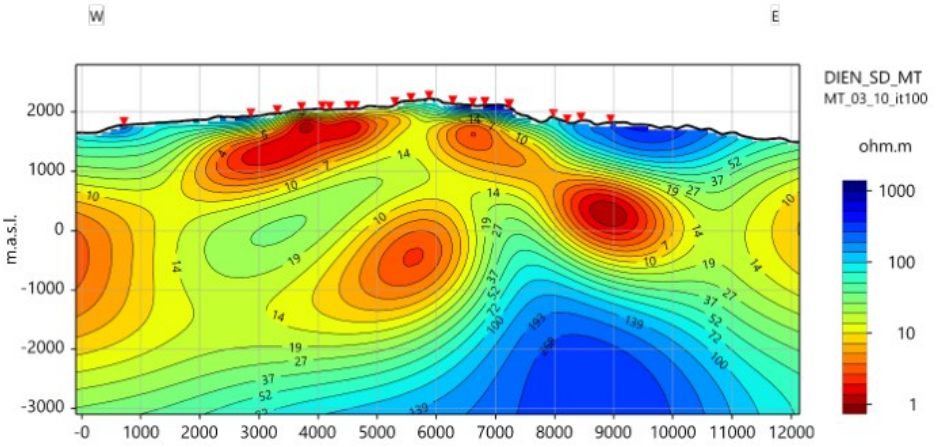

Figure 4: Deep conductor imaged below Dieng, Indonesia.

Geochemical analyses of fluids from Sibayak reveal a dominant magmatic volatile contribution and components of quenched magmatic gases (Fahmi et al., 2020). Sibayak belongs to the Singkut caldera from which Forni et al. (2024) report eruption of crystal-rich magmas and geochemical evidence for long-lived large cumulate crystal mushes.

Not enough data are available from Patuha (Fig. 3) and Dieng (Fig. 4) to provide a conclusive interpretation of the deep conductors. In view of the absence of deep roots and considering the isolated shapes of the deep conductors it could be argued that they represent fluid-rich zones, magmatic brine, or hydrothermal fluid plumes.

5. CONCLUSIONS

Deep conductors under volcanic high-temperature geothermal systems can have many origins that range from magma-related processes and favorable conditions like stable crystal mush reservoirs that represent powerful heat sources to unfavorable conditions like acidic hydrothermal plumes that cause corrosion of geothermal wells and facilities. Even amagmatic causes are possible in cases where volcanic eruption happens through sediments. The described causes for deep conductors provide only a selection, and thus, an incomplete overview. Interpretation of deep conductors requires detailed knowledge of the geological context and eruptive history of the volcanic geothermal prospect. More work is required in the field of melt electrical conductivity models to provide more complete models for composition-dependent melt resistivities. More research is also required to understand bulk resistivities of reactive multiphase magmatic systems that consist of melt, solid, and fluids in different states from liquid to vapor and supercritical. In reactive systems traditional multi-phase mixing laws to derive bulk resistivities do not apply. Finally, yet importantly, the quality of MT data used to derive 3D resistivity models must be critically evaluated and the robustness of deep conductor must be tested. Deep conductors might be artifacts with no geological explanation caused by poor data quality and systematic data bias.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to PT Geo Dipa Energi and Pertamina Geothermal Energy for the permission to publish the results from the 3D inversion modeling of MT data from Patuha and Dieng (PT Geo Dipa Energi) and Sibayak (Pertamina Geothermal Energy). FS thanks colleagues ETH Zurich for their contributions on the topic.

ABSTRACT

Long Offset Resistivity Tomography has been implemented for the first time in The Darajat Geothermal Field with the objective to image static and dynamic condition of subsurface resistivity structure. The method enables penetration depth of several hundreds to thousands of meters below the surface resulting in strong subsurface resistivity contrast image associated with deep injection fluid distribution. A prominent resistivity anomaly within the reservoir around the main injection well of the field indicates that condensate injection distributed in the deep part of the reservoir. The method also improves the conceptual understanding related to the subsurface extension of a major fault that plays an important role as one of the key geological features of the field, the Kendang Fault.

The subsurface resistivity structure of the field is characterized by a low resistivity from surface to the base of clay cap rock, which represents presence of dominantly smectite alteration mineral. Meanwhile, the underlying reservoir shows a relatively high resistivity signature in comparison to the cap rock. A strong signature of low, instead of high, resistivity in the reservoir near the main injection wells, DRJ-15, is suggesting a deep distribution of condensate injection below the bottom depth of the well. The signature confirms the impacted area of the condensate injection that was previously interpreted from a continuous monitoring of microearthquake (MEQ) that tracks vertically the fluid movement that induced pre-existing fracture at the central area of the field.

The resistivity image suggests that the Kendang Fault has 70° dip angle near the surface. The fault extends into reservoir depth as indicated by information from wells that penetrated the fault. Further evaluation provides information on how the subsurface extension of the fault acts as a fracture driver in the northern section of the reservoir where the sweet spots for production well targeting is located. The interpretation of the resistivity contrast also shows that the alteration tends to be intensive in the east side of the fault where the reservoir is located compared to a relatively fresh rock in the west side of the fault that might also signal the role of the fault as a reservoir boundary of the field.

1. INTRODUCTION

Darajat Geothermal Field is the largest vapor-dominated geothermal system in Indonesia located in West Java, Indonesia, about 230 km southeast of Jakarta (Figure 1). The field has been generating electricity for almost three decades with current operating capacity of 271 MWe from three power plant units. Commercial production began in 1994 with the commissioning of 55 MWe Unit I. The 95 MWe Unit II came online in 2000, followed by Unit III operations in 2007, which after a successful drilling campaign in 2007-2008 had been uprated to final capacity of 121 MWe. The Darajat geothermal system is a high-temperature reservoir with benign chemistry and low non-condensable gas content (<2 wt.%). The system is believed to be associated with the Kendang volcanic complex which is dominantly composed of propylitically-altered andesite lava flows intruded by microdiorite dikes (Rejeki et al. 2010). The dominant geologic structures at Darajat trend NE-SW and NW-SE with minor N-S faults.

Long Offset Resistivity Tomography has been implemented to produce subsurface resistivity model using the assumption that the subsurface rocks possess variation of resistivity values so that geological boundaries or changes in the subsurface rock condition can be identified based on the resistivity signature. If a targeted feature has an electrical resistivity contrast compared to the surrounding rocks, it can be detected by injecting a current and measuring the surface tension through a potential electrode on the surface (Figure 2). The two main objectives of the measurement are to monitor the fluid movement from the injection at DRJ-15 towards nearby production wells and to characterize the Kendang Fault as one of key geological features that often relates to permeable fracture within reservoir. Two measurement lines were designed to achieve these objectives, Line-1 and Line-2 (Figure 3). Line-1 is designed to cross the DRJ-15 from the southeast side and continue extending to the north

side with a total of 3.35 km survey line. This line was intended to image the area near DRJ-15 well TD where the condensate injection is most likely distributed. Meanwhile, Line-2 was intended to image the resistivity contrast due to the presence of the Kendang Fault by conducting a measurement on a 1.6 km of survey line on top of the northern section of the fault.

2. CHARACTERIZATION OF INJECTION FLUID DISTRIBUTION IN RESERVOIR

Injection strategy at Darajat has been focused mainly in the central and peripheral area in the northern part of the field. From 2006 to 2011, three wells in the central area were utilized as injection wells. DRJ-15 has been the main injector with an average injection rate of 120 lps (Figure 4A), alongside with DRJ-3 and DRJ-12 that were occasionally utilized as injectors for a short period of time (Figure 5). The DRJ-15 injection provides the pressure support needed by the reservoir, while at the same time the thermal fronts in the vicinity of the well has impacted the stress condition in the reservoir along the fractures. The effect was reflected in the occurrence of MEQ clusters with microseismic activity rate of around 27 events/month, covering an area with 1.5 km radius near DRJ-15.

Figure 5 shows that MEQs were located within a defined volume in the reservoir, but were mostly distributed below the well-TD (i.e. from msl to 2,000 m-bsl). The deep distribution of the MEQs indicates that the injection-induced fracture stimulation is following a vertical trend along the extension of the fracture network below the well-TD.

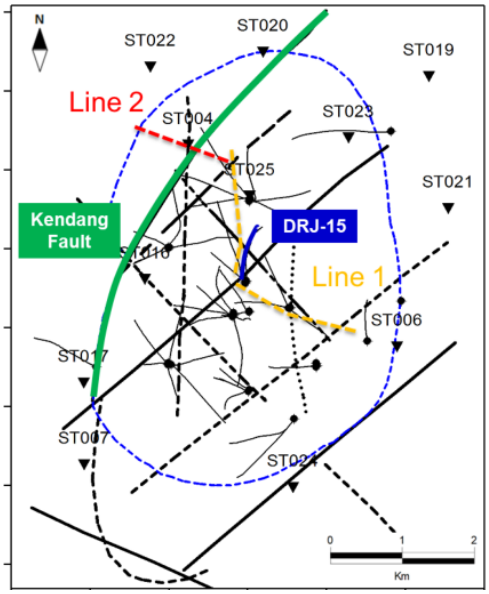

Figure 3: Map of the Darajat Geothermal Field showing reservoir boundary, structure, and drilled wells. Main injection wells, DRJ-15, is in central area (blue highlighted well). Surface expression of Kendang Fault is oriented NE-SW (green highlighted line). Long-offset Resistivity Tomography measurement line represent by Line-1 (yellow dashed line) and Line-2 (red dashed line). The black triangle surrounding the field represent the location of MEQ monitoring station.

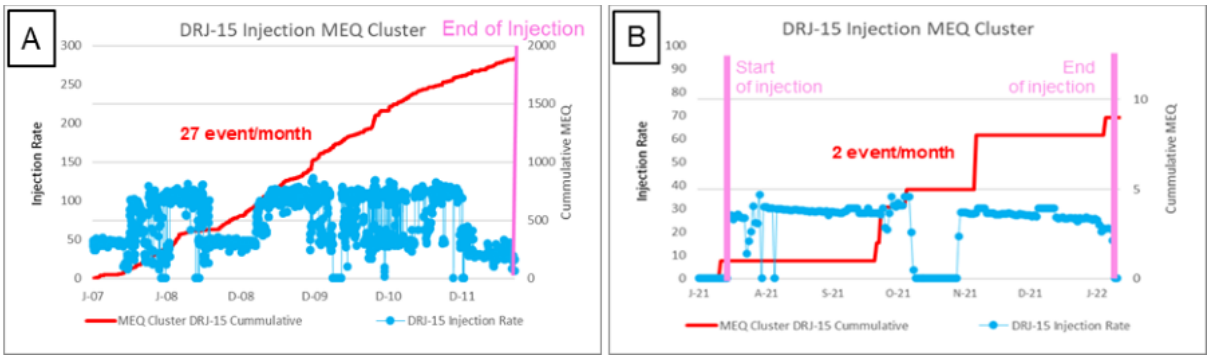

Figure 4: Chart showing the correlation between MEQ activity and injection rates at DRJ-15 in central area during period 2006 to 2011 (A), and 2021 to 2022 (B).

Since late 2011, seismic activity rates near DRJ-15 region had decreased as condensate injection was gradually moved to DRJ-19 in the peripheral area in the northern part of the field to avoid potential injection breakthrough toward the surrounding production wells in the central area. In 2021, DRJ-15 has been re-utilized as an injection well with the objective of providing pressure support to the central production area of the reservoir with a lower injection rate of 30 lps (Figure 4B) to minimize any adverse effect to the nearby production wells. The injection strategy was pursed by considering that the central production area has experienced a larger pressure drop and net-mass drainage from the long-term production activity in the field (Nelson et. al, 2023). Similar to the previous period of DRJ-15 injection, the MEQs tend to occur in the central area and are distributed in the deeper part of reservoir (Figure 5). However, the lower injection rate only results in 2 events/month, thus lowering the confidence level of delineating the area affected by the injection.

To ensure the effectiveness of the lower-rate-injection strategy, it is important to identify a more defined area of where injection fluid might move and re-saturate the reservoir fracture. The resistivity tomography enables to capture the resistivity response as deep as the TD of DRJ-15 with high resolution (Figure 6). the resistivity near the surface shown by a combination of high and low resistivity represents noisy response above the clay cap.

Below this depth, a signature of low resistivity structure represents the clay cap area which is rich with smectite alteration mineral. High smectite content lowers the resistivity, thus the clay cap structure could be delineated. In the central area of Darajat, the low resistivity clay cap structure seems to be disconnected below the DRJ-15 well pad. The observation is consistent with the result of the resistivity image from Magneto-Telluric (MT) survey where the <10 ohm. Meter clay cap structure is showing a lateral disconnection (Figure 7).

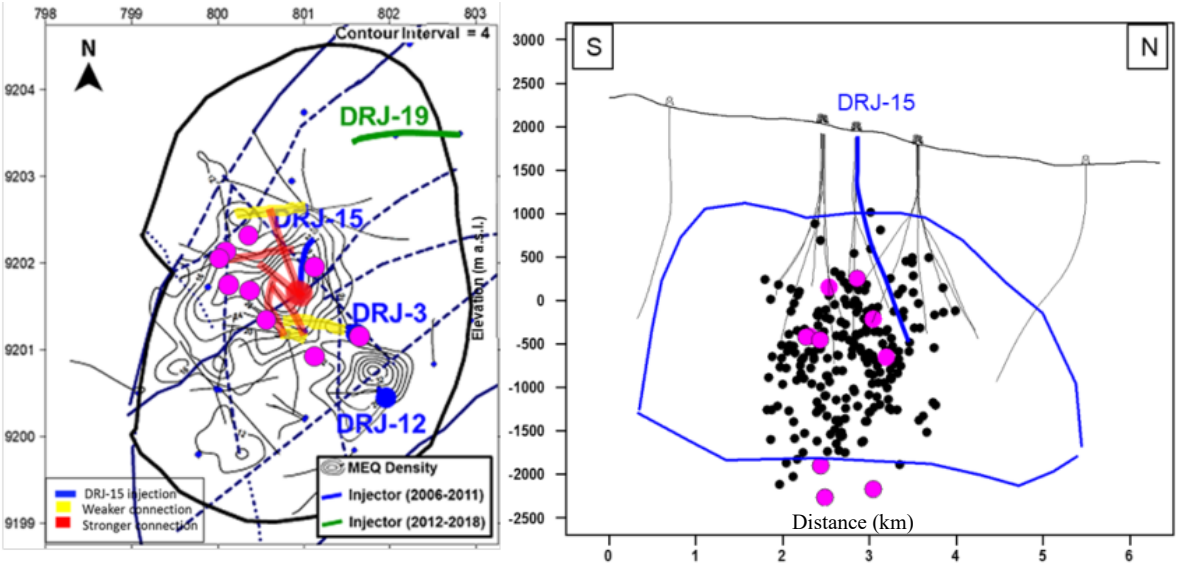

Figure 5: Map showing MEQ event density contour (black) during 120 lps injection vs MEQ event (purple) during 30 lps of injection at DRJ-15. Red and yellow colored well represent nearby well that have strong and weak connection with injection at DRJ-15 (left). Cross-section showing MEQ event (black) during 120 lps injection vs MEQ event (purple) during 30 lps of injection at DRJ-15 (right).

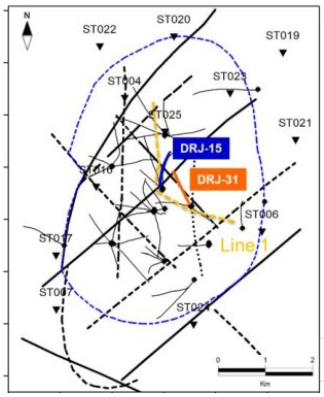

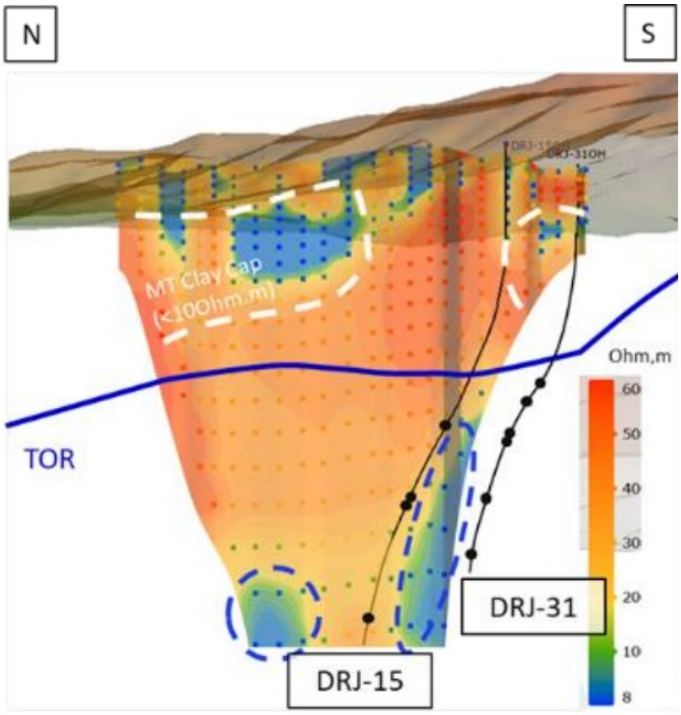

Figure 6:
Maps showing location of measurement Line-1 relative to DRJ-15 injector and DRJ-31 producer well (left). Cross-section showing the resistivity tomography image relative to DRJ-15 and DRJ-31; TOR represents Top of Reservoir, black dots represent permeable entry of the wells, white and blue circled areas highlight clay cap rock and deep low resistivity signature, respectively (right).

Further supporting this observation, a methylene-blue (MeB) analysis result from well cuttings of drilled wells in Darajat confirms this observation as the cuttings in the shallow part of DRJ-15 has lower result of measurement

(< 5 ml/gr) associated with a low composition of smectite alteration minerals (Figure 7). Instead of having a high composition of smectite, this zone shows a strong silicification in tuff and pyroclastic breccia. Below smectite-rich clap cap, the reservoir zone is characterized by the high resistivity signature as seen from MT resistivity image. Consistency is also observed in the resistivity tomography image as the high resistivity structure represents the reservoir zone below the clay cap.

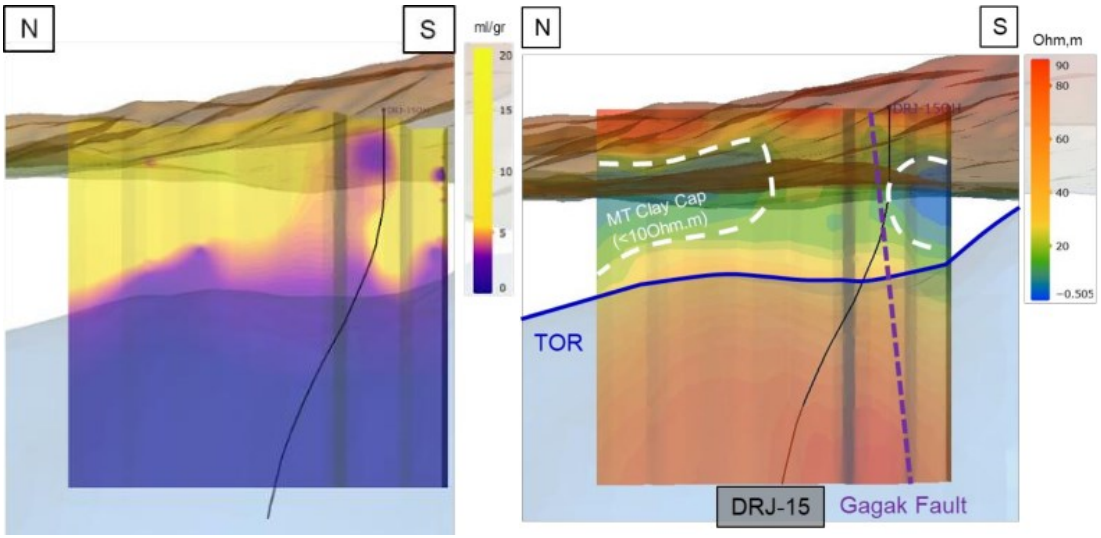

Figure 7: Cross-section showing the MT resistivity image relative to DRJ-15; TOR represents Top of Reservoir, white circled area and purple line highlights the clay cap rock and Gagak Fault, respectively (right). Cross section showing the MeB measurement corresponding with MT cross-section.

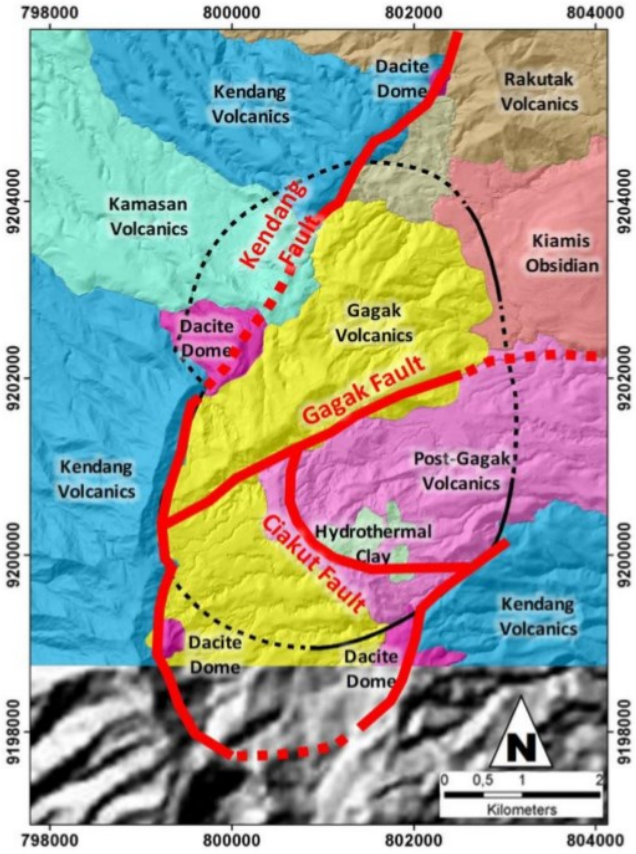

Figure 8: Geological map of Darajat Field showing the interpreted structure based on LiDAR data and offset reservoir rocks; dashed line represents inferred structure section. The Kendang Fault is one of prominent fault observed on surface beside Gagak and Ciakut Fault.

An anomaly is observed in the deep area of the resistivity tomography image. A low resistivity signature occurred near the DRJ-15 well TD where MT resistivity show a relatively uniform signature of high resistivity in the reservoir zone below the clay cap. The difference in the result at this depth is caused by the different characteristic of the measurement point between the two methods. Resistivity tomography provides a better imaging with a high level of detail as a result of more reliable measurement points near DRJ-15 well TD compared to the MT method. The deep low resistivity near DRJ-15 well TD is interpreted to be a response of the liquid phase presence that lower the resistivity response in the zone where the resistivity is expected to be high. Deep low resistivity patch in the north side might indicates a distribution of condensate injected at DRJ-15. It possibly moves deep, as suggested by the MEQ monitoring evaluation, and re-saturates the reservoir fracture toward the north direction. This indicates a good sign since the condensate injection tends to move vertically to the deep part instead of moving directly towards the nearby production wells which could cause an adverse effect for production. Meanwhile in the southern side, elongated low resistivity could be more related to the presence of marginal recharge (MR) that encountered at DRJ-31 production wells. Liquid has been produced from the deep permeable entry of this steam producing well. The distribution of low resistivity that stretched along the depth of DRJ-31 deep permeable entry could help to explain on where MR source could be possibly located.

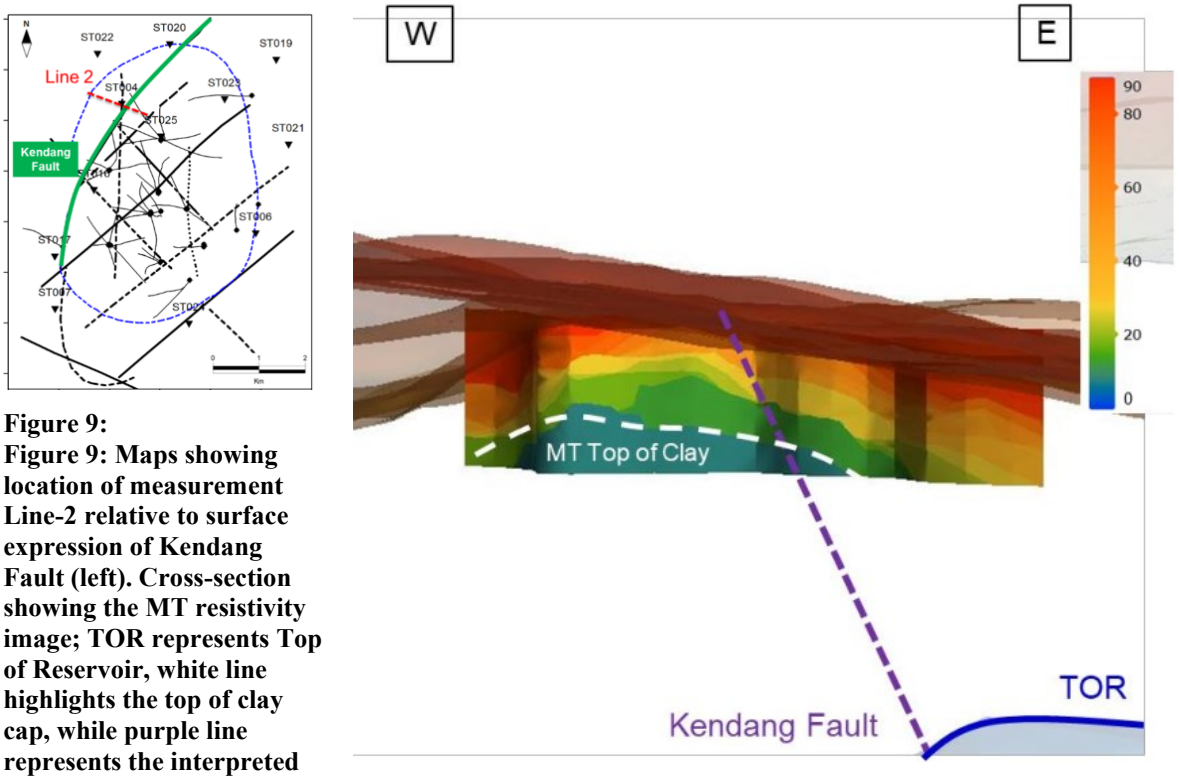

Figure 9:

Cross-section showing the MT resistivity image; TOR represents Top of Reservoir, white line highlights the top of clay cap, while purple line represents the interpreted Kendang Fault extension in subsurface with 70° dip-angle (right).

3. FAULT CHARACTERIZATION

The Kendang Fault is one of the prominent faults observed on the surface besides the Gagak and Ciakut Faults based on the analysis of LiDAR data, drainage patterns, and relative location of eruption centers (Figure 8). The fault is stretched along the western boundary of the Darajat Field with a NE-SW orientation. The surface expression of the fault is prominent in the southern side of the Darajat Field and is inferred in the northern side. Further toward the northeast side, the Kendang Fault extends to the Kamojang Field which may be an indication that it is a section of the ring structure of an earlier volcano (Intani et. al, 2021). Previous evaluation suggests that the Kendang Fault is vertically extending into the reservoir depth as indicated by information from wells that have penetrated the fault. Series of permeable entry zones encountered in penetrating wells indicate a clustering permeable fracture along an interpreted high-angle extension of the fault in the reservoir zone. In the northern side of the field the series of permeable entry zones along the fault are identified as an area where high permeability is distributed.

To better characterize this permeable fracture zone, it is essential to delineate the signature of the Kendang Fault extension in the subsurface. Resistivity tomography enables to capture a resistivity contrast below the surface

expression of the fault in the northern side showing its subsurface signature. The presence of resistivity contrast at Line-2 shows a distinctive separation between high resistivity rocks in the west part and low resistivity in the east side. This result is consistently observed on the implementation of two different measurement configuration: Wenner-Alpha and Wenner-Schlumberger configuration. Both Wenner-Alpha and Wenner-Schlumberger configurations suggest more variation in near surface resistivity, in contract with homogenous layered resistivity model of MT method. The MT resistivity shows a relatively no significant lateral variation, while tomography resistivity shows prominent lateral resistivity contrast (Figure 9).

Resistivity tomography image shows that contact between high and low resistivity coincides with expression of Kendang Fault on the surface. By delineating the contact between resistivity contrast from surface to deeper part, a signature of Kendang Fault with 70° of dip angle could be inferred (Figure 10). This evidence supports the current concept of the high angle Kendang Fault extension in the subsurface. Moreover, the consistent dip angle suggested by resistivity contrast from two configurations of measurement, suggests a better understanding on locating the cluster area of permeable fracture along the Kendang Fault section inside reservoir. Interpretation of resistivity contrast could also suggest that alteration tends to be intensive in the east side of the fault where reservoir is located compared with relatively fresh rock in the west side of the fault. This observation might also signal the role of the fault as a reservoir boundary of the field.

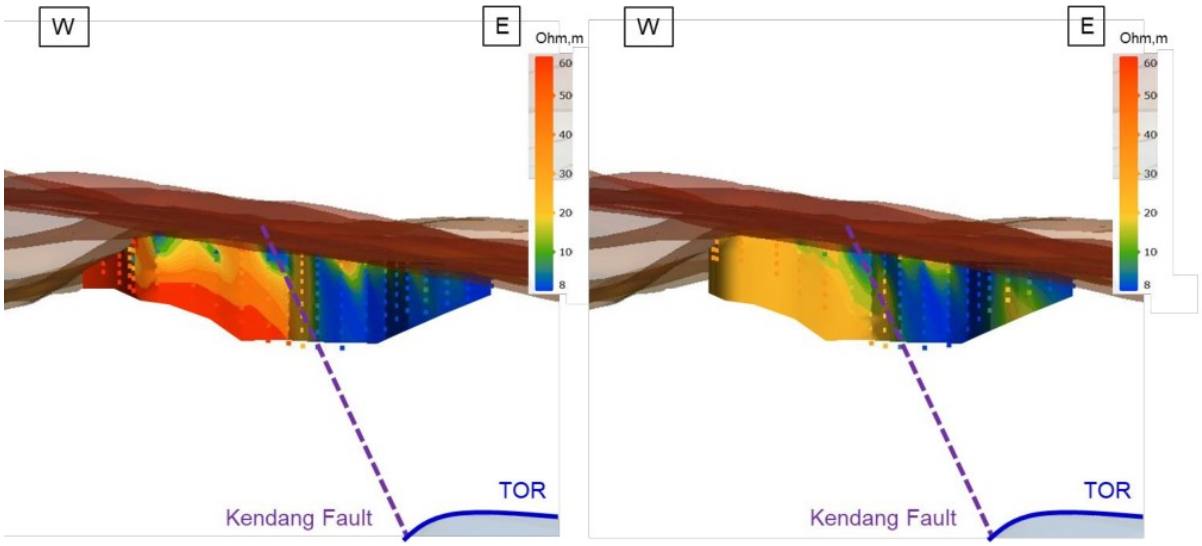

Figure 10: Cross-section showing the resistivity tomography image using Wenner-Alpha (left) and Wenner-Schlumberger (right) configuration. TOR represents Top of Reservoir; purple line highlights the interpreted Kendang Fault extension in subsurface with 70° dip-angle.

4. CONCLUSION

A newly implemented long offset resistivity tomography at the Darajat Filed has provided significant improvements on the learning from the injection monitoring at DRJ-15 and better characterization of the Kendang Fault. The resistivity image produced helps to better understand how the injection at DRJ-15 is distributed in the deeper part and impacting the nearby production wells. This understanding is helpful for the decision-making process of the Darajat Asset Management team for managing the future injection strategy. A time-lapse measurement is encouraged to monitor the evolution of impacted area for long-term injection management strategy. The evaluation of the Kendang Fault signature has also helped in refining the subsurface fault geometry by confirming the high dip angle. This has improved the understanding on the possible highly permeable fractured area along the Kendang Fault inside the reservoir that will be useful for well targeting and the development of the field in the future.

ACKNOWLEDGEMENTS

The authors would like to thank the management of Star Energy Geothermal for allowing publication of this paper. Many thanks to SEGD colleagues, ITB and ELNUSA counterparts who contributed to the development of the charts and figures in this paper, and the hours spent reviewing and improving its contents.

ABSTRACT

Faults are one of the primary targets in geothermal fields due to the role of the permeability zone in the reservoir. The data representing fault indications on the surface and in the subsurface have the potential to be interrelated. Surface data, such as lidar and surface mapping, can be combined with subsurface well data, such as borehole images and fluid movement, to confirm that a fault has existed.

The drilling campaign has begun in the Sileri area of the Dieng Geothermal Field, with some wells already drilled. Aerated drilling has become a common practice in reservoir sections to ensure that rock cutting reaches the surface or is pushed as far into the formation as possible. The air from the atmosphere enters the wellbore during drilling and may have an impact on the gas chemistry content of the existing well due to the similar permeability pathway from the fault. Evaluation of fluid flow movement during drilling is indicated by an increase in residual gas content as a result of drilling fluid injection into the reservoir. The results of gas monitoring in existing wells will deliver evidence of fault existence, which has previously been interpreted from lidar, geomorphology studies, surface mapping, and, in particular, data borehole images that provide information about fracture orientation, aperture, and fracture type in the well's wall. The primary objective can be obtained by conducting well monitoring and fracture analysis. Gas chemical analysis of CO_2 content, residual gas, NCG, and H_2S was monitored over time from pre-drilling to post-TD. Following that, geochemistry data was evaluated with a fault existence to determine the possibility of a permeable pathway from the fault.

1. INTRODUCTION

Understanding the intricate geological structures beneath geothermal fields is crucial for optimizing resource extraction and ensuring the stability of drilling operations. In this study, we focus on constructing fault systems from borehole images and monitoring the movement of drilling fluids to elucidate well connectivity within the geothermal reservoir of Dieng, Indonesia.

The research framework begins with an overview of the Dieng structure, highlighting its geological significance and the role of surface mapping and Lidar interpretation in preliminary fault identification. Dieng is known for its complex volcanic history, resulting in a dense network of faults and fractures that significantly influence geothermal fluid flow. Surface mapping and Lidar data provide an initial model of these structures, setting the stage for deeper analysis through borehole imaging.

The subsequent steps involve detailed geological structure analysis using borehole images, which offer high-resolution visualizations of the subsurface environment. By examining these images, we can identify fault planes, fracture networks, and other critical features that validate and refine the surface-based structural model. Additionally, monitoring drilling fluid movement between wells helps confirm connectivity within the reservoir. This fluid movement analysis not only supports the existence of the identified faults but also provides insights into their permeability and impact on fluid dynamics. Together, these methods form a comprehensive approach to verifying the geological structures of the Dieng geothermal field, thereby enhancing our understanding and management of this valuable resource.

2. DIENG STRUCTURE OVERVIEW

Java Island is located along the active convergent boundary where the Indo-Australian plate subducts beneath the Eurasian plate. This subduction process has resulted in intense volcanic activity, frequent seismic events, and the formation of various geological structures. The interplay of these tectonic plates has created a dynamic environment, influencing the development of faults, folds, and other structural features. Java's structural

framework is dominated by several major fault systems, including the Java Trench, the Kendeng Zone, and the Meratus Complex.

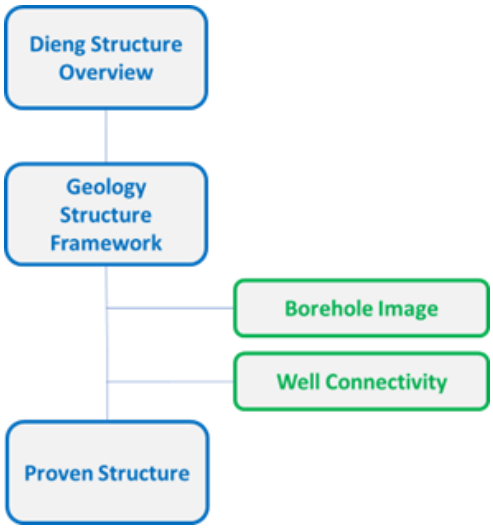

Figure 1: The research framework of this study.

The Dieng Geothermal Field is situated within the complex tectonic setting of the Sunda Arc, a geologically active region characterized by subduction along the convergent boundary between the Australian Plate and the Eurasian Plate. This tectonic interaction has led to the formation of numerous volcanic arcs throughout Indonesia, including the Dieng Plateau, where the geothermal field is located. The area is part of the larger volcanic complex known as the Dieng Volcanic Complex, which is composed of a series of stratovolcanoes and calderas.

The geology of the Dieng Geothermal Field is shaped by this tectonic setting, with volcanic activity playing a significant role in the formation of its geothermal resources. The presence of magma chambers beneath the surface provides a continuous heat source, heating groundwater and creating the conditions necessary for the formation of geothermal reservoirs. Additionally, the tectonic processes associated with subduction contribute to the fracturing and faulting of the crust, creating pathways for the circulation of fluids and enhancing the permeability of the reservoir rocks. This complex interplay of tectonic forces has endowed the Dieng Geothermal Field with its unique geological characteristics, making it a prime location for the extraction of renewable energy resources.

The structural framework of the Dieng Geothermal Field, viewed from a geological perspective, is deeply influenced by the tectonic processes associated with the subduction zone located to the south of Java Island. Subduction occurs when one tectonic plate is forced beneath another, leading to intense geological activity including volcanic eruptions and the formation of structural features such as faults and fractures. In the case of Dieng, this subduction zone plays a pivotal role in shaping the structural landscape of the region.

One prominent structural orientation within the Dieng Geothermal Field is characterized by a north-south alignment of open faults. These faults, resulting from the tectonic stresses associated with the subduction zone, create pathways for the movement of fluids within the Earth's crust. The presence of these faults facilitates the circulation of geothermal fluids, which is crucial for the development of a viable geothermal reservoir.

Another significant structural orientation in the area is aligned along a west-east axis, correlating with the broader subduction process occurring to the south of Java. This structural alignment is indicative of the broader tectonic forces at play, which exert considerable influence on the distribution of geological features and the overall structural framework of the Dieng region. Additionally, the circular structure observed in the Dieng area corresponds to the volcanic activity that has shaped the landscape over time. This circular structure is a manifestation of the volcanic calderas and related volcanic features that characterize the Dieng Volcanic Complex, highlighting the intricate relationship between volcanism and the structural framework of the geothermal field. Overall, the structural framework of the Dieng Geothermal Field reflects the complex interplay of tectonic processes, including subduction-related deformation, faulting, and volcanic activity, which collectively shape the geological characteristics of the region and influence its geothermal potential.

Furthermore, detailed mapping data has identified shear fractures with Northeast-Southwest and Northwest-Southeast trends, indicative of complex shear deformation within the field. These shear fractures, along with the extensional fractures exhibiting North-South and West-East trends, underscore the multi-directional stress regime prevalent in the region.

3. BOREHOLE IMAGE

The analysis of borehole image data from wells 31X, 7Y, and 29X in the Dieng geothermal field provides significant insights into the subsurface fracture systems and supports the existence of faults in the area. Borehole imaging is a crucial technique for visualizing and characterizing fractures and faults, which play a vital role in geothermal fluid movement and reservoir productivity. Borehole images from the three wells reveal various types of fractures, including both open and sealed fractures, as well as a range of fracture orientations. The majority aligns with North-South trends, while some exhibit new and potentially significant orientations.

The borehole image data from these wells not only confirms the existence of previously mapped faults but also reveals new fracture orientations that could indicate additional structural complexity in the Dieng geothermal field. The NW-SE oriented fractures align well with the established fault framework, validating the interpretations made from surface mapping and Lidar data. The identification of N-S oriented fractures, however, introduces new considerations for the geological model of Dieng.

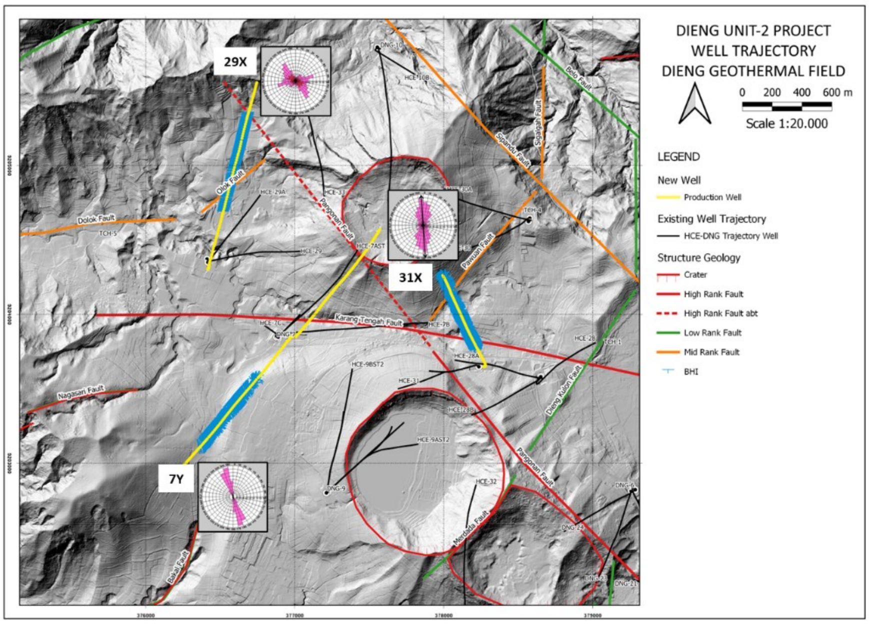

Figure 4: Borehole Image Distribution.

The discovery of N-S oriented fractures in wells 7Y and 31X are particularly intriguing. These fractures may represent a newer set of tectonic activities or localized stress fields. Their presence suggests the possibility of additional permeability pathways, which could influence fluid flow and reservoir dynamics in unexpected ways. This finding warrants further investigation to understand their origin, extent, and impact on the geothermal system.

3.1 Feed Zone-Fracture Orientation

The correlation between feed zones and fracture orientation is a critical aspect of permeability analysis, as it directly impacts the understanding of fluid flow and reservoir connectivity. In the Dieng geothermal field, borehole image data from wells 31X, 7Y, and 29X reveal distinct fracture orientations that correlate with identified feed zones. This section explores the relationship between these orientations and the respective feed zones in each well.

In well 31X, borehole image data predominantly show fractures oriented in a North-South (N-S) direction and E-W orientation (minor). These N-S fractures are closely related to the primary feed zones identified in the well. The alignment of feed zones with N-S fractures suggests that these fractures serve as significant pathways for geothermal fluids. The consistent orientation indicates a dominant stress regime influencing fracture development, facilitating effective fluid flow from the reservoir into the well.

Well 7Y exhibits a more complex fracture orientation pattern, with borehole images revealing both North-South (N-S) and Northwest-Southeast (NW-SE) fractures. These orientations are associated with the distribution of feed zones in the well. The presence of multiple fracture orientations suggests a more intricate stress regime and structural setting, which provides diverse pathways for fluid migration. The correlation between these fracture orientations and feed zones indicates that both N-S and NW-SE fractures contribute significantly to fluid flow into the well.

Lastly, well 29X presents the most varied fracture orientation among the three wells, with fractures-oriented NW-SE, East-West (E-W), and Northeast-Southwest (NE-SW). Borehole image data indicate that these varied orientations correlate with the distribution of feed zones in the well. The diversity in fracture orientations suggests a highly heterogeneous stress environment, which allows for multiple fluid pathways. Each orientation provides a different conduit for fluid flow, enhancing the overall connectivity and fluid recharge within the well.

3.2 New Fault Potential

Recent analysis of the Dieng geothermal field, combining Lidar data, surface lineament mapping, and borehole image interpretations, has suggested the presence of a previously unidentified North-South oriented fault. This section outlines the evidence supporting this new fault hypothesis and its potential implications for the geothermal system. Lidar surveys and surface mapping have revealed a prominent North-South regional lineament in the Dieng area. This lineament extends across the geothermal field and intersects with 29X and 7Y well, indicating significant subsurface structural features. The lineament's orientation and continuity suggest it is a major structural element, potentially representing a fault zone.

Borehole image data from wells 29X and 7Y provide critical subsurface validation for the North-South lineament identified in surface studies. In well 29X, borehole images show significant North-South oriented fractures correlating with feed zones, indicating active fluid flow along these fractures and directly intersecting the identified lineament. Similarly, well 7Y also displays North-South to North northwest-South southeast oriented fractures, reinforcing the continuity of this structural trend.

The correlation between feed zones and North-South fracture orientations further supports the hypothesis of a North-South fault. In both wells 29X and 7Y, the feed zones coincide with North-South fractures, indicating these orientations are crucial for fluid migration within the reservoir. The consistent presence of permeable, North-South oriented fractures in the feed zones suggests that this structural trend is a significant conduit for geothermal fluids.

4. WELL CONNECTIVITY

In the Dieng geothermal field, the connectivity between a new well and existing wells is assessed through the monitoring of gas chemistry during drilling operations. Key gases monitored include CO_2, residual gas, non-condensable gases (NCG), and H_2S. The data indicate that CO_2, residual gas, and NCG are particularly sensitive indicators of drilling fluid influence on the reservoir. This section explains the correlation between the chemistry of these gases and the interaction between drilling fluids and reservoir fluids in a two-phase liquid-dominated geothermal system. CO_2 is a major component of geothermal fluids, often present due to the degassing of magmatic sources and dissolution in reservoir fluids. The introduction of drilling fluids can alter and lead to the decreasing of CO_2 due to mixing process between hydrothermal fluid and drilling fluid. The drilling fluid, particularly during aerated drilling can add air gas, i.e., N_2 and Ar, to the reservoir, therefore there will be an increasing of N_2 and Ar gas, and decreasing of CO_2/N_2 ratio. The total NCG can increase or decrease depends on the drilling fluid mixing proportion.

The interaction between drilling fluids and reservoir fluids can cause shifts in the chemical equilibrium, leading to the release of residual gases. Monitoring these gases helps in understanding the extent of fluid mixing and the resulting chemical reactions. The mixing of drilling fluids with reservoir fluids can increase the partial pressures of NCG, leading to their liberation from the liquid phase. This provides a clear indication of well connectivity and the influence of drilling operations.

In the Dieng geothermal field, which is characterized by a two-phase liquid-dominated system, several chemical reactions can occur when drilling fluids mix with reservoir fluids. The primary reactions of interest involve the dilution of CO_2 and other gases. This reaction is particularly pronounced in areas with high permeability, where fluid mixing is more extensive. The decreased %weight of CO_2 detected in monitoring wells indicates significant interaction between drilling and reservoir fluids, confirming well connectivity. Meanwhile, the influx of drilling fluid into a geothermal reservoir can indeed destabilize the gas chemistry in existing wells due to pressure and temperature changes, chemical reactions, and fluid mixing.

4.1 29X Monitoring

Well 29X and 29 intersected the new fault from the previous interpretation. Drilling activity in well 29X has been observed to correlate with instability in the gas chemistry of nearby existing well 29, particularly regarding non-condensable gases (NCGs) and CO_2 concentrations. Monitoring data from existing well 29 before, during, and after the drilling of well 29X revealed significant variations in the concentrations of NCGs and CO_2. Up-down levels of NCGs were recorded in well 29, indicating a disturbance in the gas equilibrium. The decreasing of CO_2 and NCG during drilling of Well 29X is recorded, indicating there is some connection between Well 29X and 29. After drilling, the gas concentration of the Well 29 back to the normal condition.

4.2 7Y Monitoring

Drilling activities in well 7Y have provided crucial insights into the subsurface geology of the Dieng geothermal field, particularly the presence of a new fault. Monitoring well 7C has shown significant changes in gas chemistry, indicating a correlation with the drilling operations in well 7Y. This section explores the evidence supporting the existence of a new fault based on gas chemistry data from the monitoring wells. Monitoring well 7C has shown a decreasing trend in the concentrations of CO_2 and non-condensable gases (NCGs) during the drilling of well 7Y. However, the monitoring well 29 didn't show the similar pattern. This can be caused by the monitoring of the well 29 is not as frequent as 7C, therefore the gas concentration pattern can't be recognized comprehensively. The decrease in CO_2 and NCG in monitoring well 7C suggests the presence of a new fault intersecting Well 7Y and 7C. The drilling of well 7Y likely intersected a previously unidentified fault. This fault provides a pathway for gases to migrate from deeper reservoir zones to the monitoring wells.

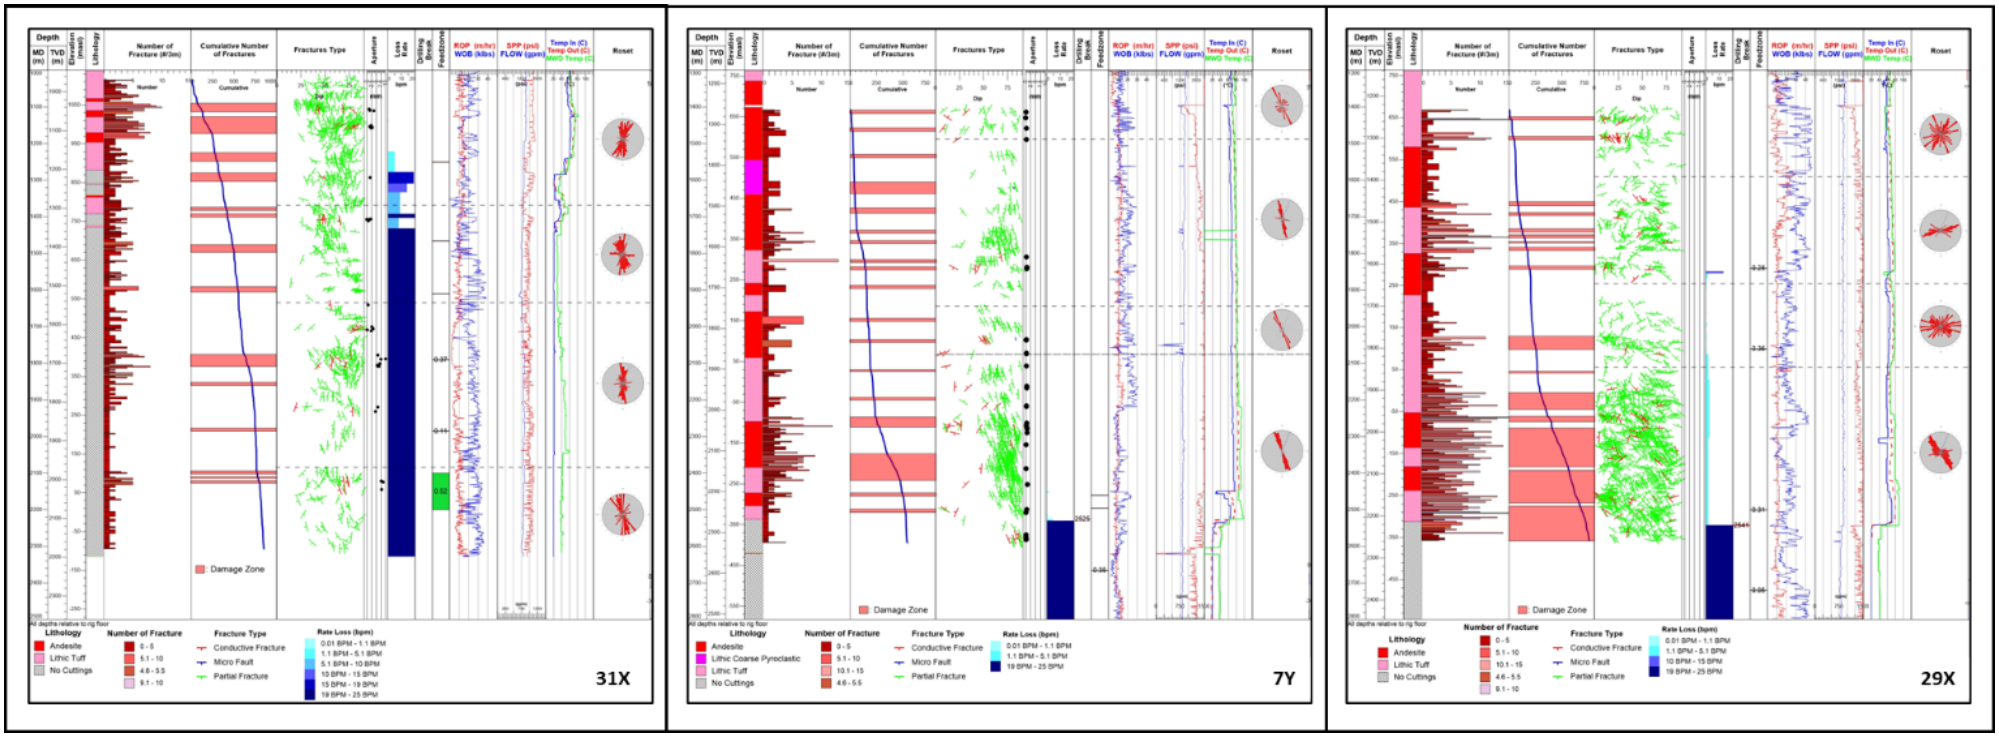

Figure 5: Feed zone fracture orientation.

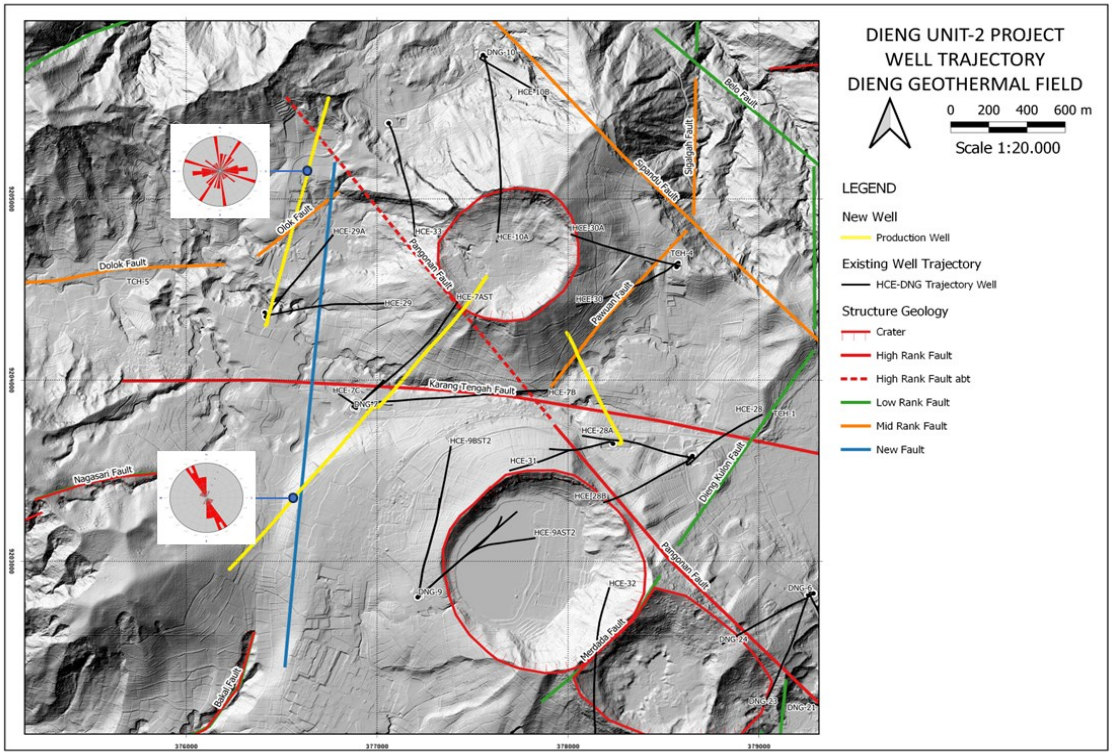

Figure 6: New fault potential.

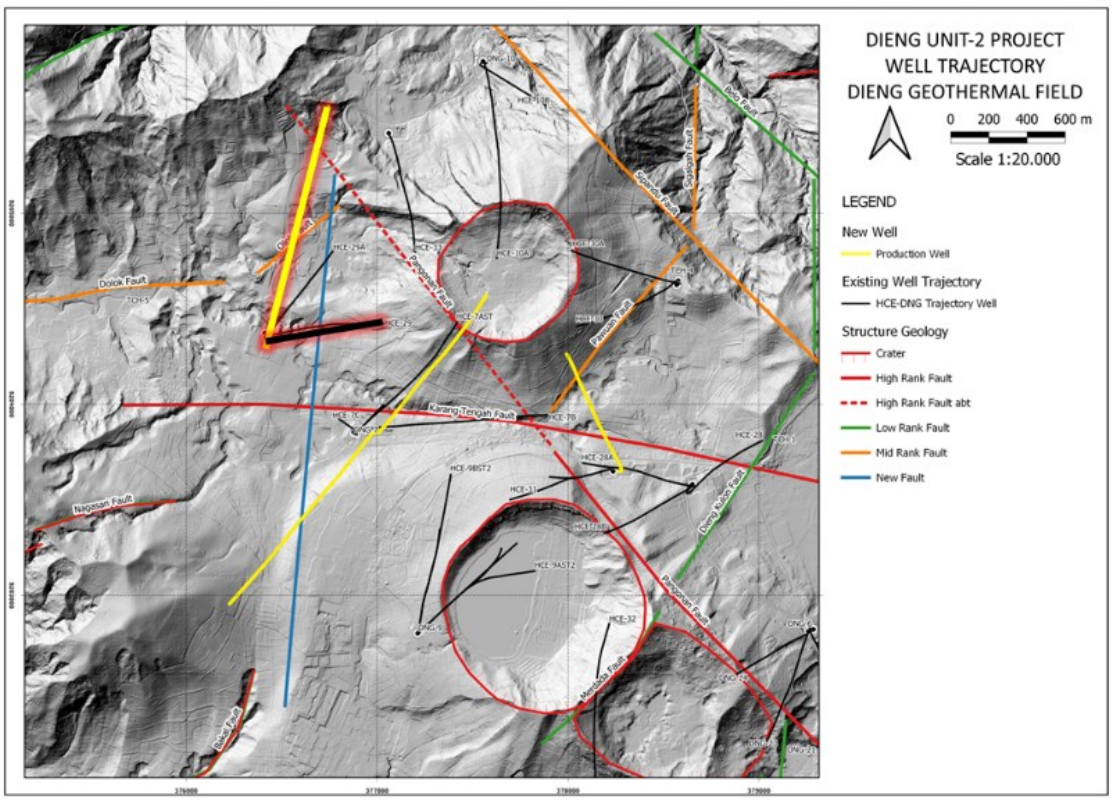

Figure 7: Trajectory of 29X well (glow yellow line) and 29 well (glow black line).

4.3 31X Monitoring

The drilling of well 31X in the Dieng geothermal field was strategically planned to intersect three significant geological features: the Karangtengah fault, the Pawuan fault, and the Pagerkandang volcanic neck damage zone. Neighbor's wells 30, 31, and 28A were used to observe changes in gas chemistry during and after the drilling process. However, during the drilling of Well 31X (February 1 to March 26), the monitoring wells are in the shut

in or bleeding condition due to overhaul of Dieng Unit 1. The complete geochemistry data were obtained on the second week of June. The results provide valuable insights into the subsurface structures and their permeability. Well 30 intersects the Pawuan fault and there is significant changes in CO2 (decreasing), N2 (increasing), Ar (increasing), CO2/N2 ratio (decreasing), and NCG (slight increasing) were observed after the drilling of well 31X. This changes suggests that the Pawuan fault may be act as a significant permeable structure in the Dieng geothermal field and show the connection between Well 31X and 30. The similar pattern is observed in the well 28A and 31 that intersect Karangtengah fault, that shows that this fault probably is a permeable structure and there is connection of well 31X with 28A and 31. This finding indicates sufficient evidence to confirm the existence or influence of the Pawuan and Karangtengah fault on fluid migration and gas transport within the reservoir.

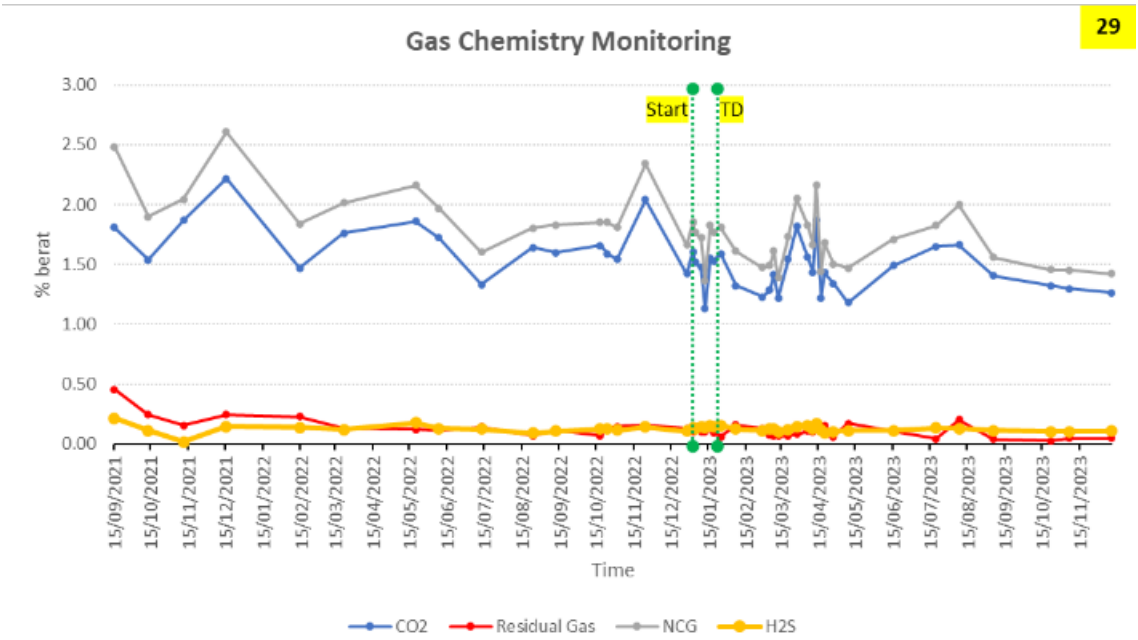

Figure 8: Gas monitoring in the existing well during 29X well drilling.

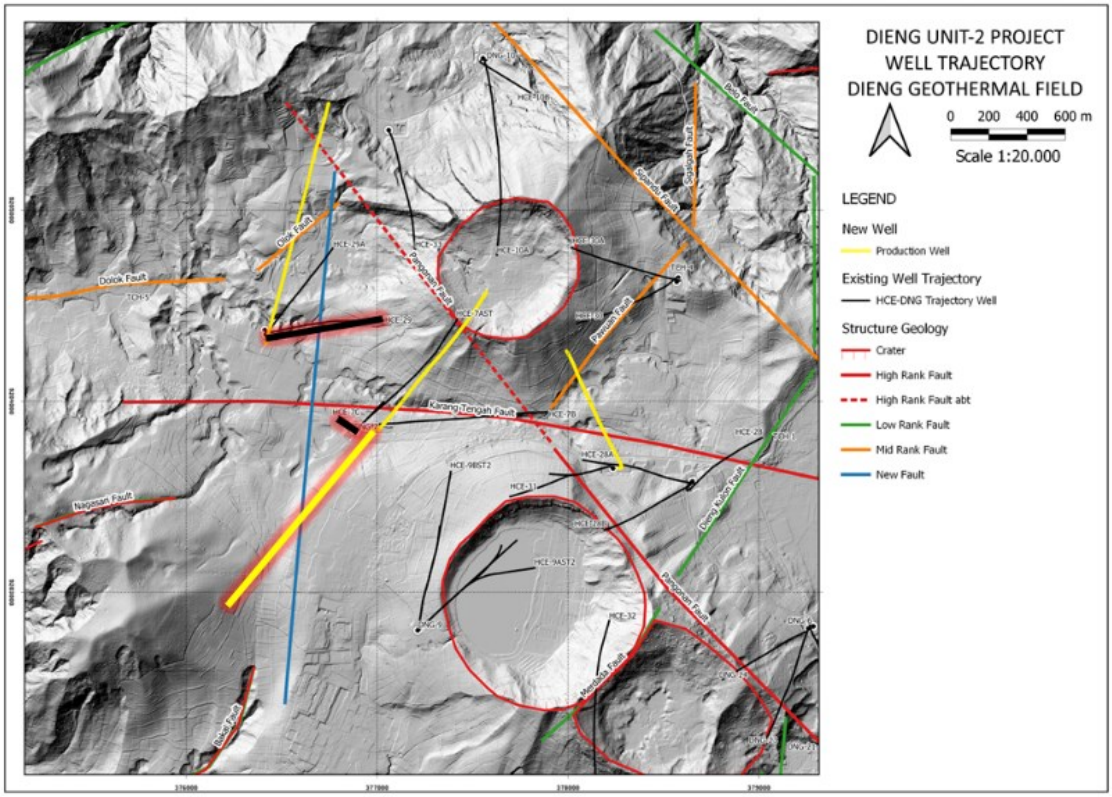

Figure 9: Trajectory of 7Y well (glow yellow line), and 29, 7C well (glow black line).

5. PROVEN STRUCTURE

The identification and characterization of faults in the Dieng geothermal field are crucial for understanding subsurface permeability and optimizing geothermal resource management. Based on surface data, borehole image data, and gas chemistry monitoring from various wells, some faults have been confirmed as significant permeable structures, while others require further investigation. This section summarizes the findings and implications of the existing data.

The integration of surface data, borehole image data, and monitoring well results has led to the confirmation of several key faults as significant permeable structures in the Dieng geothermal field. The newly identified North-South oriented fault, Karangtengah fault, and Pawuan fault have been validated through their impact on gas chemistry. Conversely, Pangonan fault and other remaining structures require further investigation to determine their roles within the geothermal system. Continued data collection and analysis will be essential for fully understanding and optimizing the Dieng geothermal reservoir.

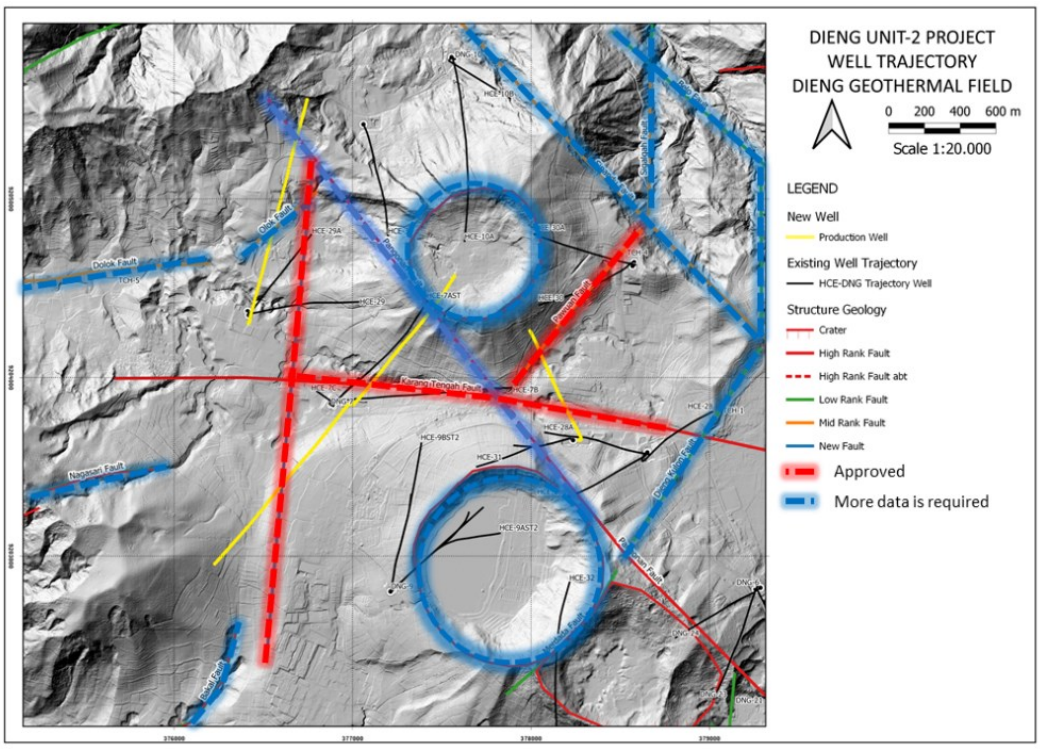

Figure 13: Confirmed fault-based integration data in the research.

6. CONCLUSION

The correlation of surface data, borehole image data, and monitoring chemistry is crucial for accurately proving fault existence and permeability in subsurface geothermal reservoirs. Borehole image data serves as hard evidence for identifying fracture existence and orientation, allowing us to confirm the presence and characteristics of subsurface faults and structures. Monitoring well data, gathered before, during, and after drilling, provides

additional support by revealing patterns of fluid flow and permeability zones, thereby evidencing the connectivity between wells. This comprehensive approach is essential for proving the existence and permeability of faults in the geothermal field.

Furthermore, integrating borehole image data with surface mapping and gas chemistry monitoring creates a robust framework for understanding subsurface dynamics. Borehole images offer direct insights into fracture patterns, which, when correlated with gas chemistry changes observed in monitoring wells, validate the presence of permeable faults. This multi-disciplinary approach not only confirms fault existence but also elucidates the fluid migration pathways within the reservoir.

For future research, it is imperative to incorporate detailed monitoring of pressure and temperature changes. These additional parameters will provide a more nuanced understanding of well connectivity and reservoir characteristics, further enhancing our ability to characterize and manage geothermal resources effectively. This comprehensive monitoring strategy will enable a more detailed and accurate assessment of subsurface structures, improving the overall efficiency and sustainability of geothermal energy production.

Power Density Assessment of Geothermal Fields in Indonesia

Eko Hari Purwanto and Andi Susmanto

Directorate of Geothermal, Ministry of Energy and Mineral Resources, Jl. Pegangsaan Timur No. 1 Jakarta

eko.hari@esdm.go.id

Keywords: Power Density, Resource Estimation

ABSTRACT

This study evaluates geothermal resource estimation using power density approach. During exploration phase of geothermal development where subsurface data is limited, power density method is frequently utilized by geothermal industry practitioners as an initial resource estimation which is usually expressed in MW/km^2. This technique estimates geothermal resource using the extent of indicative area by statistical means and associates them to other commercially productive fields based on similarities of temperature indication and geological condition.

Power density evaluation in this assessment is carried out on 31 medium and high temperature (>200^{o}C) geothermal fields in Indonesia, in which exploration drilling and/or development drilling are already completed. This enables comparison to be taken place equally between prospects in which geothermal subsurface conditions such as temperature, chemistry and resource dimension are identified and confirmed by exploratory/ development drilling.

This study suggests that medium to high temperature fields in Indonesia exhibit the range of power density from 0,3 to 28,3 MW/km^2. The mean power density in this study is 9,8 MW/km^2. The result is comparatively within the range of findings that has been formulated by Grant and Bixley (2011) whom suggest that typical power density is typically 10-15 MW/km^2 and slightly near from results that have been proposed by Wilmarth and Stimac (2015) which suggested that mean power density distribution from 66 geothermal fields is 15.4 MW/km^2.

This paper proposed that the mean area of proven reserves during exploration and field development phase is 6,5 km^2 and tend to be less than the mean area in production phase which is approximately 16,1 km^2. This is possibly due to increasing number of step-out production wells which may expand proven geothermal delineation area. Meanwhile the power density analysis results for geothermal fields located in different regions in Indonesia indicate that the geothermal fields in Java and Sumatra show a power density of 10.7 to 12.4 MW/km^2. This value is far greater than the power density in the fields located in Sulawesi and Nusa Tenggara, which is 6.7 to 7,2 MW/km^2.

1. INTRODUCTION

1.1 Resource Estimation Importance

Estimation of geothermal resources and reserves is an important stage of activity in geothermal exploration and development. This task is carried out with aims to estimate feasible and commercially-exploitable geothermal prospects and as a technical basis to plan geothermal power plant capacity to be built. Apart from quantifying technical feasibility of geothermal resources, preliminary resource assessment also has a very crucial role in affecting project economics i.e., influencing decision making on project continuance and attracting project funding for further phase of development. The process of estimating geothermal resources and reserves is an iterative process. Generally, updating of geothermal resources and reserves is carried out at almost during important milestones in project implementation which include preliminary survey phase, exploration drilling, feasibility studies and project expansion.

In Indonesia, power density method is one of the resource estimation methods which is used in estimating energy potential, especially in the early stages in preliminary exploration where sufficient geoscientific subsurface data are limited. In Indonesia, several methods of resource and reserve estimations have been standardized in the Indonesian National Standard as follows:

1. Indonesian National Standard 6169:2018 concerning Geothermal Energy Potential Estimation Methods, where this standard regulates the determination of formulas and procedures for each method of estimating geothermal energy potential in Indonesia.
2. Indonesian National Standard 6482:2018 concerning Parameters in Estimating the Potential of Geothermal Energy, where this standard regulates the determination of parameters and values in the methods of estimating the potential of geothermal energy in Indonesia.

3. Indonesian National Standard SNI 6009:2017 concerning Classification of Indonesia's Geothermal Energy Resources and Reserves. This standard explains the purpose of classifying geothermal resources and reserves based on geological, geophysical and geochemical investigations, drilling and reservoir engineering data as shown in Table 1. It is explained from the table that geoscientific data reliability is increasing as geothermal resources changes from speculative resources to proven reserves, where more parameters from well bore are measured and use in estimation. By using this standard, we hope that bankability of geoscientific data can be obtained.

As we observed from the table below, power density method is commonly used to estimate speculative resources where sufficient and detailed geoscientific data is unavailable.

Table 1: Resource classification according to Indonesia National Standard Number 6009 of 2017 modified from BSN (2017).

	RESOURCES CLASSIFICATION

Resource estimation	Power density	Volumetric stored heat	Volumetric stored heat	Volumetric stored heat	Reservoir simulation

1.2 Power Density Method Overview

Power density method is used to estimate speculative resource potential by means of statistics and to equate the energy potential of a new geothermal field in which the potential is unknown to other developed geothermal fields in which geothermal potential is known, showing sustainable production and has similar geoscientific signatures. Atkinson (2012) explained that power density analysis (MW per km^2) is applied by identifying a developed field with sufficient production history, which has characteristics similar to the field being assessed, and then applied to the field which is being assessed by considering suitable adjustments such as reservoir temperature or plant specific steam consumption.

Grant and Bixley (2011) explains that power density is a method which is frequently used in the early stages of exploration and development to estimate resource capacity based on areal consideration. Proven geothermal area is justified by each successful well within a 1 km circle or square around the well. This area is then multiplied by a power density - typically 10-15 MW/km^2.

Wilmarth and Stimac (2015) suggest that the advantage of estimating geothermal prospects using power density is that it returns a reasonable value immediately, whereas stored heat estimation may also provide certain errors, and numerical simulation may involve longer simulation time and efforts to construct the model but may not be more accurate than power density unless well calibrated by using well temperature and pressure profiles and/or any relevant subsurface geoscientific data.

1.3 Purpose of This Study

This paper aims to provide an overview of power density evaluation of geothermal resources in Indonesia which obtained from 31 medium to high temperature geothermal fields in Indonesia which exploration and/or development drilling have already conducted. This is to provide an even comparison where the fields which will be used as a reference already have temperature, fluid chemistry, geothermal system dimensions confirmed by exploration drilling. We hope that power density result of this study can be used as an initial parameter in estimating geothermal resource for other exploration fields particularly in Indonesia.

2. METHODOLOGY AND CRITERIA IN THIS STUDY

2.1 Power Estimation

In estimating power output for power density, Atkinson (2012) emphasizes the use of sustainable MWe which have been producing for at least 30 years whereas Wilmarth and Stimac (2015) point out net power output especially from fields with long generation histories. This is considered more practical and easily paired with current wellfield configuration. However, power density estimation for small fields is prone to error due to a small uncertainty in output can be a large portion of the output of a small field.

For this study, in order to accommodate more in-depth understanding of geothermal fields that have been explored and currently under development, we use power output from existing power plants, newly commercial operating fields that have been in production for > 2 year (Muara Laboh, Sorik Marapi, Rantau Dedap and Sokoria) and also estimation of proven reserves from brown fields and green fields which are currently being developed. For estimating power output in exploration areas, we use proven reserves data which has been calculated using volumetric and/or reservoir simulation methods and have a P90 probability of success. Thus, we notice that proven reserve is equipped with well data and parameters which accord with Indonesian National Standard because it uses subsurface data which measured directly from the wellbore.

2.2 Area Estimation

Several studies recommend that in order to delineate geothermal prospect area radius maximum from 500 m up to 1000 m buffer/circle around productive wells as proposed by Grant and Bixley (2011) and Wilmarth and Stimac (2015). The area assumption used in this paper is obtained from proven resource calculations that conform with the Indonesian National Standard. With the aims in increasing data reliability and assurance in area measurement, we use area magnitude with the highest probability of success (P90). It is essential that the P90 boundary must be supported by drilling result where the commercially-productive zone is intersected vertically and display reservoir conditions. This assumption is consistent with that made by Atkinson (2012), who suggests that for proved reserves, based on credible analysis, there is a 90% likelihood that the actual value achieved will be greater than or equal to value estimated. However, each company which operates in different fields may use different set of parameters to determine P90 area.

2.3 Reservoir Temperature Estimation

Reservoir temperature estimation use in this study is taken from geoscientific report which already been supported by drilling result and is measured directly from well. However, uncertainty regarding temperature data may be occurred i.e.:

1. Temperature data which collected form geothermal fields are not in similar state (whether it is collected during static or dynamic reservoir condition). Ideally, it should also consider the temperature recovery of the well in the heating-up process.
2. While the other geothermal fields only offer maximum temperature information, some geothermal fields display temperature readings within ranges. This nonconformity of temperature assumptions may have an effect on the power output that was estimated in the earlier stage.

3. RESULTS AND DISCUSSIONS

3.1 Power Density

The power density distribution resulting from 31 prospect populations in 29 geothermal working areas ranges from 0.3 (Tulehu) to 28.3 MW/km^2 (Blawan Ijen), indicating mean value of 9.7 MW/km^2 and standard deviation of 6.6 MW/km^2. The study results display that ~50% of geothermal fields in Indonesia have power density ranges from 6-15 MW (**Figure 1**). These results are in good correlation with several studies which suggest by Grant and Bixley (2011) that typical power density worldwide is typically 10-15 MW/km^2 and slightly near from results that has been proposed by Wilmarth and Stimac (2015) which suggested that mean power density distribution from 66 geothermal fields is 15.4 MW/km^2.

3.2 Geothermal System Type

The vapor-dominated geothermal system fields with reservoir temperature ranges from 239-270 ^{o}C have mean value of 9.6 MW/km^2, whereas liquid dominated fields with reservoir temperature ranges from 235-340 ^{o}C have mean value of 10.7 MW/km^2. This possibly indicates that fields with liquid-dominated characteristics are commercially more optimize in terms of potential energy utilization. This condition is possibly due to brine excess utilization using a bottoming scheme which allows additional power output (i.e., Sorik Marapi, Sokoria, Sarulla and Blawan Ijen) and utilization of low-pressure steam coupled with high-pressure turbines in double flash power plants (i.e., Muaralaboh and Rantau Dedap).

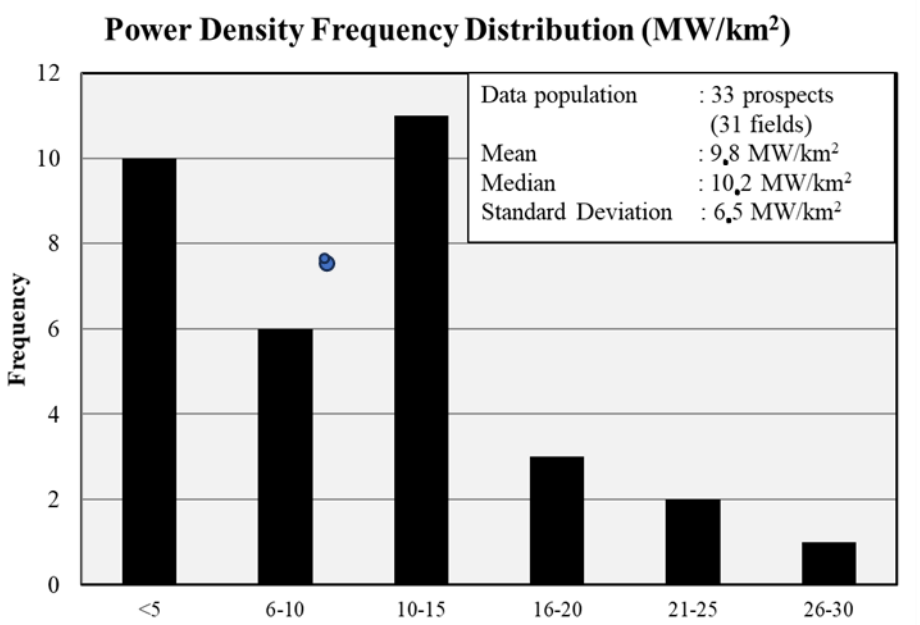

Figure 1: Frequency Distribution of Power Density in Geothermal Fields in Indonesia.

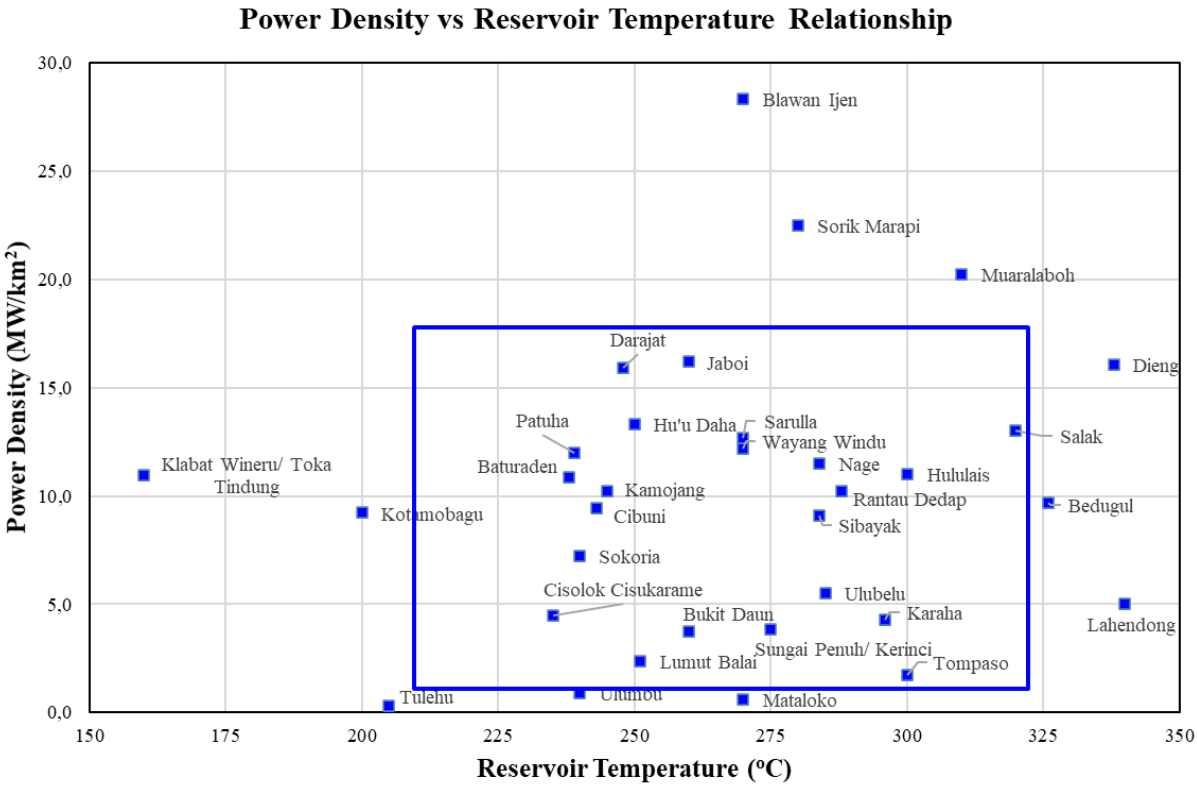

Figure 2: Power Density vs Reservoir Temperatures Plot of Geothermal Fields in Indonesia.

3.3 Relationship with Reservoir Temperature

At least 93% of geothermal fields that have been evaluated in this study are high temperature geothermal fields which have an average power density of ~10 MW/km^2. Power density versus reservoir temperature plot in Figure 2 exhibits scattered data in center and upper right quadrant of the plot. This may indicate certain trend of increasing power density along with the low-gradual rising temperature.

3.4 Indonesia Regional Comparison

Comparison of geothermal power density regionally indicates that geothermal systems on the islands of Java and Sumatra with reservoir temperatures > 235 ºC are areas that have a considerably large average of power density ranges from 10.7 (Sumatera) to 12.4 MW/km^2 (Java) as seen in Table 2. This is possibly due to most field in Java and Sumatera are located in volcano-hosted geothermal system.

Table 2: Regional Comparison of Power Density

Regional	Average Proven Reserve (MW)	Average Proven Area (km^2)	Average Power Density (ºC)	Average Temperature (ºC)
Jawa	146.2	12.3	12.4	267.5
Sumatera	117.9	16.3	10.7	278.5
Bali and Nusa Tenggara	28.5	4.9	7.2	268.3
Sulawesi	71.0	14.0	6.7	250.0
Maluku	2.0	7.0	0.3	205.0

4. CONCLUSIONS AND RECOMMENDATIONS

4.1 Conclusion

Generally, mean power density of geothermal fields in Indonesia are in good agreement and within magnitude with previous studies of ~10 MW/km^2. However, the mean result is slightly lower than previous studies, possibly due to use of P90 area delineation which allows for more accurate power output estimation since it uses the pessimistic case with the higher probability of success. Regional comparison indicates that geothermal systems on the islands of Java and Sumatra, which comprises reservoir temperatures of more than 235 ºC, are areas that have a considerably large average of power density ranges of 10.7-12.4 MW/km^2, compared to other area such as Sulawesi and Nusa Tenggara.

We hope that the results of this study can be used in estimating geothermal resources in Indonesia particularly at pre-detailed exploration stage. This approach is expected to eliminate overestimation of resources assessment.

4.2 Further Works

Sufficient access to comprehensive and thorough geothermal subsurface and engineering production data will allow several aspects to be included further relating to this analysis. Authors would like to suggest several further works as follows:

1. Introducing geoscientific parameters such as geological structure, geothermal system dating and specific geothermal plays to be incorporated in this study. This will allow us to understand the geoscientific correlation with power density.
2. Detailed reservoir temperature both static and dynamic data will provide more provide consistency in the estimation of power output so that it is expected to have an influence on the correlation between power density and reservoir temperature.
3. Proposing new and updated National Guidelines for resource estimation assessment in order to ensure that the techniques employed are consistent and applicable to geothermal areas particularly for low and medium temperatures.

Keywords: Remote sensing, GIS, NDVI, VARI, forest, conservation, vegetation, monitoring, geothermal

ABSTRACT

Geothermal projects and power plants are mostly surrounded by forest or conservation area that needs programs to ensure the sustainability of the forest which indirectly affect the sustainability of the geothermal operation. Patuha Geothermal Area managed by PT Geo Dipa Energi (Persero) has 34.900 ha operational area (WKP/Wilayah Kuasa Pengusahaan Panasbumi) which 57% of it is overlaid with conservation forest, protected forest, and production forest. As the company has several programs in forest conservation, continuous monitoring of these forested areas is essential to evaluate the program progress and achievement.

Regarding the forest monitoring, this research focuses on two monitoring tools, Normalized Difference Vegetation Index (NDVI) and Visible Atmospherically Resistant Index (VARI) to assess vegetation/plant health around the Patuha Geothermal Area. Considering the large area or forest and limited monitoring resource, drone/UAV imagery (remote sensing) and digital mapping software (ArcGIS) is used to see either the progress of forest conservation program or if there is any affected plants caused by geothermal activity in different locations. Meanwhile NDVI is a common method which considered the reflectance of the near-infrared band, VARI is more suitable for areas with dust or haze in the air. This study creates the maps based on both NDVI and VARI to get a complete picture of plant health across the geothermal region. Combining this information with mapping software can identify the areas where the healthier plant is.

The results show that compared to VARI, NDVI visualize more detailed plant health result. However, VARI's data patterns strongly resemble those of NDVI. Thus, identifying the plant health by VARI is applicable considering the time efficiency and cost-effective, especially for the early or interim monitoring. While VARI offers a promising alternative, it is important to define certain standard of Health Plant Thresholds of VARI's result because plant health varies across species. In the other hand, NDVI still needed as an initial reference point to support the validation of VARI's results. In Patuha Geothermal Area, NDVI methods used as the initial or baseline data, while for VARI methods used as periodic monitoring tools to collect better data series. With these methods, the forest monitoring of 41 that usually done in xx days, can be done in half a day. This approach using multiple tools will provide fast and valuable information for monitoring the environment and making informed decisions about developing geothermal power while also protecting plants in the Patuha Geothermal Area.

1. INTRODUCTION

PT Geo Dipa Energi (Persero) Unit Patuha is one the Geothermal Power Plant located in West Java, Indonesia. The company is now running 55 MW electricity connected to Java-Madura-Bali electricity grid through Perusahaan Listrik Negara as national electricity company. Geothermal projects and power plants are mostly surrounded by forest or conservation area.. Patuha Geothermal Operation Area (Wilayah Kuasa Pengusahaan Panasbumi) consist of 34.900 ha which 57% of it involves social forestry, conservation forest, protected forest, and production forest.

Vegetation plays a crucial role in geothermal ecosystems, influencing heat transfer, soil stability, and gas emissions. Monitoring vegetation health in these areas is essential to understand the environmental impact of geothermal development and for implementing sustainable management practices. Vegetation in terms of forestry also important for geothermal production sustainability because they conserve groundwater which may contribute the geothermal reservoir recharge. As seen in Figure 1, Patuha Geothermal recharge area is marked by the blue pattern that most of it overlayed with the protected forest zone. Thus, protecting forest is not only benefits the biodiversity conservation, but also maintains the sustainable geothermal operation.

PT Geo Dipa Energi (Persero) Unit Patuha has several programs related to forest conservation, such as revegetation and collaborative forest patrols in the social forestry area. They needs to be monitored periodically to assess the program achievement. Usually the vegetation (plants) health is assessed directly on the dedicated

sampling plot. Therefore, plot-based methods become impracticable in some situations where plants in area are unevenly distributed, or when it is too hard to draw borders in dense vegetation (Buckland, 1993 and White, 2008 in Amagnide, 2021). That traditional field-based methods can be time-consuming and expensive, particularly in large or difficult-to-access areas which risks the results accuracy.

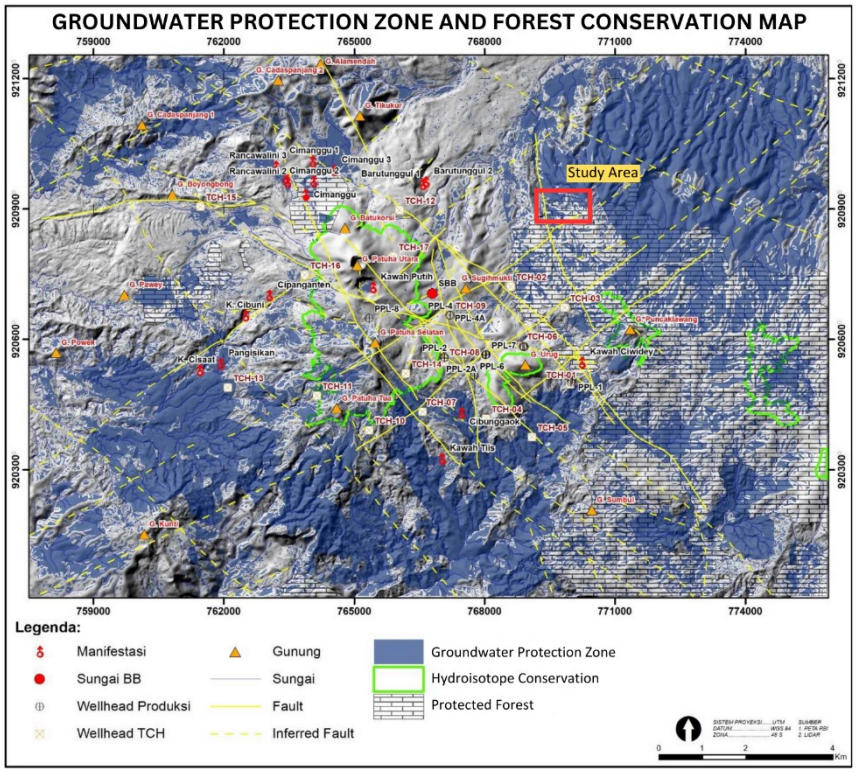

Figure 1: Patuha forestry and groundwater recharge area. (Report Hydrogeology and Recharge Area Patuha, 2023)

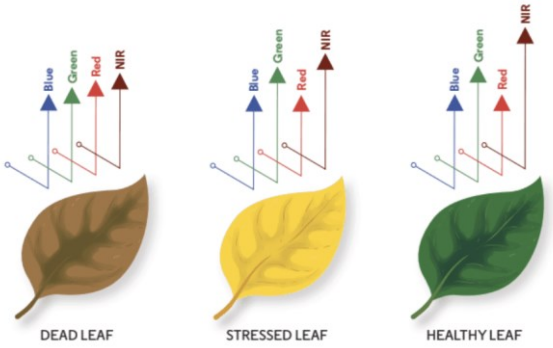

Figure 2: Spectrum/Band to monitoring vegetation health. (Picture from Farmingdynamic.com.)

Remote sensing techniques offer a cost-effective and efficient alternative for monitoring vegetation over large spatial scales. By measuring the amount of light reflected in different parts of the spectrum/bands, scientists developed Normalized Difference Vegetation Index (NDVI) to assess plant health. NDVI is a commonly used vegetation index that takes the difference between the reflectance in the near infrared (NIR) and red wavelengths, and then divides it by their sum. Higher NDVI values indicate healthier vegetation. as seen in the 2 below

This paper aims to compare the effectiveness of NDVI and VARI methods to monitor vegetation health. Both techniques leverage remote sensing data to assess the condition of plant life. By comparing NDVI and VARI, the paper aims to equip readers with a better understanding of these valuable tools for monitoring vegetation health and selecting the most appropriate technique for their specific needs.

2. METHODS

2.1 Study Area

The study focused on a social forestry area near the Patuha Geothermal area, located in Sugihmukti Village, at coordinates 770013 E and 9209376 N, with an elevation ranging from 1,500 to 1,700 meters. The area is planted with various crops, including coffee, lemon, eucalyptus, and others. It is also bordered by the Gunung Tilu conservation forest. This study area is located within a groundwater protection area as seen in Figure 1.

2.2 Research Methodology

The problem and purpose for this study is to compare and recommend the best vegetation monitoring methods by remote sensing technology. Start with determining the study area, followed by data collection, consist of 2 different aerial imaginaries captured by drone equipped with and without NIR camera, and manual vegetation monitoring data in the sample plot. Partial drone data is merged by Agisoft Metashape. Then, the analysis of data is conducted with NDVI and VARI methods with the ArcGIS Pro 3 with the additional module of ArcGIS Pro Deep Learning. The result of NDVI and VARI methods will be compared to the manual sampling report as the confirmatory terms of ability and accuracy.

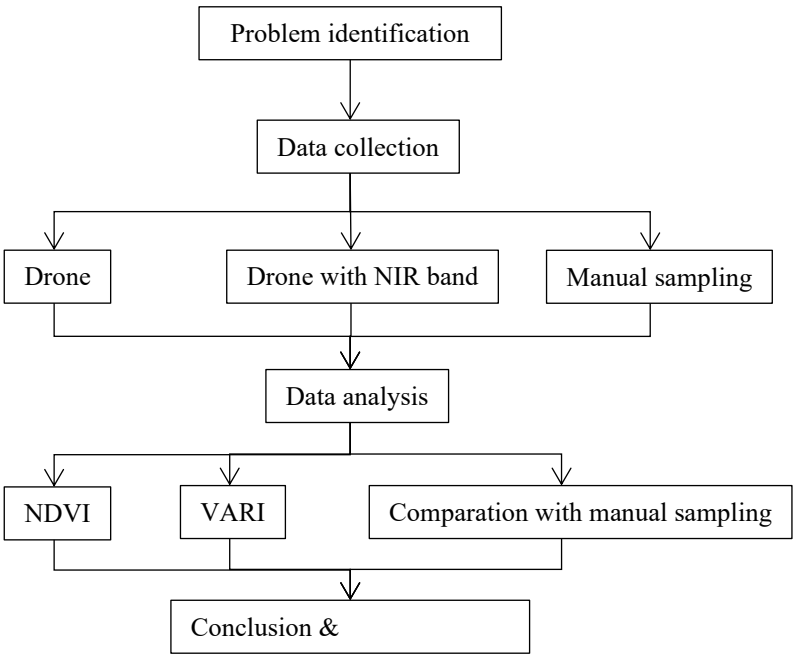

Figure 3: Research methodology.

2.3 Remote Sensing and Geographical Information System

Geographycal Information System(GIS) and remote sensing are powerful tools working together to effectively monitor vegetation health and change over time. These tools have its own benefits, as described below.

2.3.1 Remote Sensing

In the data collection ability, satellites, drones, and airplanes can capture imagery of the Earth's surface. This data comes in various forms, including multispectral (capturing different wavelengths of light) and hyperspectral (capturing a very wide range of wavelengths). Remote sensing data can be further analyzed to define the Vegetation Index, like NDVI. These index leverage the unique spectral reflectance of healthy vegetation to estimate factors like biomass, leaf area, and overall plant health as mention by Jensen, J. R. (2005). By analyzing time series of remotely sensed data, it can identify changes in vegetation cover which usually correspond to drought, deforestation, or agricultural practices. The equipment used in this study are DJI Phantom 4 with NIR camera for NDVI identification and DJI Mavic 2 Pro for VARI identification, to capture the RGB Band. Agisoft Metashape is used to process the drone imagery.

Figure 4: DJI Mavic 2 and DJI Phantom 4 Multispectral .

2.3.2 Geographical Information System (GIS)

GIS used as the spatial data management, this platform can store, manage, and analyze the vast amount of spatial data collected through remote sensing. This analysis ability includes not only the imagery itself but also its response with another information like soil types, topography, and weather data. As a spatial analysis tools, GIS allows users to overlay various data sets to identify spatial patterns and relationships. For example, comparing the areas with declining NDVI with the precipitation data can be used as a tools for assessing drought impacts in certain area GIS able to create informative maps, graphs, and reports that effectively communicate vegetation health trends and changes across a landscape.

In general, the synergy between GIS and remote sensing offers a powerful approach for comprehensive vegetation monitoring, providing valuable insights for sustainable land management practices (Jensen,2005). It can conduct the large scale monitoring which overcoming logistical limitations of field studies, do the time series analysis, allows data integration among the spatial information data, and provides the cost effective methods to monitor large areas. In this study, Arcgis Pro 3.0 software is used to process Drone imagery data consideringits ability to run rapid processing imagery including NDVI and VARI identification

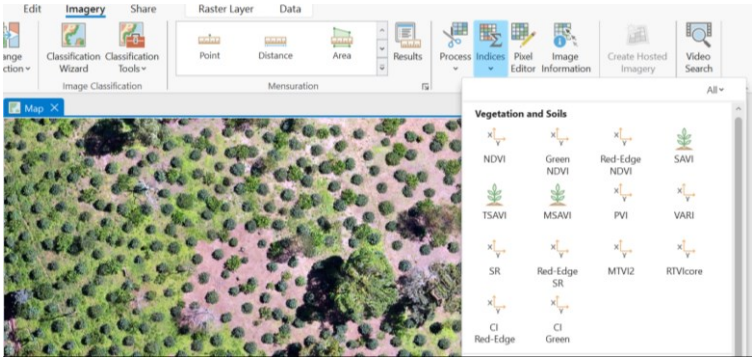

Figure 5: Interface of ArcGIS Pro Tools for Vegetation and soils Monitoring.

2.4 Normalized Difference Vegetation Index (NDVI) and Visible Atmospheric Resistant Index (VARI)

NDVI is a widely used vegetation index that exploits the contrasting reflectance properties of vegetation in the red and Near-infrared (NIR) portions of the electromagnetic spectrum. Healthy vegetation absorbs strongly in the red band and reflects highly in the NIR band. NDVI is calculated using Equation 1.

$$NDVI = \frac{(NIR-Red)}{(NIR+Red)} \quad (1)$$

NDVI values range from -1 to 1, the higher values indicate the denser and healthier vegetation cover. However, NDVI can be sensitive to atmospheric conditions and soil background (Jensen,2005)which may affects its accuracy in certain environments as seen in the Figure 5 below

Figure 5: NDVI Value for Vegetation Health Indicators.

VARI is a modification of NDVI that aims to minimize the influence of atmospheric effects on the index. VARI incorporates a soil adjustment factor to accommodate the background variations. The specific formulation of VARI can be vary, but one common version shown in Equation 2.

$$VARI = \frac{(Green - Red)}{(Green + Red - Blue)} \quad (2)$$

VARI values range depends on the type of plant, generally the higher values indicate the denser and healthier vegetation cover (Gitelson 1996)

Both NDVI and VARI are vegetation indices used in remote sensing to assess vegetation health and cover. They offer valuable insights, but have their own strengths and weaknesses as listed in Table 1 (Nunes 2015).

Table 2: Summarizing the key differences.

Feature	NDVI	VARI
Advantages	Widely used, simple	Less atmospheric impact, less soil background influence
Disadvantages	Sensitive to atmosphere, soil background	Less widely used, variable formula
When to use	Established method, readily available data	Areas with variable atmospheric conditions, areas with sparse vegetation

3. RESULTS AND DISCUSSIONS

In this study, DJI Phantom 4 and DJI Mavic 2 drones were flown at an altitude of 150-200 m above the ground surface, with the same reference point (the same Ground Control Point/GCP). After that, the image data from the drone was processed using Agisoft Metashape to combine the pieces of aerial photographs that had been taken. Figure 6 shows the final result of processed image.

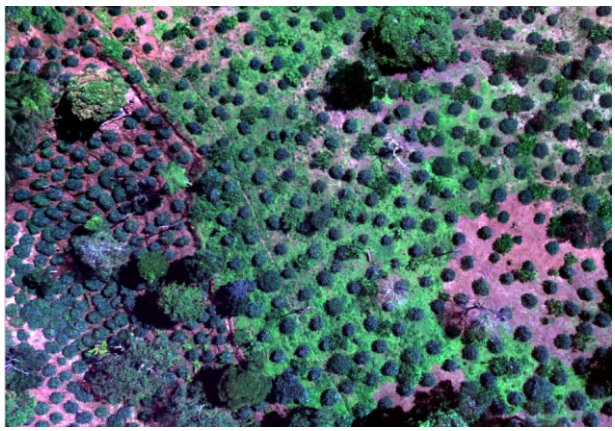

Figure 6: Final result of combined drone image.

Next, the data were processed using ArcGIS Pro 3, it categorized the plant healthy index into 4 classes: Dead Plant, Unhealthy Plant, Moderate Healthy Plant,and Very Healthy Plant, as shown in Figure 6. Refer to Figure 6, VARI only able to detect dead plant to moderate healthy plan. The very healthy plant class is undetected because VARI does not use NIR band to analyze the data.

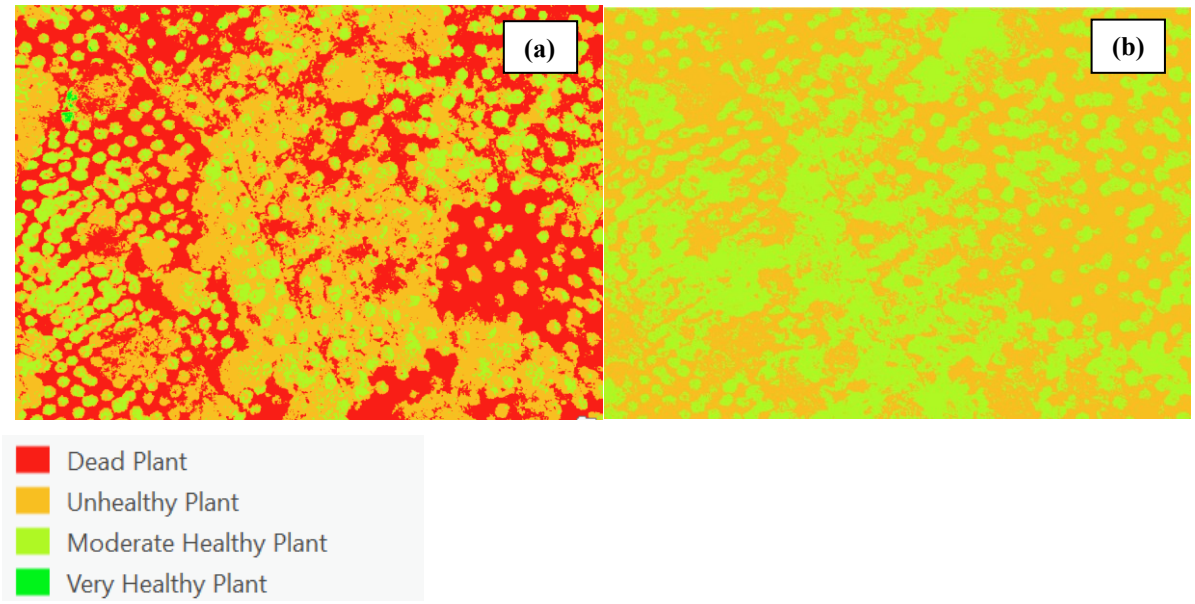

Figure 6: NDVI (a) vs VARI (b) result.

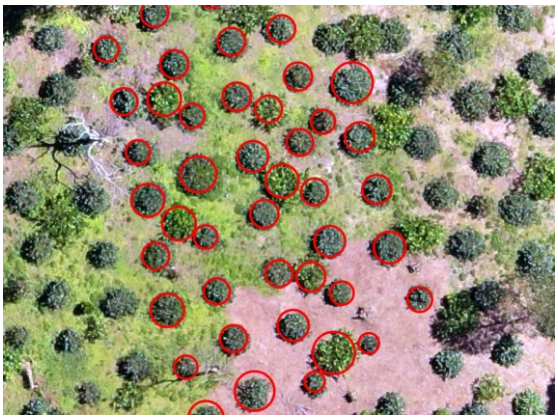

Figure 7: Sampling Point on Block A.

In order to confirm assessment result fromVARI acuracy, samples are taken as the confirmatory of the very healthy plant class, sampling area is located in Block A. The plant marked in red circle on Figure 7 is considered as very healthy plant by manual assessment . This approach allows direct comparison between VARI and NDVI, which established as a benchmark reference point. In addition to this confirmatory approach, ArcGIS Pro Deep Learning is used to enhance plant detection and counting capabilities. By incorporating this sampling technique, will effectively evaluate the precision of VARI in quantifying vegetation health and distribution compared to the well-defined NDVI method, resulted in Figure 8 Furthermore, ArcGIS Pro Deep Learning is used to automate plant identification and enumeration within the Block A, concerning more efficient and objective assessment.

Based on the comparison of NDVI and VARI in Figure 8, NDVI provides a more accurate assessment of vegetation health compared to VARI. NDVI can detect and assess vegetation health, particularly in terms of identifying stress or damage in plants. It utilizes the reflectance of red and near-infrared (NIR) light to determine the photosynthetic activity of plants. VARI, on the other hand, is a relatively new method that utilizes a combination of green and red-light reflectance. While VARI shows promising, NDVI's ability to detect subtle changes in plant health makes it a more reliable.

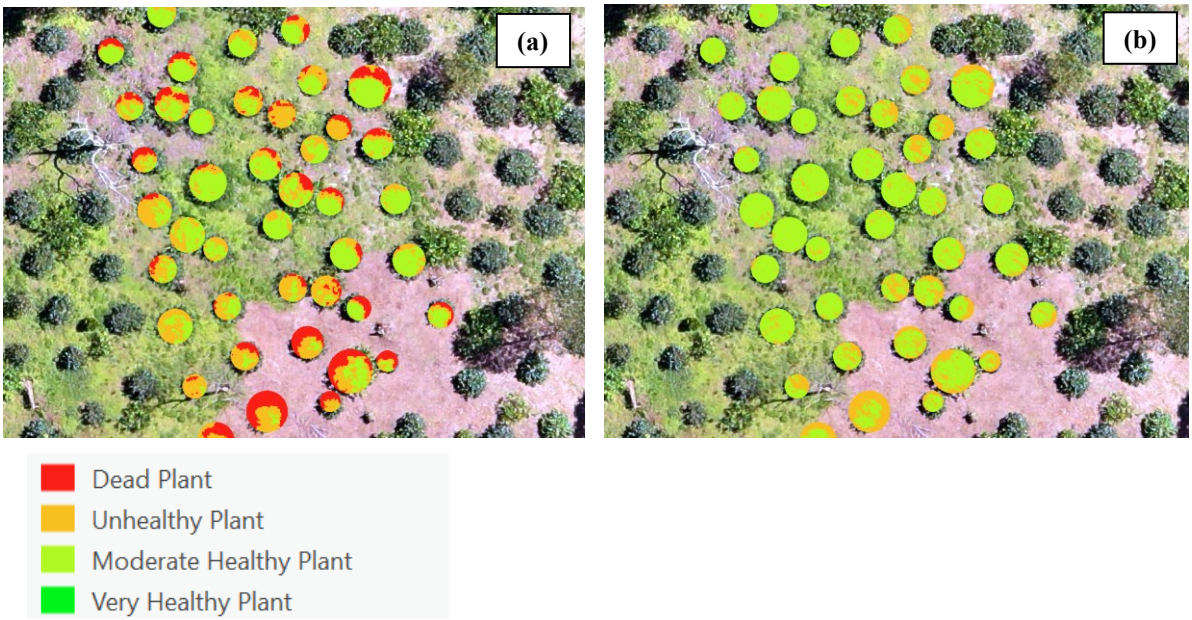

Figure 8: Comparison of NDVI (a) vs VARI (b) Results on Block A.

Figure 8(a) shows that NDVI can effectively identify even partially damaged leaves on moderately unhealthy plants.NDVI's sensitivity to changes in plant health allows it to detect stress or damage even when it is limited to a portion of the plant's leaves. This is particularly important for moderately unhealthy plants, where damage may not be uniformly distributed across the foliage. VARI, while capable of providing general health information, may not be as effective in identifying such localized damage (Figure 8(b)). However, VARI's data patterns closely resemble those of NDVI. Despite VARI's limitations in detecting subtle changes, its overall data patterns exhibit a strong correlation with NDVI results.

In addition regarding the equipment spesification, the affordability of VARI drones allows for frequent monitoring compared to NDVI.VARI drones are generally less expensive than those equipped with NIR sensors required for NDVI measurements. This cost advantage enables more frequent monitoring using VARI, providing a higher temporal resolution for tracking vegetation health changes, and provides more data to conduct the time-series analysis

While VARI offers a promising alternative, it is important to note that standardized health thresholds are yet to be established for VARI. Unlike NDVI, which has well-defined health thresholds for different plant species, VARI lacks standardized guidelines for interpreting its results. This variability necessitates the use of NDVI as an initial reference point and field verification to validate VARI's findings. Considering the variation of plant health for each species, NDVI still needed as an initial reference point and field verification to validate VARI's results. Different plant species exhibit varying ranges of reflectance values that correspond to their health status. Without defining the standard thresholds for each species, VARI's results may be difficult to interpret accurately. Therefore, NDVI methods become a crucial reference point to establish baselines and assess the relative health of plants using VARI. Moreover, field verification is essential to confirm VARI's accuracy and ensure that its results align with actual plant health conditions.

Forest management, or forest conservation monitoring program in particular, needs a balance between quickly monitoring the large areas and getting highly detailed data. For enormous plantations or forest area, flying over the remote sensing technology over the trees equipped with tools like NDVI and VARI gives a general idea of vegetation healthiness across a wide area, even if it is not super precise. In this case, what matters most is the relative size of any affected areas. NDVI might be a better choice than VARI because it uses a specific band to capture chlorophyll health which is NIR sensor, but NDVI cameras on drones are more expensive. The most valuable advantage of using drones with remote sensing for tree health monitoring comes from surveying large areas quickly, especially in remote or steep locations where ground crews would be difficult or dangerous. This study showed they could survey a significant area (over 41 hectares) in just half a day, compared with manual monitoring which can take 7 days.

Choosing Between NDVI and VARI:

- If need a well-established method with abundant data and prioritize simplicity, NDVI might be a good choice.

- If working in an area with variable atmospheric conditions or have sparse vegetation, VARI could offer a more reliable picture of vegetation health.

Ultimately, the best choice depends on your specific needs and the characteristics of study area. Consider factors like:

- Atmospheric conditions: If consistent, NDVI might suffice. For variable conditions, use VARI.
- Vegetation cover: In dense vegetation areas, NDVI might be fine. For sparse vegetation, VARI has an advantage.
- Data availability: Choose the index with readily available data for study area and timeframe.

Additional Considerations:

- Newer, more advanced vegetation indices have been developed that address some limitations of NDVI and VARI. Consider exploring them if needs are specific.
- Combining NDVI or VARI with other remote sensing data (e.g., temperature, soil moisture) can provide a more comprehensive picture of vegetation health.

4. CONCLUSION

Regarding the plant health monitoring in forest conservation program, it can be concludes that NDVI provides more accurate assessment of vegetation health compared to VARI. However, VARI's data patterns still closely resemble those of NDVI but with less detailed. Thus, identifying the plant health by VARI is applicable considering the time efficiency and cost-effective, especially for the early or interim monitoring. While VARI offers a promising alternative, it is important to define certain standard of Health Plant Thresholds of VARI's result because plant health varies across species. In addition, NDVI still needed as an initial reference point in order to conduct the field verification to validate VARI's results. In Patuha Geothermal Area, NDVI methods used as the initial or baseline data, while for VARI methods used as periodic monitoring tools to collect better data series.

Keywords: geothermal, drilling, market, service company, tender, procurement, attractiveness, competitiveness

ABSTRACT

Indonesia's geothermal drilling demand is projected to increase as necessity for extensive drilling activities for both new projects that in exploration and development, also and maintenance of existing fields, emphasizing the potential market growth. The analysis begins with an overview of the current state of geothermal drilling contractors and rig availability in Indonesia. It notes the competition with the oil and gas industry for drilling rigs, a situation exacerbated by fluctuations in oil prices that can affect the availability and cost of rigs for geothermal drilling. The scarcity of rigs can lead to geothermal operators hiring more expensive, over-capacitated rigs, impacting project economics.

This study advocates for a comprehensive market survey as a foundational step in the procurement process, enabling developers to make informed decisions and select the most efficient procurement strategies. Such surveys help estimate costs accurately and tailor procurement activities to market realities, crucial for enhancing competitiveness and decision-making. To address market competitiveness, this research proposes several strategies, including the development of a centralized integrated vendor database (CIVD) to streamline the tender process, the adoption of well bundling strategies, and ensuring clarity and fairness in payment terms and conditions. Site readiness, clear communication, and stable international currency use for foreign transactions are also recommended to attract more competition and efficiency in the sector.

Furthermore, to increase international participation in Indonesia's geothermal drilling market, the paper suggests promoting local-international partnerships, establishing clear legal frameworks, ensuring transparent and fair operational records, and encouraging technology exchange and R&D collaborations. These strategies aim to create a more open and attractive market for international players, facilitating technology transfer and enhancing overall market dynamism. In conclusion, the research outlines a strategic approach for Indonesia to leverage its geothermal resources more effectively, proposing practical measures to improve market conditions for drilling activities. These strategies are designed to foster a more competitive and attractive environment, encouraging both local and international investment and collaboration in Indonesia's geothermal sector.

1. INTRODUCTION

Indonesia's geothermal resources present significant potential for sustainable energy development with numerous fields invarious stages of exploration and development, making the country a key player in the global renewable energy sector, especially for geothermal energy. This sub-section provides an analysis of Indonesia's geothermal drilling market, correlating the upcoming projects, key contractors, and market dynamics.

The sub-section is also examining the methods used to survey the market, the competitiveness of the Indonesian geothermal sector, and the involvement of international drilling companies. Beyond discussing the research methodologies applied to ensure a comprehensive understanding of the market, this sub-section also delves into strategies to enhance geothermal drilling market competitiveness. This section aims to provide a clear picture of the current market landscape and the opportunities and challenges in Indonesia's geothermal drilling industry.

1.1 Projected Drilling Market Demand: Ongoing and Future Geothermal projects in Indonesia

This sub-section of the report provides a detailed list of the ongoing and planned geothermal projects in Indonesia that mainly based on the RUPTL PLN 2021 – 2030 as the research background of this study. The significance of these information lies not just in their enumeration of projects but in their portrayal of the dynamic nature of Indonesia's geothermal drilling market still large.

Table 1 shows the lists of identified geothermal exploration projects scheduled from 2023 to 2030, detailing their location, managing companies, expected Commercial Operation Dates (COD), and Megawatt (MW) targets. This

exploration phase is critical, as it sets the foundation for future development and commercial exploitation of geothermal resources.

Then, Table 2 shifts the attention to geothermal development projects within the same timeframe. This table provides a more in-depth look at each project, including additional remarks that shed light on their current status and progress. Projects like Jaboi #1 in Aceh and Dieng #2 in Central Java are highlighted with their respective CODs and MW targets, along with notes on their current stages, such as feasibility study reviews or the EPCC process.

In total, there are approximately 25 geothermal fields that in exploration projects and 23 geothermal fields that identified in development projects identified based on RUPTL PLN 2021 - 2030. Some of these projects are anticipated to require extensive drilling activity, indicating a growing market for geothermal drilling in Indonesia. Furthermore, the presence of make-up well and workover projects in existing geothermal fields to sustain operational efficiency and compensate for any declines in production capacity also contributes to the increasing demand in the geothermal drilling market.

1.2 Research Objectives and Methods

The primary objective of this research is to develop and propose integrated strategies aimed at increasing the attractiveness and competitiveness of the geothermal drilling market in Indonesia. This involves analyzing the current state of the market, identifying key challenges, and suggesting practical measures to enhance market dynamics, efficiency, and international participation.

This study seeks to address the following central research question: What integrated strategies can be implemented to enhance the attractiveness and competitiveness of Indonesia's geothermal drilling market?" To support this primary question, the research will explore sub-questions such as:

- How do current market conditions and rig availability impact the competitiveness of geothermal drilling in Indonesia?
- How can market survey help on generating cost estimate and updating the latest condition of current available contractor?
- What kind of strategies for increasing market competitiveness and increasing participation of international drilling companies?

To achieve the research objectives and answer the research questions, a comprehensive and multi-faceted research methodology will be employed, such as literature review, experts consultation and interview, and market research. By employing this comprehensive research methodology, the study aims to provide actionable insights and recommendations that can drive improvements in the geothermal drilling market in Indonesia, making it more attractive and competitive on a global scale.

2. GEOTHERMAL DRILLING CONTRACTORS AT A GLANCE

The objective of this sub-section is to provide an update related to the availability of drilling rigs in Indonesia. This includes cataloguing the rig size, numbers, as well as the typical technical specification which is essential for planning and executing geothermal projects effectively.

2.1 Current Geothermal Drilling Rig Availability in Indonesia at a Glance

The objective of this sub-section is to provide an update related to the availability of drilling rigs in Indonesia. This includes cataloguing the rig size, numbers, as well as the typical technical specification which is essential for planning and executing geothermal projects effectively.

Figure 1 shows the current rig inventory for geothermal project in Indonesia. It is important to acknowledge that this visualization does not encompass the entirety of drilling rigs in the country. The listed rigs and their specifications, as summarized by Hartono (2023), represent only rig list that submitted by identified drilling rig contractors.

Based on current rig contractor that surveyed by Hartono (2023), the most common rig size is 350 horsepower (HP), accounting for 27% of the inventory with 36 rigs. This is followed by the 1500 HP rigs, comprising 25% of the inventory with 20 rigs, highlighting a substantial investment in high-capacity rigs. Notably, rigs with 1000 HP and 2000 HP each make up 12% of the inventory, with 16 rigs available in each category.

Table 1: List of Identified Geothermal Exploration Project 2023 - 2030 (EBTKE, 2023b; PLN, 2021)

No.	Geothermal exploration drilling project	Province	Geothermal Company	COD[1] Target	MW Target	Additional Remarks
1	Atadei #1	East Nusa Tenggara	PT PLN (Persero)	2024	10	-
2	Tulehu	Maluku	PT PLN (Persero)	2025	20	-
3	Songa Wayaua	North Maluku	PT PLN (Persero)	2025	10	-
4	Rajabasa	Lampung	Supreme Energy	2025	220	-

23	Seulawah Agam	Aceh	PT Pertamina Geothermal Energy Tbk	N/A	N/A	

[1] The Commercial Operation Date (COD) targets referenced are derived from the presentation by the EBTKE 20223 and RUPTL PLN for the period 2021-2030. It is important to note that Author has not conducted individual interviews with geothermal developers to obtain updated COD targets. This approach ensures that the data presented is consistent and based on officially published sources, thereby maintaining the accuracy and reliability of the information. However, it also implies that any recent adjustments or updates to COD targets by individual developers may not be reflected in this analysis.

No.	Geothermal exploration drilling project	Province	Geothermal Company	COD[1] Target	MW Target	Additional Remarks
24	Jailolo	North Maluku	N/A	N/A	40	• Returned by Star Energy in 2017 • Licensing n oprogress by Geo Dipa Energi (PT SMI) • Planned for government drilling in 2024 through GEUDP program. • Tender process starts from 2027. • IPB (*Izin Panas Bumi*) granted target in 2028
25	Marana	Central Sulawesi	N/A	N/A	20	• Tender failed in year 2015. • Additional data provided by the Geological Agency in 2021, outside the exploration priority for 2023-2027
26	Suwawa	Gorontalo	N/A	N/A	20	• Offered to state-owned enterprises, but not yet expressing of interest. • Proposed additional data collection by the Geological Agency outside the exploration priority for 2023-2027
27	Gunung Endut	Banten	N/A	N/A	40	• Planned for government drilling in 2026 by Geological Agency • Tender process starts from 2028. • IPB (*Izin Panas Bumi*) granted target in 2029. • Conservation Forest Area (utilization area) • Temperature gradient survey by the Geological Agency in 2023
28	Iyang Argopuro	East Java	N/A	N/A	55	• Returned by PGE in 2014 • Conservation Forest Area
29	Bora Pulu	Central Sulawesi	N/A	N/A	40	• Tender process starts from 2023. • Additional data provided by the Geological Agency in fiscal year 2023. • Potential liquefaction zone • Proposed for tender, but no bidders yet. • Outside the exploration priority for 2023-2027
30	Sembalun	West Nusa Tenggara	N/A	N/A	10	• Results of PSP PLN • Rinjani National Park • Additional data provided by the Geological Agency in 2021, outside the exploration priority for 2023-2027
31	Gunung Pandan	East Java	N/A	N/A	40	• Results of the East Java Provincial Government's PSP
32	Telaga Ranu	North Maluku	N/A	N/A	5	• Results of Star Energy's PSP • Government drilling proposal by PT SMI • Interest shown by ORMAT. • Proposed as a replacement for WKP Bora Pulu to be tendered in year 2023. • IPB (*Izin Panas Bumi*) granted target in 2024.
33	Songgoriti	East Java	N/A	N/A	20	• Planned for government drilling in 2026 by Geological Agency • Tender process starts from 2028. • IPB (*Izin Panas Bumi*) granted target in 2029.
34	Gunung Wilis	East Java	N/A	N/A	20	• Results of MRI Energy 's PSP • Tender failed in year 2016
35	Gunung Galunggung	West Java	N/A	N/A	55	• Results of Energy Kinan International's PSP • Tender failed in year 2016 • Planned for government drilling in 2026 by Geological Agency

No.	Geothermal exploration drilling project	Province	Geothermal Company	COD[1] Target	MW Target	Additional Remarks
						• Tender process starts from 2028.
36	Gunung Ciremai	West Java	N/A	N/A	20	• Returned by Chevron in 2013 • Tender failed in year 2016 • Social issues of community rejection • Additional data provided by the Geological Agency in 2021
37	Lainea	Southeast Sulawesi	N/A	N/A	20	• Tender failed in year 2019. • Proposed additional data collection by the Geological Agency
38	Sumani	West Sumatra	N/A	N/A	20	• Planned for government drilling in 2024 by Geological Agency • Tender process starts from 2026. • IPB (*Izin Panas Bumi*) granted target in 2027.
39	Sipoholon Ria-Ria	North Sumatra	N/A	N/A	20	• WKP established based on the Geological Agency's survey results. • Additional data provided by the Geological Agency in 2022 • Planned for government drilling in 2025 by Geological Agency • Tender process starts from 2027. • IPB (*Izin Panas Bumi*) granted target in 2029.
40	Nage	East Nusa Tenggara	N/A	N/A	20	• Already drilled two (2) wells through government drilling in 2021 by Geological Agency • Tender failed in 2023. • Proposed for re-auction.
41	Wae Sano	East Nusa Tenggara	N/A	N/A	N/A	• Government drilling by PT SMI not implemented due to community rejection. • World Bank withdrawal • PT SMI requests a replacement WKP

Table 2: List of Geothermal Development Project 2023 - 2030 (EBTKE, 2023b; PLN, 2021)

No.	Geothermal development drilling project	Province	Geothermal Company	COD Target[2]	MW Target	Additional Remarks

23	Jaboi #3	Aceh	PT Sabang Geothemal Energy	2030	2.5	-

This diverse range of horsepower availability indicates a robust capability for various drilling/workover demands. The smaller rigs, like the 550 HP constituting 14 rigs, and the 750 HP with 5 rigs, demonstrate versatility in the inventory, ensuring that different drilling requirements can be met efficiently.

This detailed inventory assessment is critical for strategic planning, as it ensures that drilling/workover operations can be matched with appropriate rig capacities, optimizing both performance and cost. The presence of high-capacity rigs in significant numbers also suggests an ability to undertake more demanding drilling operations, which may be required in challenging geothermal developments.

No	Rig Size	No of Rig	%
1	150 HP	1	0.75%
2	250 HP	3	2.26%
3	300 HP	2	1.50%
4	350 HP	36	27.07%
5	400 HP	2	1.50%
6	450 HP	4	3.01%
7	500 HP	2	1.50%
8	550 HP	14	10.53%
9	630 HP	1	0.75%
10	650 HP	3	2.26%
11	700 HP	2	1.50%
12	750 HP	5	3.76%
13	800 HP	4	3.01%
14	1000 HP	16	12.03%
15	1500 HP	20	15.04%
16	1700 HP	1	0.75%
17	1750 HP	1	0.75%
18	2000 HP	16	12.03%
Total Observed Land Rig		133	

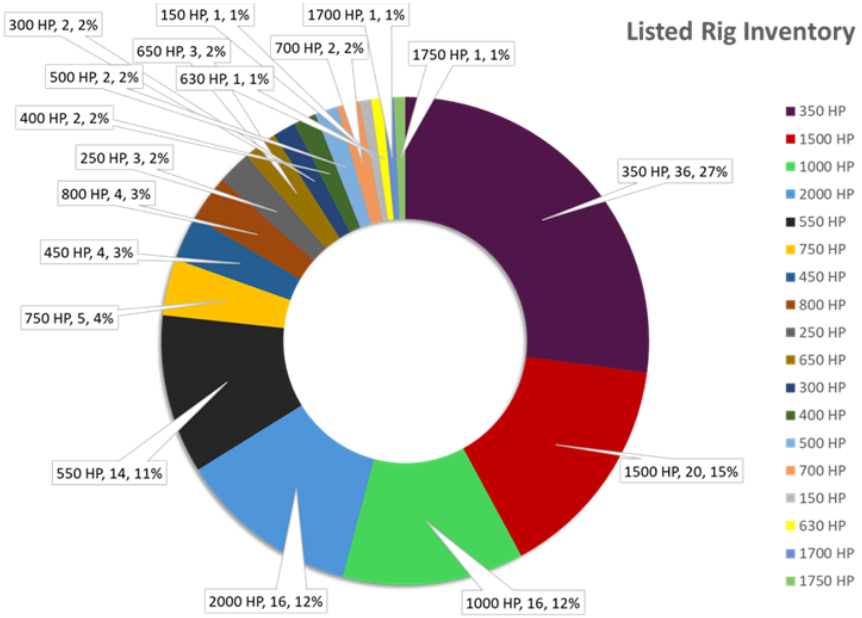

Figure 1: Summary of Current Rig Inventory in Indonesia (Modified from Hartono, 2023)

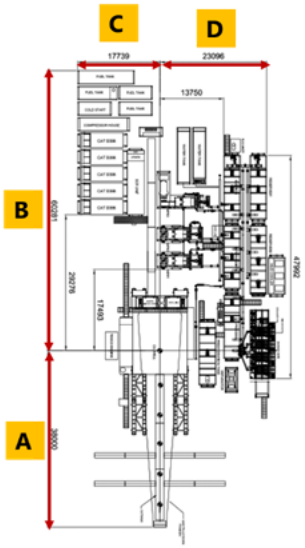
The Figure 2 shows the typical of required footprint of drilling rig in Indonesia. It presents an overview of the spatial requirements for different rig sizes, a crucial factor in planning and preparing drilling sites. It delineates the length and width dimensions needed for rigs ranging from 750 HP to 3000 HP, converting these into the total area in square meters necessary for the rig setup.

For instance, a 1000 HP rig with two joints necessitates a space measuring 62.4 meters in length and 37.0 meters in width, with typical required area of 2308.8 square meters. This contrasts with the same 1000 HP rig with three joints, which requires a substantially larger area of 3803.8 square meters due to its increased length and width.



Rig Size	Length, m A + B	Width, m C + D	Area, m2 Only Rig Eq.
750 HP	52.2	35.5	1853.1
750 HP	56.3	17.3	974.0
1000 HP, 1 joint	53.2	47.1	2505.7
1000 HP, 2 joints	**62.4**	**37.0**	**2308.8**
1000 HP, 3 joints	91.0	41.8	**3803.8**
1200 HP, Ideal Rig, 2 Joints	82.9	18.9	**1566.8**
1500 HP	98.2 102.7	40.8 35.0	**4006.6** **3594.5**
1800 HP	82.0	47.7	**3911.4**
2000 HP	89.0	37.0	**3293.0**
3000 HP	62.2	57.8	**3595.2**

- All rig with **3 joints rig mast** → need more **3300 m2**
- Rig with **2 joints Rig mast** → need only **2300 m2** or **30% smaller area**

Figure 2: Summary of Typical Required Footprint for Drilling Rig in Indonesia (Modified from Hartono, 2023)

A noteworthy observation is the comparison between rigs with different mast joint counts: those with three joints require over 3300 square meters, while rigs with two-joint masts demand approximately 30% less space, around 2300 square meters. This information is pivotal for drilling operations where site constraints exist, and it assists in logistical planning, ensuring that the chosen rig will fit within the available area, aligning with the operational and environmental parameters of the project site in Indonesia

From 133 input data of technical specification of drilling rig, Hartono (2023) summarizes the technical rig specification as presented in Table 3. The data are categorized by the rigs' rated drilling depth, mast capacity, rotary table dimensions, mud pump horsepower, mud tank volumes, and Top Drive System (TDS) sizing, offering a comprehensive snapshot of the equipment's capabilities.

Table 3: Rig Specification Summary (Modified from Hartono, 2023)

Capacity (Min-Max)	Unit	650	700-850	1000-1150	1200-1340	1500	1700-1800	2000
Rated Drilling Depth (Written Capacity from Contractors)	Meter	1800	2500 3993	3000 4100	3700 5000	**3500 6095**	**5100 9144**	**3500 6700**
Adjusted Rated Drilling Depth (Based on Hartono, 2023)	Meter	-	1400 2100	**2500 3300**		**3500 6095**	**5100 9144**	**3500 6700**
Mast Capacity (Hook Load)	klbs	350 400	400 500	**440 650**	**441 672**	675 769	850 1000	975 1250
Rotary Table Opening	Inch	17.5 27.5	20.5 27.5	27.5	27.5 37.5	27.5 37.5	37.5	37.5
Rotary Table Height	Meter	**4.9 5.5**	**4.9 7.6**	**5.7 10.25**	**7.71**	6.1 9.1	8.2 9.4	8.2 9.1
Mud Pumps	HP	1000 1300	900 1300	1000 1600	1000 1300	1300 1600	1300 1600	1300 1700
Mud Tanks	Bbls	500 1000	750 1230	1050 1547	1383 2100	1000 2400	1080 1960	1476 1812
TDS Sizing	Ton HP	-	**250 Ton 600 HP**	**350 Ton 800 HP**		**350 Ton 800 - 1000 HP**	**500 Ton 1000 – 1200 HP**	**500 Ton 1000 – 1200 HP**

In the observed capacity brackets, ranging from 650 HP to 2000 HP, the contractors' written capacities are juxtaposed with adjusted depths based on Hartono's 2023 analysis. These adjustments bring to light the practical operational depths, which are notably different from the written specifications. For example, while a rig with a capacity of 700-850 HP is initially rated to reach depths of 2500 meters, Hartono's adjustments indicate a reduced effective depth of 1400 to 2100 meters, which is vital for setting realistic project expectations.

Mast capacities, essential for determining the weight a rig can handle, range from 350 K-Lbs for the lower-end rigs to a substantial 1250 K-Lbs for the highest capacity rigs. This specification is crucial for safety and efficiency considerations during drilling operations.

The rotary table opening, another critical dimension, shows a variation from 17.5 inches (which up to 37.5 inches, impacting the size of the equipment that can be used on the rig. The height of these tables also varies, with some rigs offering up to 10.25 meters, which may influence the choice of rig based on the drilling environment and the spatial constraints of the site.

Mud pumps, which are integral for circulating drilling fluid, show a range in horsepower from 900 to 1700 HP, providing insights into the fluid circulation capabilities of each rig. Similarly, mud tank capacities are delineated, from 500 barrels for the smallest rigs up to 2400 barrels for larger setups, essential for managing the volumes of fluid necessary during the drilling process.

Finally, the TDS sizing, which pertains to the mechanical device used to facilitate the drilling process, is listed, though some entries are not specified. The available data, however, indicate sizes up to 500 tons and power up to 1200 HP, reflecting the operational range of the rigs.

This summary of rig specifications underscores the diversity of drilling equipment available, each with specific features tailored to various drilling requirements. The detailed categorization assists project managers and

technical teams in identifying the appropriate rig for their unique drilling objectives, ensuring that all operational aspects are optimally aligned with the technical demands of geothermal drilling projects.

2.2 Summary of Geothermal Drilling Contractors in Indonesia

Table 4 presents an overview of the geothermal drilling contractors operating in Indonesia. It categorizes these entities based on the type of services, goods, or materials they offer, and briefly explain the potential procurement challenges faced in each type of services, goods or material. It should be noted that the potential contractor or provided in Indonesia that might be unidentified on this study.

A crucial aspect outlined in this sub-section is the potential procurement challenges. These challenges encompass issues related to logistical complexities, quality control, compliance with environmental standards, and the effectiveness of service delivery. Such challenges can significantly impact project timelines and costs, highlighting the need for strategic planning and management in contractor selection and procurement processes.

Table 4: List of Geothermal Drilling Contractors in Indonesia

No.	Type of services, goods, or materials	Potential contractor or provider in Indonesia	Potential procurement challenges
1.	Drilling rig	**STANDARD AND BIG HOLE WELL SIZE (ROTARY RIG):** 1. PT Daya Alam Tehnik Inti (DATI) 2. PT Plumpang Rayah Anugrah (PRA) 3. PT Pertamina Drilling Services Indonesia (PDSI) 4. PT ELNUSA 5. PT Bormindo Nusantara (BORMINDO) 6. PT Asia Petrocom Services (APS) 7. PT Alam Bersemi Sentosa (ABS) 8. PT Apexindo Pratama Duta 9. PT Exspan Petrogas Intranusa (EPI) 10. PT Great Wall Drilling Asia Pacific (GWDC) 11. KS Drilling 12. PT Remaja Bangun Kencana (Rabana) 13. PT Wijaya Bangun Remaja (WBR) 14. PT Eastern Drilling Indonesia Jaya 15. PT Roda Drilling Nusantara (RDN) 16. PT. Tiga Lestari Energi (TLE) 17. PT Harmand Intimarin Indonesia **SLIMHOLE – Small Rotary, Multipurpose and Coring Rig**: 1. PT Petrotec Guna Perkasa 2. PT Boart Longyear 3. PT Integra Oilfield Services 4. PT Bormindo Nusantara 5. Federal International 6. PT Surveyor Indonesia – PT Tridiantara 7. PT Bintang Mandiri Perkasa Drill 8. Iceland Drilling 9. PT Asia Drill Bara Utama 10. PT Bauer Pratama Indonesia 11. PT Parts Sentra Indomandiri 12. PT Asia Petrocom Services (APS)	**STANDARD AND BIG HOLE WELL SIZE** • Rig availability is often defined by the market conditions of the oil and gas industry, which are influenced by fluctuations in oil prices. This market is shared with oil and gas projects, so when oil prices are high, oil and gas companies typically conduct aggressive drilling campaigns to increase production (Purba, et al., 2020a). • Higher oil prices generally lead to not only reduced availability of rigs in the market, but also increasing the rig rental rate. • Rig is the largest cost component in the drilling project, when rig is under IDS leader (Service company) the rate might be higher than usual that lead to significant incremental of drilling cost. • The number of wells might impact significantly to the rig rental rate • Rig company that has experiences in geothermal drilling project are limited. • Several contractors has poor historical safety/environmental records. **SLIMHOLE RIG CHALLENGES** • Experienced coring rig contractors for geothermal projects in Indonesia are limited, hence only a few can meet the technical and safety requirements (for instance, the use of a Blowout Preventer (BOP)). • Importing rigs from abroad faces the challenge of high costs due to the uncertainty in the number of wells to be drilled. Therefore, if the cost of importing these rigs is based solely on a limited number of wells, it will be excessively high.
2.	Directional Drilling	1. Schlumberger 2. Halliburton 3. Scientific Drilling Indonesia (SDI) International 4. Parama Data Unit (PDU) 5. Baker Hughes	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. Most likely, the higher the oil price the less available the reliable unit in the market.

3	Cementing services	1. Schlumberger 2. Halliburton 3. Baker Hughes 4. Duta Wisesa Servisindo (DWS) 5. China Oilfield Services Limited (COSL)	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. Most likely, the higher the oil price the less available the reliable unit in the market. • The company and personnel that has experience in geothermal drilling project are limited.
4	Drilling fluid/mud services	1. MI Swaco - Schlumberger 2. Baroid – Halliburton 3. Baker Hughes 4. PT Huile Indonesia	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. Most likely, the higher the oil price the less available the reliable unit in the market. • The company and personnel that has experience in geothermal drilling project are limited.
5	Mud logging	1. Parama Data Unit (PDU) 2. Pakarti Rekayasa Utama (Parama) 3. PT DHI Excellence Logging (Exlog) 4. Promosindo Midia Tenaga (PMT)	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. Most likely, the higher the oil price the less available the reliable unit in the market.
6	Wireline logging and explosive Handling	1. Schlumberger 2. Halliburton 3. Baker Hughes 4. PT Wahana Kerja Indonesia 5. Tiger Energy 6. Expro 7. NPS 8. SABS	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. Most likely, the higher the oil price the less available the reliable unit in the market. • There are only a few companies that possess logging equipment with high-temperature ratings.
7	Aerated drilling	1. PT Air Drilling Associates (ADA) Indonesia 2. Alfapilar 3. PDSI 4. KAL	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. Air drilling and well testing/stimulation also influenced by oil and gas as air drilling is typically for Managed Pressure Drilling (MPD) operation in oil and gas drilling for underbalance operation • The number of suppliers is limited, with ADA being the current major player and facing limited competition. As a result, the pricing is highly uncompetitive.
8	Casing and liner Provision	1. PT Citra Tubindo TBK (Vallourec) 2. PT Seamless Pipe Indonesia Jaya (SPIJ) / Tenaris 3. PT Tridaya Esa Pakarti 4. PT Telaga Mas Mulia (TMM)	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. Availability of raw material may also impact the price. • Issues arise with domestic content requirements (TKDN) especially when funding comes from international financial institutions, which prohibit local content stipulations during procurement. • Has long lead time. The lead time is estimated 8 – 12 months at the latest for common specification. For special specification such as CRA (Corrosion Resistance Alloy) might take up to 18 months
9	Casing Running	1. PT Carana Bunga Persada 2. PT Varcoindo Bina Jaya 3. PT Indo Kaya Energi	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation
10	Casing inspection	1. PT. Sucofindo (Persero) 2. PT. Sekawan Eka Sejati (SES) 3. PT. Grace Technic 4. PT Radiant Utama Interinsco 5. Akura Bina Citra 6. Tuboscope 7. OMS Oilfield Service (OMSOS) 8. PT WIDE & PIN Engineering & Inspection 9. PT Inspektindo Sinergi Persada 10. PT Tridaya Esa Pakarti	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation.
11	Fishing and milling Tools	1. Baker Hughes 2. PT Sustraco Adikreasi 3. Schlumberger 4. Expro	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation.
12	Drilling Bit	1. National Oilwell Varco (NOV) 2. Baker Hughes 3. Smith – Schlumberger 4. Halliburton 5. Imeco	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. • Some companies do not allow/reluctant to consignment basis agreements, therefore necessitating outright purchases, which in turn impacts efficiency and the total cost
13	H2S Services	1. PDSI 2. Rutledge 3. Dyfco 4. Fergaco Indonesia 5. Total Safety Engineering (TSE) 6. Menara Inti Energi	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation.

14	Drilling Waste Management	1. MI Swaco - Schlumberger 2. Scomi Oiltools 3. PPLI 4. HOLCIM	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation.
15	Fuel Supply	1. Pertamina 2. PT Berdikari Jaya Bersama 3. Total 4. Shell	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation.
16	Well testing and stimulation	1. Thermochem 2. NMS 3. CBN	• Limited players/available contractors
18	Wellhead, Master Valve, X-Mast Tree, and accessories	1. PT Nurman Mitra Sentosa (NMS) 2. Sagatrade 3. DEU (Kyokuto) 4. FMC 5. IKS-TIX 6. Imeco Inter Sarana 7. Wefic Group	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation. Availability of raw material may also impact the price. • Has long lead time. The lead time is estimated 8 – 12 months at the latest for common specification. • Issues arise with domestic content requirements (TKDN) especially when funding comes from international financial institutions, which prohibit local content stipulations during procurement.
19	Drilling Insurance	1. Tugu Mandiri 2. Aswata 3. Howden	-
20	Rig Inspection	1. PT. Sucofindo (Persero) 2. PT. Akordia Venatama 3. PT. Ansari Jaya Sakti (AJS) 4. PT. OCS Indonesia 5. Moduresources 6. PT Inspektindo Sinergi Persada 7. PT Indo Yasa Prima 8. PT PJ-Tek Mandiri 9. Applus	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation
21	Tubular Inspection	1. Tuboscope 2. Bureau Veritas (BV) 3. OMS Oilfield Service (OMSOS) 4. Akura Bina Citra 5. PT Grace Technic 5. PT Besmindo Andalas Semesta	• Usually defined by market condition of oil and gas, which influenced by the oil price fluctuation

As shown in Figure 6, In the landscape of geothermal exploration in Indonesia, procurement challenges for both standard and big hole rotary rigs, as well as slimhole rigs, present significant hurdles. For the larger rigs, costs are a primary concern, often exacerbated when rigs are under the leadership of Integrated Drilling Services (IDS) providers, which can push rental rates above average. The overall availability of these rigs is closely tied to the fluctuating oil market, with price hikes leading to aggressive drilling in the oil and gas sector and consequent scarcity and cost increases for geothermal projects. Adding to the complexity, there is a scarcity of contractors with a strong track record in both safety and environmental performance in geothermal drilling.

However, because of conventional rotary rig is commonly used in oil and gas industry, so that there is an impact on the geothermal industry regarding rig availability, especially in Indonesia. In Indonesia, it is uncommon for geothermal companies to own and operate the rig and both industries usually rent the rig and crew from a rig company (Purba, et al., 2020).

In line with this research hypothetic, as explained by Gul & Aslanoglu (2018), If there are any significant incremental on oil price and become higher level than before, oil company frequently do massive drilling campaign aggressively to produce the oil and gas from their field. As illustrated in Figure 4, the implication of this kind of condition, there is a high possibility that many oil and gas company will fully occupy rig for their operation.

The recent surge in oil prices has significantly influenced the demand for rig occupation, as exemplified by the drilling campaign of Pertamina Hulu Rokan (PHR). Since 2022, PHR has been conducting drilling and workover activities on a massive and aggressive scale, operating approximately 60 rigs in parallel within their zone/concession area.

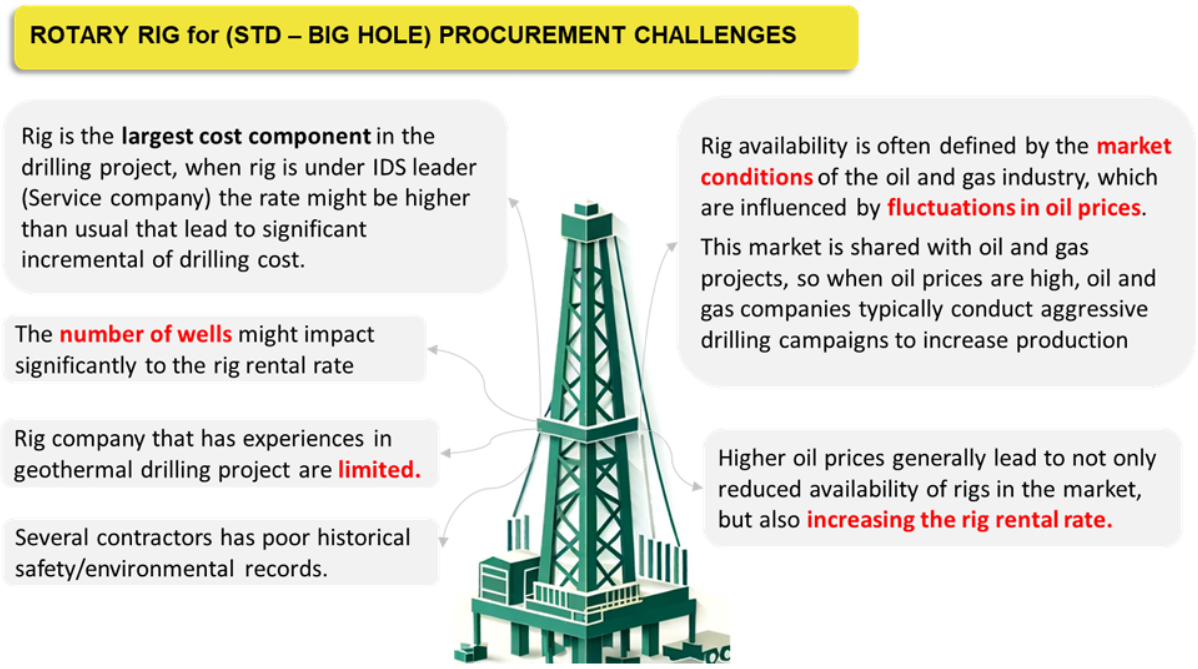


Figure 3: Summary of Rotary Rig Procurement Challenges

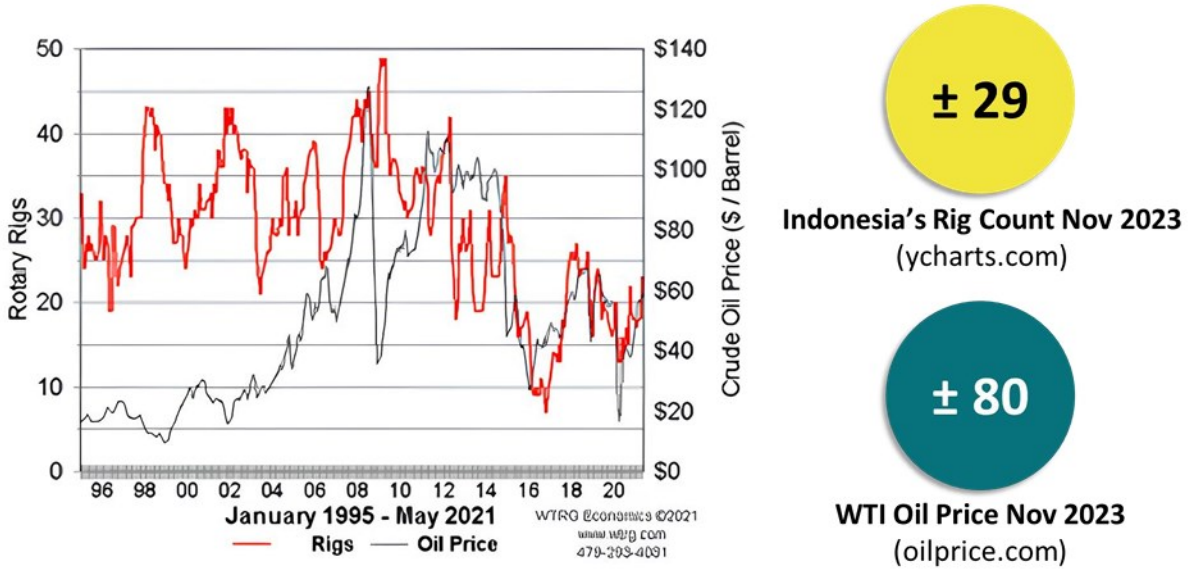

Figure 4: Indonesia's rig count vs oil price. Modified from (Energy Economist, 2021)

Consequently, this situation has created challenges for geothermal companies in securing drilling rigs due to a scarcity and limited availability of proper rig contractors with the suitable capacity required by these companies. Then in such cases, the geothermal company is frequently forced to contract a rig with a capacity greater capacity than required due to a rig availability issue (Purba, et al., 2020).

Conversely, as presented in Figure 5 about slimhole rigs , which are a cost-effective alternative, face their own set of challenges. The pool of contractors with the expertise and equipment to meet the stringent technical and safety standards for geothermal drilling is limited. This situation is further complicated by the high costs associated with importing rigs, a cost that becomes unsustainable if based on a limited number of wells to be drilled.

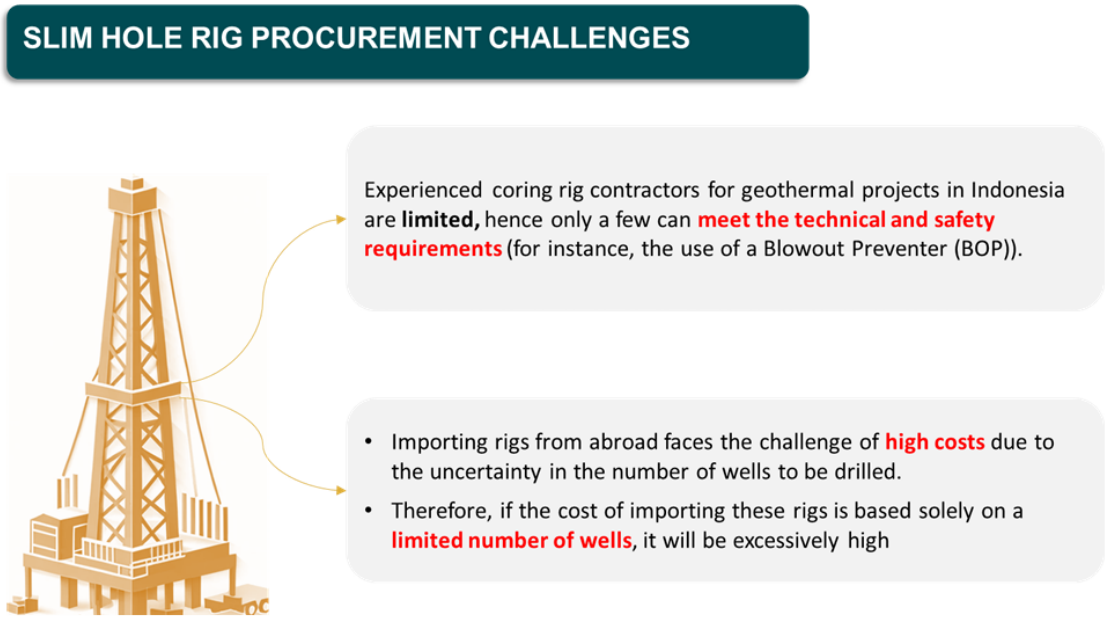

Figure 5: Summary of Slimhole Rig Procurement Challenges (GRG-Geoenergis, 2024)

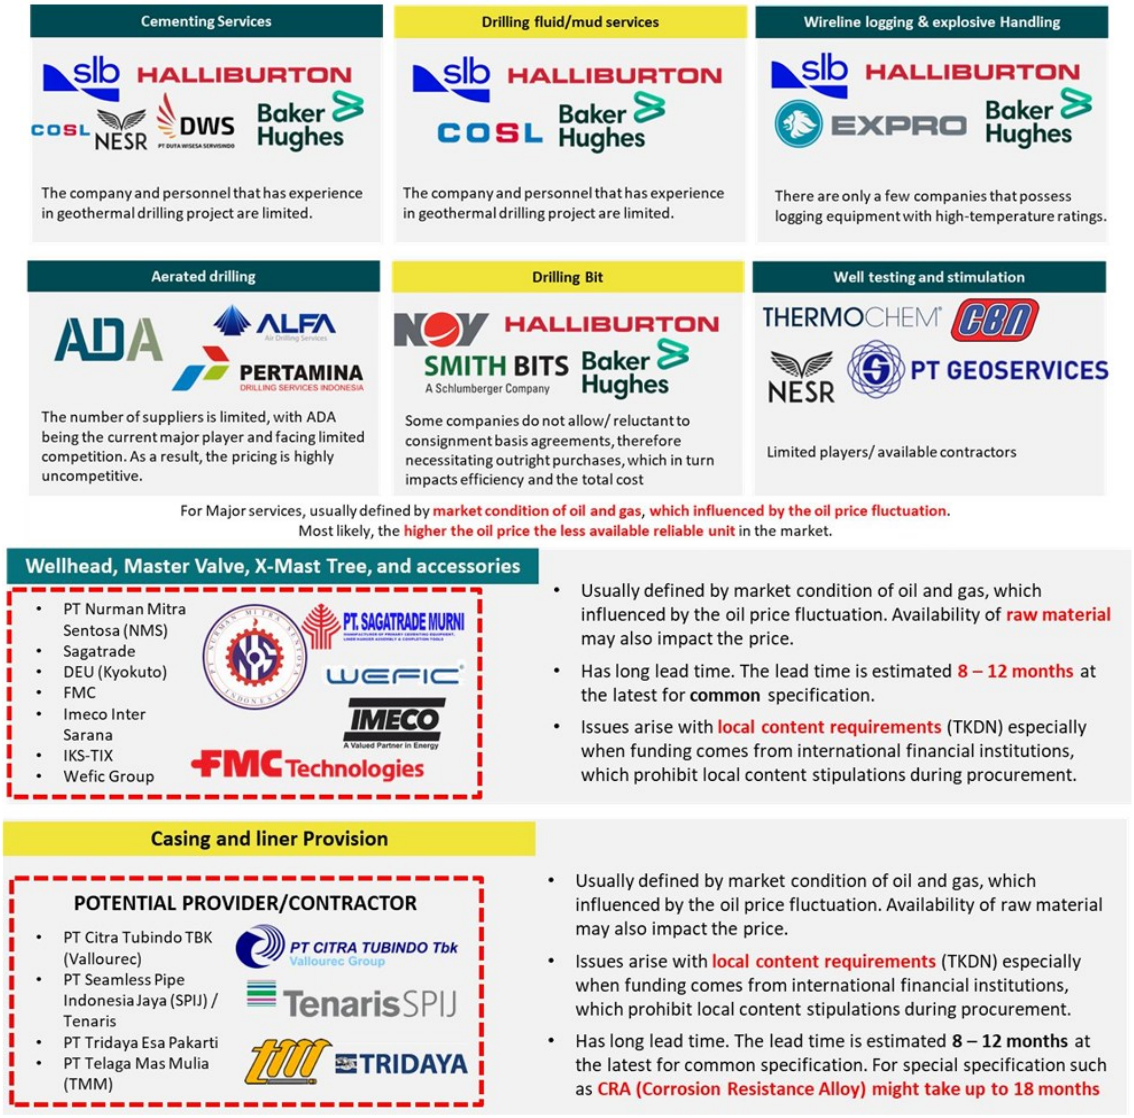

Figure 6: Summary of General Drilling Services Procurement Challenges

Navigating these procurement challenges requires strategic planning and adaptability. Developers must balance the need for cost efficiency with the technical and safety requirements of geothermal drilling, all while operating within a market influenced by the broader energy sector's demands and global price shifts.

The procurement landscape for general drilling services in geothermal exploration presents a multi-faceted challenge as presented in Figure 6, encapsulated by the image detailing the range of services required for a successful operation. Companies such as Schlumberger and Halliburton dominate the space across various service categories, from cementing to drilling fluid services, reflecting a market with limited players. This limited competition is exacerbated by the fact that few companies possess the necessary high-temperature equipment for wireline logging, or have the specific expertise in geothermal projects, further narrowing the options available to developers.

Moreover, the procurement of essential components like drilling bits, well testing, and stimulation services, and even crucial wellhead and x-mass tree accessories, is heavily influenced by the volatile oil market. The fluctuating oil prices not only impact the availability and cost of services but also the reliability of supply. Additionally, the procurement process for casing and liner provision is not immune to these market dynamics, with local content requirements (TKDN) posing additional hurdles, especially when projects are funded by international financial institutions, leading to longer lead times and potential compliance issues.

This procurement environment suggests a need for strategic sourcing, where developers must navigate a complex web of service providers, market conditions, and regulatory requirements to ensure the timely and cost-effective delivery of drilling services.

Based on the analysis in Table 4, Figure 5, and Figure 6 it is observed that several service providers face various challenges during the procurement and tender process for geothermal drilling projects in Indonesia. The procurement and tender challenges are summarized in Figure 7.

Figure 7: Summary of Procurement Challenges in Geothermal Drilling Project

3. MARKET SURYVEY AS THE RELIABLE METHOD FOR INVESTIGATING DRILLING MARKET CONDITION

Market survey for a geothermal drilling/workover project is a comprehensive analysis aimed at gathering and evaluating information pertinent to the drilling sector's current market conditions. This process includes assessing the availability and costs of crucial equipment such as drilling rigs, which are often influenced by the oi price. It also involves the careful evaluation of potential contractors and suppliers, considering their capabilities, financial stability, and adherence to safety and environmental standards.

The market survey is crucial for project planners and decision-makers, as it provides essential insights for informed decision-making regarding equipment procurement, contractor selection, budgeting, and overall risk management, thereby enhancing the likelihood of a project's success.

A critical key to have a successful procurement for the project is by understanding the current market condition as well as the ongoing government regulation related to the procurement process. Strategy of the procurement

process will be easily developed by having a good mapping on those market condition and government procurement regulations. For instance, in the period of low demand due to plunging of oil and gas price, the geothermal company could optimize the contract scopes, remuneration strategy, and performance target leverage to be on geothermal developer company side. Meanwhile, during high demand period it is necessary to balance the leverage in order to attract potential bidders in joining the competitive tender process.

The market survey was conducted with a distinct separation of services deemed critical to the project timeline. For example, certain long lead items (LLI) were identified as top priority and marked as the 1st (first) priority to be completed prior other services. As such, within the methodology of the market survey, priorities are categorized as follows:

1. Long Lead Items, which consist of casing provision, liner hanger, wellhead and master valve, also casing accessories.
2. Drilling rig bundling, usually consist of drilling rig, top drive, H2S, water pump, and heavy equipment.
3. Major drilling services, which usually consist of drilling fluid services, aerated drilling, directional drilling & MWD, cementing services, drilling bit, solid control equipment, mud logging unit, wireline logging, fuel supply.
4. Other supporting services such as casing inspection, tubular inspection, rig inspection, acidizing, well testing, civil work, and others.
5. Logistic and manpower services, which usually consist of project management team and on-site supervision (personnel

The common approach to conducting a market survey involves issuing a Request for Information (RFI) or Request for Quotation (RFQ). The market survey process usually initiates with the establishment/preparation of the well design and drilling program for the basis generating detailed lists of required services and materials. If the technical specifications are not yet determined, a list of potential suppliers or bidders is created to refine the specifications. If the specs are fixed, a technical specification survey is conducted.

Documents are then prepared to engage potential service providers in a market survey. Responses from the survey, in the form of budgetary proposals, are received and compiled into a database. This database is used to create a budgetary estimate, leading to the generation of an Owner Estimate (OE) report, which follows the development of the commercial form and the scope of work. The entire process is designed to ensure that the OE is based on thorough market research and accurate specifications. The workflow is designed to be dynamic, with a continuous loop back to the generation of OE, reflecting the iterative nature of project planning and execution. The common approach of the market survey is illustrated in Figure 8.

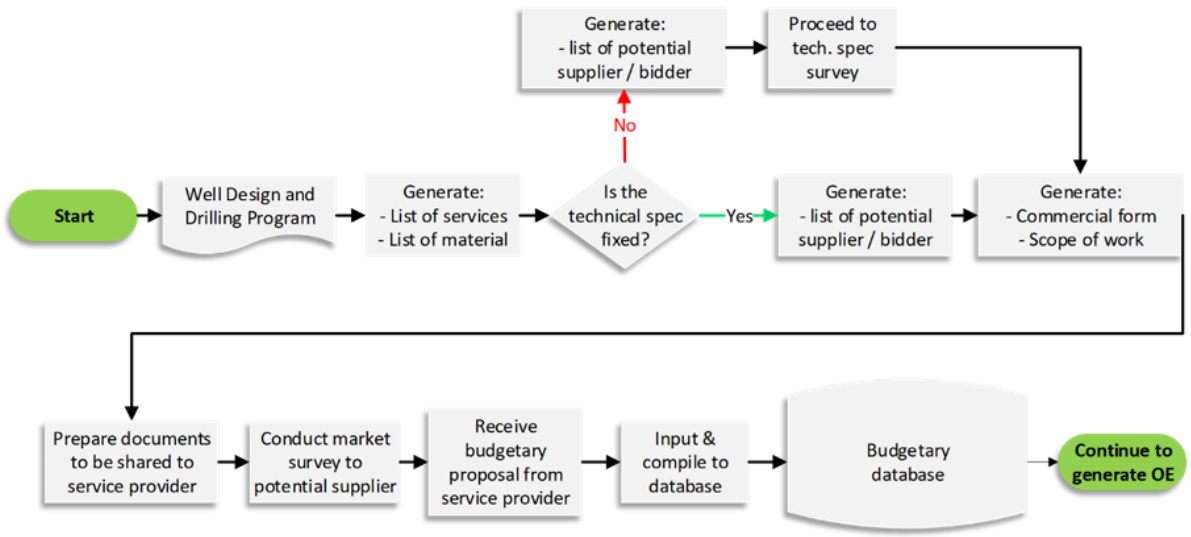

Figure 8: General Market Survey for Generating Engineering / Owner Estimate Workflow for Geothermal Drilling Project

The detail of the market survey methodology for generating engineering / owner estimate is explained below:

1. Obtaining/developing well schematics and general drilling program

This document is prepared by the technical team containing information on well design and drilling activities to be conducted. Some information contained in this document such as the required rig capacity, casing size, casing

shoe depth, Bottom Hole Assembly (BHA) configuration, and so on. This document is the basis used for determining each item in the BEP.

2. Compiling a list of services and materials

The list of services and materials is a document detailing the specifications required for drilling activities. This list is compiled based on the well scheme and the general drilling program previously prepared. At this stage, it is crucial to confirm with the technical team their confidence in the established well scheme and drilling program.

Significant changes in these plans may necessitate changes to the list of services and materials. Should the technical team express low confidence in the existing technical specifications, conducting a technical specification survey may be warranted. Figure 9 is an example of some well materials and well services collected based on well needs.

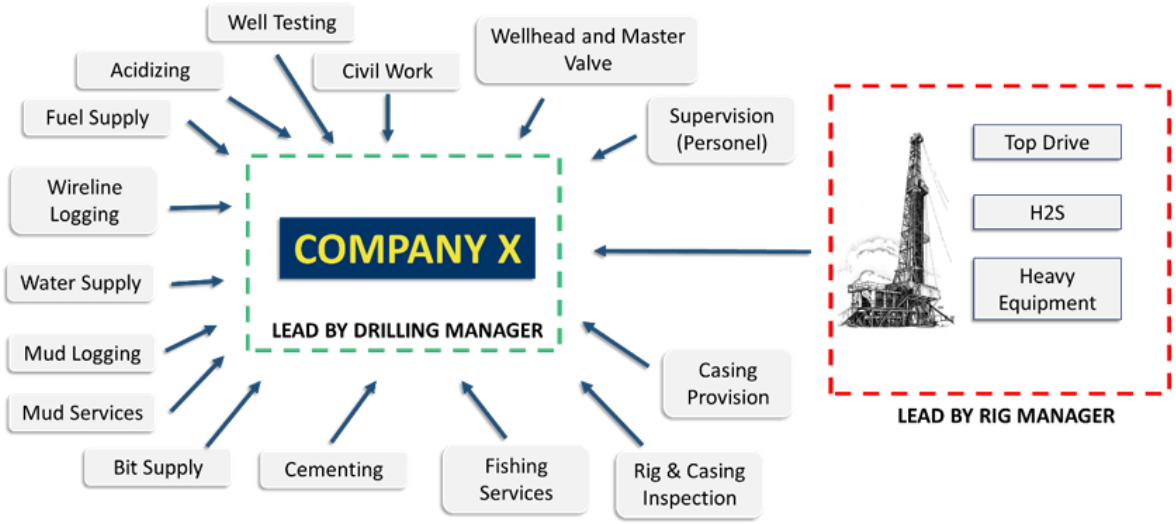

Figure 9: Example of Drilling Services List with Discrete Contract Type

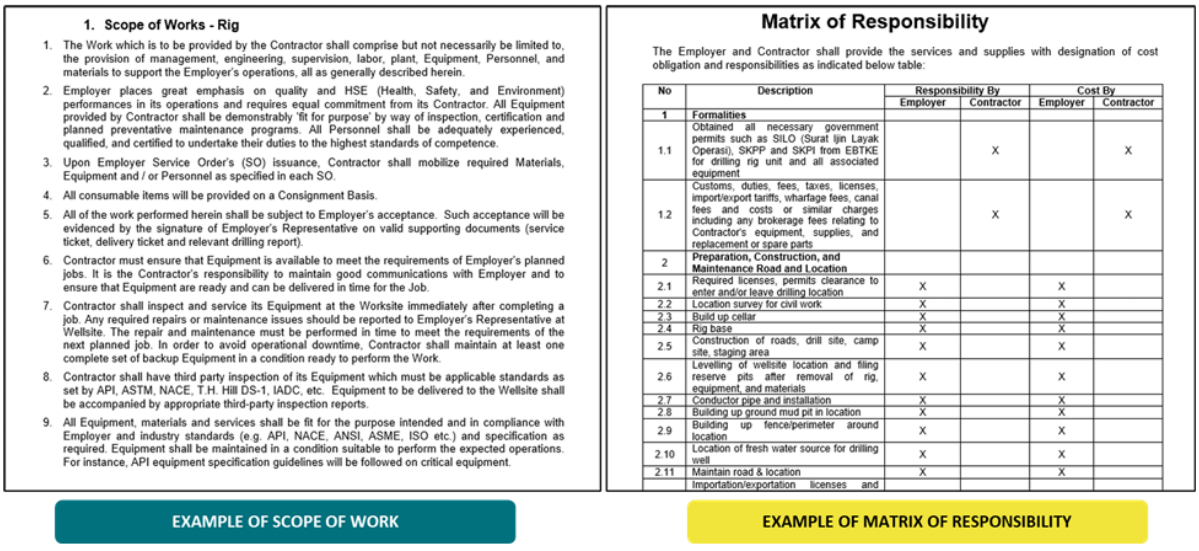


1. Scope of Works - Rig

1. The Work which is to be provided by the Contractor shall comprise but not necessarily be limited to, the provision of management, engineering, supervision, labor, plant, Equipment, Personnel, and materials to support the Employer's operations, all as generally described herein.
2. Employer places great emphasis on quality and HSE (Health, Safety, and Environment) performances in its operations and requires equal commitment from its Contractor. All Equipment provided by Contractor shall be demonstrably 'fit for purpose' by way of inspection, certification and planned preventative maintenance programs. All Personnel shall be adequately experienced, qualified, and certified to undertake their duties to the highest standards of competence.
3. Upon Employer Service Order's (SO) issuance, Contractor shall mobilize required Materials, Equipment and / or Personnel as specified in each SO.
4. All consumable items will be provided on a Consignment Basis.
5. All of the work performed herein shall be subject to Employer's acceptance. Such acceptance will be evidenced by the signature of Employer's Representative on valid supporting documents (service ticket, delivery ticket and relevant drilling report).
6. Contractor must ensure that Equipment is available to meet the requirements of Employer's planned jobs. It is the Contractor's responsibility to maintain good communications with Employer and to ensure that Equipment are ready and can be delivered in time for the Job.
7. Contractor shall inspect and service its Equipment at the Worksite immediately after completing a job. Any required repairs or maintenance issues should be reported to Employer's Representative at Wellsite. The repair and maintenance must be performed in time to meet the requirements of the next planned job. In order to avoid operational downtime, Contractor shall maintain at least one complete set of backup Equipment in a condition ready to perform the Work.
8. Contractor shall have third party inspection of its Equipment which must be applicable standards as set by API, ASTM, NACE, T.H. Hill DS-1, IADC, etc. Equipment to be delivered to the Wellsite shall be accompanied by appropriate third-party inspection reports.
9. All Equipment, materials and services shall be fit for the purpose intended and in compliance with Employer and industry standards (e.g. API, NACE, ANSI, ASME, ISO etc.) and specification as required. Equipment shall be maintained in a condition suitable to perform the expected operations. For instance, API equipment specification guidelines will be followed on critical equipment.

EXAMPLE OF SCOPE OF WORK

Matrix of Responsibility

The Employer and Contractor shall provide the services and supplies with designation of cost obligation and responsibilities as indicated below table:

No	Description	Responsibility By		Cost By	
		Employer	Contractor	Employer	Contractor
1	**Formalities**				
1.1	Obtained all necessary government permits such as SILO (Surat Ijin Layak Operasi), SKPP and SKPI from EBTKE for drilling rig unit and all associated equipment		X		X
1.2	Customs, duties, fees, taxes, licenses, import/export tariffs, wharfage fees, canal fees and costs or similar charges including any brokerage fees relating to Contractor's equipment, supplies, and replacement or spare parts		X		X
2	**Preparation, Construction, and Maintenance Road and Location**				
2.1	Required licenses, permits clearance to enter and/or leave drilling location	X		X	
2.2	Location survey for civil work	X		X	
2.3	Build up cellar	X		X	
2.4	Rig base	X		X	
2.5	Construction of roads, drill site, camp site, staging area	X		X	
2.6	Levelling of wellsite location and filing reserve pits after removal of rig, equipment, and materials	X		X	
2.7	Conductor pipe and installation	X		X	
2.8	Building up ground mud pit in location	X		X	
2.9	Building up fence/perimeter around location	X		X	
2.10	Location of fresh water source for drilling well	X		X	
2.11	Maintain road & location	X		X	
	Importation/exportation licenses and				

EXAMPLE OF MATRIX OF RESPONSIBILITY

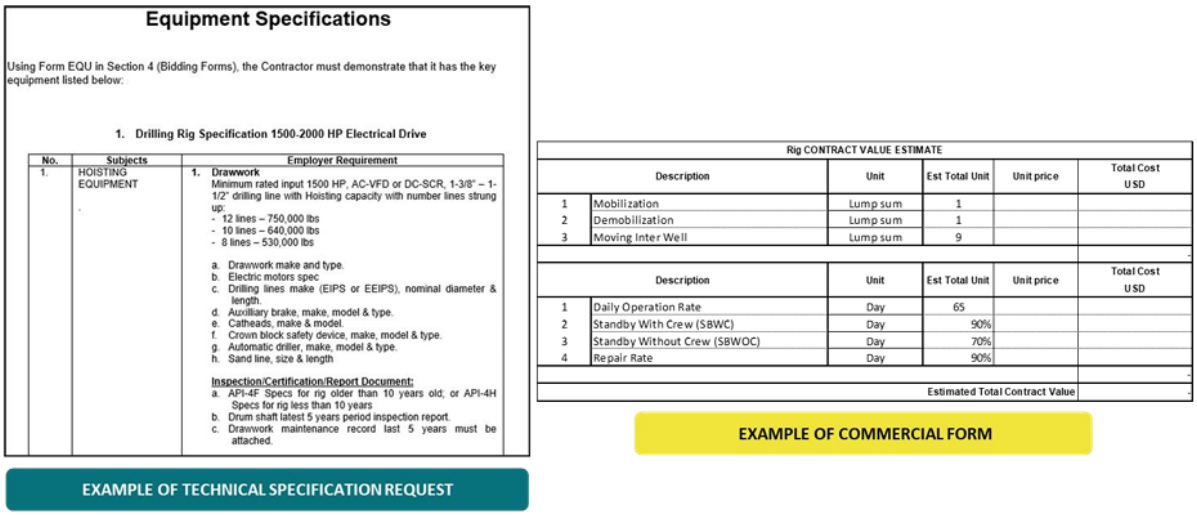
Figure 10: Example of rig scope of works (left), Example of contractor's matrix of responsibility (right).

3. Generate list of potential suppliers / bidders

The list is generated by identifying contractors or suppliers who have previously tendered for similar services and materials in drilling activities. Additionally, an evaluation of each available supplier's capacity in the market to fulfill the required services and materials is conducted. The purpose of this stage is to identify potential suppliers likely to participate in the tender process. Table 4 in previous sub-section shows an example list of potential suppliers.

4. Develop Commercial Form and Scope of Work

The commercial form is a document listing the materials required for procurement, detailing the specifications and quantities that suppliers must adhere to. Conversely, the scope of work document outlines the specific tasks or services to be carried out, including information on the minimum requirements and quantities involved. Figure 10 shows the examples of the contents of the scope of work, and Figure 11 show examples of items depicted in the commercial form.



Equipment Specifications

Using Form EQU in Section 4 (Bidding Forms), the Contractor must demonstrate that it has the key equipment listed below:

1. Drilling Rig Specification 1500-2000 HP Electrical Drive

No.	Subjects	Employer Requirement
1.	HOISTING EQUIPMENT	1. Drawwork Minimum rated input 1500 HP, AC-VFD or DC-SCR, 1-3/8" – 1-1/2" drilling line with Hoisting capacity with number lines strung up. - 12 lines – 750,000 lbs - 10 lines – 640,000 lbs - 8 lines – 530,000 lbs a. Drawwork make and type. b. Electric motors spec c. Drilling lines make (EIPS or EEIPS), nominal diameter & length. d. Auxilliary brake, make, model & type. e. Catheads, make & model. f. Crown block safety device, make, model & type. g. Automatic driller, make, model & type. h. Sand line, size & length Inspection/Certification/Report Document: a. API-4F Specs for rig older than 10 years old; or API-4H Specs for rig less than 10 years b. Drum shaft latest 5 years period inspection report. c. Drawwork maintenance record last 5 years must be attached.

EXAMPLE OF TECHNICAL SPECIFICATION REQUEST

Rig CONTRACT VALUE ESTIMATE

	Description	Unit	Est Total Unit	Unit price	Total Cost USD
1	Mobilization	Lump sum	1		
2	Demobilization	Lump sum	1		
3	Moving Inter Well	Lump sum	9		
					-
	Description	Unit	Est Total Unit	Unit price	Total Cost USD
1	Daily Operation Rate	Day	65

Figure 12: Example of Market Survey Result Database

5. Preparing document for drilling service and material supplier.

This step involves ensuring that the commercial form and scope of work documents for service-material providers are accurate and meet the required information needs. It includes an internal peer-review and re-confirmation with the technical team on specific material-service specifications.

6. Conducting Market Survey

The purpose of the market survey is to gather estimated market prices for the prepared commercial form and scope of work. This involves formal correspondence with listed potential providers, sending them the commercial form and scope of work documents. Providers are expected to reply with price lists that they can accommodate. However, there is a possibility of non-response from some providers, necessitating regular follow-ups by the developer.

7. Compiling Market Survey Database

This database is a compilation of all market survey results. It includes detailed information about the items, responding suppliers, and the prices quoted by them, organized in a table by service-material group. The database's objective is to integrate existing data for easier analysis in subsequent processes. The example of database is illustrated in Figure 12.

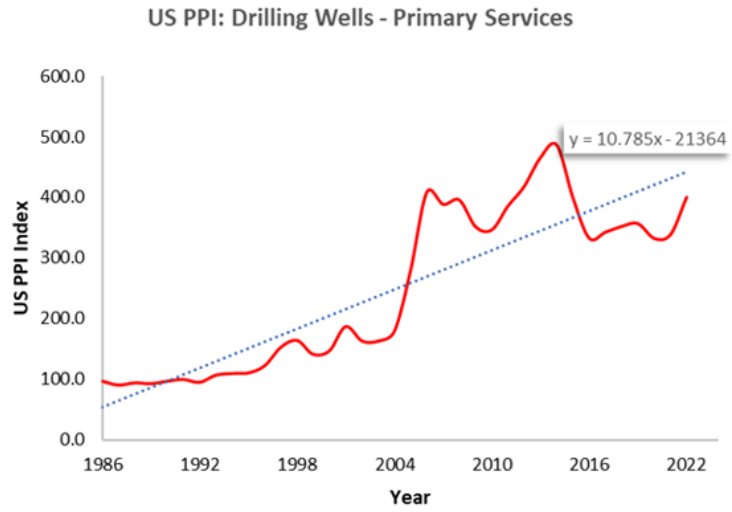
8. Generate Cost Estimate

From the market survey results, the budgetary proposal that have been submitted by respondents are utilized for estimating project cost, also known as the Owner Estimate (OE) / Engineering Estimate. The owner estimate is an estimate of the service-material prices used as a guide for budget preparation and procurement in a drilling project. The importance of determining OE for a project is to help evaluating fairness of price value which offered in tender process.

Generating of an owner estimate (OE) involves leveraging data from an existing database to establish reference values and then calculating the individual and total project costs based on the specified quantities and these reference values. The example of owner estimate results is shown in Figure 14. To analyse the updated price list, the market survey data is reviewed to identify the range of prices, taking note of the lowest, median, average, and highest values. Subsequently, an internal analysis is performed to select the appropriate price for inclusion in the owner estimate. The selection of the price can be based on the following consideration:

- The average value from the market survey may be chosen when there is minimal variation in market prices among suppliers for the same item, indicating that the average price is reflective of the market.
- The median value from the market survey might be more appropriate when there is a wide variation in prices among suppliers, which could render an average price calculation inaccurately high.
- Expert team assessments may be preferable when market price data appears anomalous. In such cases, it is advisable to consult prices from several other drilling projects to derive a more representative price point.

If the geothermal developers already has previous drilling contract prior the upcoming drilling campaign, the owner estimate (OE) also require to be compared with previous contract with adjustment inflation rate for sanity check the fairness of current cost estimates. The common approach for inflation rate adjustment is using US PPI Index of Drilling Industry. As shown in Figure 13 as the example for this research, the cumulative inflation rate from 2021 until 2023 is 1.3 (30%) for the drilling industry. Figure 14 and Table 5 shows the example of Engineering Estimate (EE) / Owner Estimate (OE) results of geothermal drilling project.



Year	Annual	Index (normalize to 2023)
2020	332.1	1.4
2021	338.2	1.3
2022	399.8	1.1
2023	454.055	1

Figure 13: Inflation Factor from US PPI: Drilling Wells – Primary Services

Figure 14: Example-1 of Cost estimation distribution for each service (Adityatama et al, 2023).

It should be noted the there are several challenges associated with generating an accurate or close enough cost estimate for geothermal drilling in Indonesia such as:

- Geothermal drilling requires various services and materials that may be provided by different companies, complicating the estimation of cost for each service/material.
- The drilling industry is tightly linked to the market condition of the oil & gas industry, which will fluctuate the price of the services and goods for drilling depending on the oil price.

This condition is further aggravated by the absence of any accessible geothermal drilling cost database in Indonesia, in contrast with the oil and gas industry that may have several databases such as IHS Markit's Rushmore for cost estimate and performance benchmark. Those difficulties in generating accurate geothermal drilling cost estimates are problematic as drilling is one of the major cost components in the whole geothermal project.

Moreover, several geothermal developers in Indonesia have their own procurement guidelines that may dictate the tender process to be redone if the cost estimate is way below the price quoted by service companies. The time spent redoing the whole procurement process is disadvantageous to the developers especially in the exploration phase, as the exploration duration is limited by the Government in Indonesia. Therefore, having an accurate cost estimate is crucial to preventing such events.

In short, by performing a comprehensive market survey, the geothermal developers can determine the current market condition and accurate cost estimation, which plays crucial roles in the decision-making process for the best procurement strategy. Additionally, with the selective and progressive method in the market survey, it has narrowed down the bias cost data (if any) for some of the major drilling services contract. The proper market survey can be the basis of remuneration strategy which leads to a cost saving in the project and also helps to fit in the project timeline.

4. VARIOUS STRATEGIES FOR INCREASING GEOTHERMAL DRILLING MARET ATTRACTIVENESS AND COMPETITIVENESS

Building upon the strategies for boosting the competitiveness of the geothermal drilling market, we must also consider the pivotal role that international drilling companies play in advancing this sector. The following section, therefore, shifts focus from domestic competitive enhancements to the global stage, where attracting and retaining international expertise becomes paramount. It explores the strategic factors that make Indonesia's geothermal

market appealing to international entities, thus complementing our overarching goal of fostering a more dynamic and competitive industry. The integration of international players not only broadens the technological and operational horizons but also introduces more advanced practices and standards crucial for the sector's growth.

Table 5: Example-2 of Cost estimation distribution for each service

No	Description	Engineering Estimate Results (Total Cost for 2 wells)	ALA-5 Well (1,400 mMD)	ALA-6 Well (1,800 mMD)
1	**DRILLING SERVICES (Well Cost)**	**$17,387,697**	**$8,282,169**	**$9,105,528**
		Rp260,815,447,580	**Rp124,232,532,580**	**Rp136,582,915,000**
1.1	**DRILLING OPERATIONS**	**$11,831,576**	**$5,643,346**	**$6,188,230**
1.1.1	Contract Rig Bundling (Top Drive, Mud Logging Unit, H2S, Drilling Waste, Heavy Equipment and Transportation, Meals & Accommodation, etc) - Include Mob Demob	$6,216,080	$2,929,628	$3,286,452
1.1.2	Mud, Chemical & Engineering Services and Materials	$652,614	$311,173	$341,441
1.1.3	Drilling Bits	$955,261	$477,631	$477,631
1.1.4	Equipment Rentals (Fishing Equipments)	$274,340	$137,170	$137,170
1.1.5	Directional Drilling and Surveys	$1,094,853	$518,910	$575,943
1.1.6	Geothermal Drilling Services (Aerated Drilling, Welding, and Waste Management)	$1,453,244	$686,316	$766,928
1.1.7	Casing Installation (Casing Running Services and Fill Up Equipment)	$261,755	$130,878	$130,878
1.1.8	Cement, Cementing, and Pump Fees	$479,700	$229,777	$249,923
1.1.9	Miscellaneous (Casing Inspection, Tubular Inspection, and Rig Inspection)	$105,729	$52,864	$52,864
1.1.10	Water System (Water Supply Service & Management)	$338,000	$169,000	$169,000
1.2	**FORMATION EVALUATION**	**$657,787**	**$324,560**	**$333,227**
1.2.1	Coring	$245,687	$122,844	$122,844
1.2.2	Open Hole Electrical Logging Services	$240,500	$115,917	$124,583
1.2.3	Logging Tool Run	$171,600	$85,800	$85,800
1.3	**GENERAL**	**$2,836,254**	**$1,288,497**	**$1,547,757**
1.2.4	Supervision	$447,162	$207,611	$239,551
1.2.5	Insurance	$63,000	$27,000	$36,000
1.2.6	Permits and Fees	$166,358	$76,419	$89,939
1.2.7	Other Transportation	$849,333	$384,667	$464,667
1.2.8	Fuel of Drilling Rig and Associated Services	$1,310,400	$592,800	$717,600
1.4	**TANGIBLES** (Casing, Casing Accessories, Well Equipment Surface, Well Equipment Subsurface, Other Tangible Cost)	**$2,062,080**	$1,025,766	$1,036,314
2	Well Testing Services	Rp500,000,000	Rp250,000,000	Rp250,000,000
3	Civil Work	Rp10,000,000,000	Rp5,000,000,000	Rp5,000,000,000
Total (Rp)		**Rp271,315,447,580**	**Rp129,482,532,580**	**Rp141,832,915,000**
Total (USD)		**USD 18,087,697**	**USD 8,632,169**	**USD 9,455,528**

4.1 Strategies for Increasing Market Competitiveness

The geothermal drilling sector in Indonesia presents unique challenges and opportunities for enhancing market competitiveness. The aim of this sub-section is to evaluate and propose strategies that can intensify competition within Indonesia's geothermal drilling market. This encompasses a thorough assessment of bidding approaches, ranging from discrete to bundled contracts, and their respective impacts on risk and performance.

Additionally, the sub-section seeks to address the significance of updated market surveys tailored to preferred contract types and the importance of timing in the tendering process. Moreover, the potential cost benefits of well bundling and the influence of the number of wells on rig rental rates will be scrutinized. The objective is to equip stakeholders with a clear understanding of the variables that can enhance market dynamics and drive cost-effective procurement.

Figure 15 provide the illustration summary and Table 6 provide the brief explanation of various options to increase geothermal drilling market competitiveness.

4.2 Strategies Strategy for Increasing Participation of International Drilling Companies

The objective of the sub-section is to identify and analyze strategic factors that could enhance the attractiveness of Indonesia's geothermal market to international drilling firms. This will involve examining the impact of contract currencies, the potential cost benefits associated with drilling multiple wells, the readiness of drilling locations, and the reputational considerations of job owners in terms of safety, environmental stewardship, and payment reliability. The sub-section aims to provide actionable insights that could lead to increased international engagement, contributing to the growth and success of Indonesia's geothermal industry. Figure 16 provide the visualization summary and Table 7 provide the brief explanation of various options to increase geothermal drilling market competitiveness.

The Indonesian geothermal drilling market presents significant opportunities amidst its challenges. By implementing strategic initiatives to enhance market competitiveness and attract international participation, Indonesia can leverage its geothermal potential more effectively. Stakeholders, including government bodies, local and international companies, and investors, must collaborate to foster a conducive environment for the growth of this sector.

Figure 15: Summary of Various Options to increase geothermal drilling market competitiveness

Figure 16: Summary of Various Options to increase participation of international drilling companies

Table 6: Various options to increase geothermal drilling market competitiveness.

Strategy	Impact on Market Competitiveness	Benefits	Challenges	Remarks
Develop Open Access Centralized Integrated Vendor Database (CIVD) for Open Tender Announcement of geothermal drilling project	The development of an Open Access Centralized Integrated Vendor Database (CIVD) for open tender announcements in the geothermal drilling projects in Indonesia presents a significant advancement in the procurement process. The CIVD is a widely adopted system within the oil and gas industry, particularly in operations managed by SKK Migas. This platform is renowned for its transparency, providing exhaustive details in tender documentation, including the scope of work, well numbers, drilling depths, and contract specifications. This centralized database streamlines the tender process by providing a single, accessible platform where all necessary procurement information, including prequalification invitations, public auction details, and a comprehensive procurement list, is available. The adoption of the CIVD ensures that all stakeholders have equal access to critical information, thereby facilitating a fair and competitive tendering process.	**Enhanced Transparency and Accessibility:** By centralizing procurement information, the CIVD ensures greater transparency in the tender process. This openness is crucial for maintaining fair competition and allowing all potential vendors equal access to tender information. **Efficiency in Tendering Process:** Streamlines the procurement process, saving time and resources for both developers and vendors. Data Accessibility: Provides easy access to comprehensive tender information, aiding in decision-making. Standardization: Offers a standardized platform for tender announcements, simplifying the procurement process. **Efficiency in Procurement Process:** With all information centralized, the time and effort required to search for tenders, understand requirements, and prepare submissions are significantly reduced. This efficiency is beneficial for both the geothermal developers and the vendors. **Improved Decision-Making:** The CIVD provides geothermal developers with a broad view of available vendors and their capabilities. This comprehensive insight aids in making more informed decisions during the tendering process. **Reduced Risk of Compliance Issues:** A centralized database helps ensure that all vendors accessing the tenders are aware of and comply with the necessary regulatory and legal requirements, reducing the risk of non-compliance in procurement processes. **Facilitation of Market Analysis**: For geothermal developers, the CIVD can be a valuable tool for market analysis, offering insights into the range of available services, pricing trends, and vendor capabilities. This information is crucial for strategic planning and budgeting.	• Transparency and Fairness: Centralized data fosters a more transparent and fair tendering process. • Efficiency in Tendering Process: Streamlines the procurement process, saving time and resources for both developers and vendors. • Data Accessibility: Provides easy access to comprehensive tender information, aiding in decision-making. • Standardization: Offers a standardized platform for tender announcements, simplifying the procurement process.	The development of a CIVD represents a progressive step towards modernizing procurement processes in Indonesia's geothermal sector. This approach aligns with global best practices in tendering and procurement, promoting efficiency, transparency, and competitiveness. Successful implementation requires careful planning, robust technical infrastructure, and ongoing stakeholder engagement to address potential challenges and maximize benefits.

Strategy	Impact on Market Competitiveness	Benefits	Challenges	Remarks
		Level Playing Field: The CIVD ensures all potential contractors, regardless of size or prior engagement with the geothermal sector, have equal access to tender information. This can increase the number of bidders and foster a more competitive environment. **Vendor Visibility:** Smaller or newer vendors, who might otherwise be overlooked, gain visibility in a centralized system. This increased exposure can lead to more diverse and competitive bids. **Quality and Innovation:** With more vendors competing, there's a natural drive towards higher quality and innovation in services offered. Companies may invest more in their capabilities to stand out in a larger pool of vendors. **Cost Effectiveness:** Increased competition often leads to more cost-effective bids for geothermal projects. Developers can benefit from lower prices due to the competitive pressure on vendors.		
Various Contract Bidding Strategy During Tender Process	A clear and well-defined bidding strategy can influence the competitiveness of the geothermal drilling market. By offering various contract types, the market can appeal to a broader range of contractors, each with different preferences and risk appetites. This strategy involves implementing distinct contract models like Discrete, Bundled, Semi-IPM, IPM Day Rate, and Turnkey. Each model caters to different aspects of drilling operations, with varying degrees of risk and control allocated between the developer and the contractor.	The primary benefit of a clear bidding strategy is the attraction of a wider pool of bidders. For instance, discrete contracts, where services and materials are procured separately, tend to be more appealing to providers due to the lower associated risks and clearer scope, thereby reducing the likelihood of performance penalties.	• One of the main challenges is ensuring that the selected bidding strategy aligns with the organization's capability. While discrete contracts may reduce risk, they require the geothermal developer to have a higher level of project management and coordination skills. • Additionally, each type of contract carries its inherent complexities and requires careful consideration of market conditions and project specifics.	It should be noted that discrete contracts are generally more attractive to providers due to the reduced risk. However, this **does not necessarily mean that discrete contracts are always the best option.** The choice of contract type should be based on the geothermal developer's organizational capabilities and the specific requirements of the project. For instance, while discrete contracts might minimize risk, bundled contracts could offer efficiencies of scale and simpler management structures. The selection process should involve a detailed analysis of the project's nature, the developer's expertise, and market conditions to determine the most suitable contract type.

Strategy	Impact on Market Competitiveness	Benefits	Challenges	Remarks
Conduct Market Survey as per Preferred Contract Type Prior to Tender Process	Conducting a market survey tailored to the preferred contract type before initiating the tender process can enhances the competitiveness of the geothermal drilling market. This approach ensures that the tenders reflect current market conditions and pricing, which can lead to more competitive and realistic bids. This strategy involves conducting detailed market surveys for various types of contracts, such as discrete, IPM, or bundled contracts. The survey should focus on gathering current pricing and availability data for services and materials relevant to the specific contract type. The market data collected should be recent to ensure precision and relevance.	A key benefit of this approach is the reduction of risks associated with tender failures due to outdated or irrelevant market data. By aligning the market survey with the contract type, developers can ensure that the prices quoted by contractors accurately represent the market. For discrete contracts, which might generally be lower in cost, such alignment is crucial to ensure budget accuracy especially if geothermal developers are planning to use bundled/IPM contracts.	One of the challenges is ensuring the timeliness and accuracy of the market survey data. Market conditions can change rapidly, making it difficult to maintain up-to-date information. Another challenge is correctly and fairly interpreting the data in the context of different contract types, as costs may vary significantly between discrete, IPM, or bundled contracts.	The more recent and precise the market survey data, the lower the risk of tender failures. It is essential that the contract type is clearly defined so that the contractor's price accurately reflects market conditions. For instance, discrete contract costs may be lower, but if a project is developed using an IPM or bundled contract, the costs from a discrete-only market survey may not be applicable. In such cases, a conservative approach might involve adding an estimated 25%-30% to the total cost of items, materials, and services as gathered from the market survey. This ensures that the owner's estimate is realistic and accounts for potential variations in market conditions across different contract types.
Minimize time gap between market survey and tender process	Maintaining a minimal time gap between conducting the market survey and the bid submission phase can impact the competitiveness of the geothermal drilling market. This approach ensures that the tender process is informed by the most current market data, making the bids more reflective of the current market conditions. This strategy involves closely aligning the timing of market surveys with the initiation of the tender process. It requires efficient planning and execution of market surveys to ensure that the data collected is relevant and immediately applicable for upcoming tenders.	The primary benefit is the increased relevance of market data, which leads to more accurate and competitive bidding. Contractors can base their bids on the latest pricing and availability information, reducing the risk of outdated or inaccurate estimations. This timely alignment can also increase the willingness of contractors to participate in the tender process, as they are assured of current market conditions.	One of the main challenges is the rapid execution and analysis of market surveys without compromising the quality of data collected. Another challenge lies in the coordination between different teams handling the market survey and tender process to ensure seamless integration of data and actions.	The shorter the time gap between the market survey and bid submission, the higher the likelihood of increased participation in tenders. Up-to-date market intelligence directly impacts the accuracy and competitiveness of bids. However, it is crucial to balance the speed of conducting market surveys with the need for comprehensive and reliable data collection. It is essential to have a well-coordinated approach that ensures the market survey data remains relevant throughout the tender process. Streamlining internal processes and communication channels can aid in achieving this synchronization. Careful planning and swift execution are key to maximizing the advantages of this strategy in enhancing market competitiveness.

Strategy	Impact on Market Competitiveness	Benefits	Challenges	Remarks
Well bundling (high number wells that will be drilled in single contract)	Well bundling during the procurement or tender process can substantially enhance market competitiveness in geothermal drilling. By integrating multiple wells into a single tender and campaign, the strategy can lead to more cost-effective bidding and efficient utilization of resources. This strategy involves grouping drilling multiple wells (typically a minimum of five) into a single procurement or tender package. Instead of individual tenders for each well, a bundled approach is adopted, offering multiple wells as a package deal to potential contractors.	One of the key benefits is the potential reduction in unit price, as contractors often offer lower rates for larger volume contracts. This cost efficiency arises from the economies of scale, where the fixed costs of mobilization and setup are spread across multiple wells, thereby reducing the average cost per well. Additionally, well bundling can streamline the procurement process, reducing administrative burdens and time.	A significant challenge is managing the complexity of a bundled tender, which might involve more extensive planning and coordination. Additionally, this approach might limit participation to only those contractors capable of handling multiple wells simultaneously, potentially excluding smaller players from bidding.	The strategy's success largely depends on the careful planning of the bundle size and scope. While larger bundles (more wells) can lead to greater cost savings, they require contractors with sufficient capacity and resources. The strategy also has a notable impact on rig rental rates, with larger contracts often attracting more competitive rates due to the guaranteed volume of work. It's important to balance the advantages of cost savings against the risks of limited contractor participation and the complexities of managing large-scale contracts. Well bundling should be aligned with the capacity and capabilities of the available contractors in the market. A thorough market analysis is essential to determine the optimal number of wells to bundle in a tender to achieve the best balance between cost efficiency and contractor capability.
Drilling site location readiness (well-prepared and accessible)	The readiness of drilling site locations is a crucial factor that impacts the competitiveness of the geothermal drilling market. Ensuring that sites are well-prepared and accessible can streamline project initiation and reduce logistical challenges. This strategy involves thorough site preparation, including ensuring proper access routes, pre-installing necessary infrastructure, and conducting preliminary assessments to facilitate smooth mobilization. It also includes environmental and safety assessments to ensure compliance with regulations.	Ready and accessible sites greatly reduce startup times for drilling projects. By addressing logistical challenges beforehand, contractors can mobilize more efficiently and begin operations sooner. This not only to help to meet the project timeline but also makes bidding for projects more attractive due to reduced initial overheads and uncertainties.	Challenges include the logistics of preparing remote or difficult-to-access sites and ensuring that all preparation work is completed within project timelines and budgets. Inadequate preparation or improper mobilization routes can lead to project delays, resulting in financial losses for both the developer and the contractor.	Site readiness extends beyond mere physical preparation; it encompasses a comprehensive approach to making a site operationally ready. This includes addressing potential social, environmental and regulatory hurdles, ensuring the availability of utilities and services, and preparing for contingencies plan. A well-prepared site attracts more competitive bids as contractors can more accurately estimate costs and timelines without needing to factor in extensive preliminary work. It is critical for project developers to invest time and resources into proper site preparation. Early engagement with contractors can also be beneficial to understand their requirements and challenges. This proactive approach not only enhances market competitiveness by making projects more attractive to bid on but also aligns with best practices for project management, reducing the risk of delays and additional costs.
Using Stable Currency	The choice of currency for contracts can influence the competitiveness of the geothermal drilling market.	By offering contracts in stable currencies, the risk associated with currency fluctuation is minimized.	One of the main challenges is the exposure to currency exchange rate fluctuations, which can impact the actual costs and revenues when converted to the local currency.	The implementation of this strategy requires careful monitoring of global financial markets and an understanding of the implications of using different currencies.

Strategy	Impact on Market Competitiveness	Benefits	Challenges	Remarks
	Utilizing stable and widely accepted currencies can reduce risks associated with currency fluctuations and make contracts more attractive, especially to international contractors. This strategy involves drafting contracts in currencies that are stable and globally recognized, such as the US dollar or the Euro. This choice can be determined based on current financial trends and the currency's stability in the international market.	This stability is particularly appealing to international contractors who operate across various currency zones, as it provides predictability in financial planning and reduces the potential for unexpected losses due to exchange rate changes.	Additionally, depending on the currency chosen, there might be implications for local financial regulations and tax implications.	The benefits of reduced currency risk need to be weighed against potential challenges such as exchange rate volatility and the impact on local financial operations. It is also essential to consider the preferences and capabilities of both local and international contractors when deciding on the contract currency. While opting for stable, widely accepted currencies can make contracts more attractive on the global stage, it is crucial to remain vigilant about the fluctuations in the global financial market and the potential impact on project costs. Regular financial assessments and consultations with financial experts can aid in navigating these complexities, ensuring that the chosen currency strategy aligns with the overall objectives of enhancing market competitiveness in geothermal drilling.
International geothermal drilling contractors' engagement	Engaging international geothermal drilling contractors can enhance the competitiveness of the market. This strategy brings global expertise and experience into the local industry, potentially raising the standard of services offered and fostering a more competitive environment. This involves actively seeking out and encouraging the participation of international drilling contractors. Strategies might include outreach initiatives, partnerships with global drilling firms, participation in international trade shows, and simplifying the entry process for foreign companies.	The main benefit of engaging international contractors is the infusion of global knowledge and advanced drilling techniques into the local market. This can lead to the introduction of more efficient, innovative practices and technologies, enhancing the overall quality and competitiveness of geothermal drilling operations in the region.	One significant challenge is navigating the complex web of international regulations and compliance requirements. Additionally, cultural and operational differences between local and international firms can pose challenges in terms of communication, work styles, and project management. International drilling contractors might have an issue with local content (TKDN) regulation. Then there is import duty that might compromise the economical aspect from international drilling contractor's side if.	A comprehensive approach is required to successfully integrate international contractors into the local market. This includes understanding and adapting to different business cultures, legal requirements, and operational standards. The potential benefits of enhanced service quality and competitiveness need to be balanced against the logistical and regulatory complexities involved in facilitating international participation. While inviting international expertise into the local market can be a powerful catalyst for growth and improvement, it requires a well-thought-out strategy to address the accompanying challenges effectively. Emphasis should be placed on establishing clear communication channels, understanding the nuances of different working cultures, and ensuring regulatory compliance. This approach not only elevates the local market's standards but also fosters a more diverse and dynamic competitive landscape in geothermal drilling. The engagement of international geothermal drilling contractors is crucial for boosting the competitiveness of the geothermal drilling market. The relationship between regulatory protections and operational costs, such as rig day rates and casing rates, significantly affects market dynamics. By reassessing and potentially reducing certain protections, governments can lower these costs, making the market more attractive to international players. This could lead to enhanced efficiency, innovation, and a competitive edge in the global geothermal energy sector.

Strategy	Impact on Market Competitiveness	Benefits	Challenges	Remarks
				Evaluating the impact of protections on unit rates is essential for attracting international contractors and improving market competitiveness. Reducing regulatory barriers could make geothermal projects more financially appealing, encouraging investment and technological advancements. Strategic adjustments in these regulations could foster a more robust, competitive geothermal energy industry worldwide.
Clear Scope of Work and Transparent Communication	Establishing a clear scope of work and maintaining transparent communication can enhances market competitiveness in geothermal drilling. It fosters a trustworthy and efficient procurement environment, which can attract a broader range of contractors and lead to more competitive bids. This strategy involves clearly defining the project's scope of work in tender documents and maintaining open lines of communication with all potential contractors. This can be achieved through regular updates to contractors, invitation for discussions, transparent bidding processes, and providing detailed project specifications.	Clear communication ensures that all parties have a mutual understanding of project requirements, reducing the risk of misunderstandings or misinterpretations. This clarity can lead to more accurate and competitive bids, as contractors can tailor their proposals to precisely match the project's needs. Moreover, it builds trust among contractors, encouraging more companies to participate in the bidding process.	The main challenge lies in maintaining consistent and effective communication across different stages of the procurement process. It requires a dedicated effort to provide timely updates and respond to inquiries, which can be resource-intensive. Additionally, managing a transparent process while adhering to confidentiality and competitive fairness can be complex.	For this strategy to be effective, a well-planned communication protocol must be in place. This includes proactive dissemination of information, structured feedback mechanisms, and the ability to efficiently handle a high volume of inquiries. The scope of work needs to be detailed yet flexible enough to accommodate any unforeseen changes or clarifications. While the benefits of clear and transparent communication are substantial, they hinge on the ability to implement a thorough and structured communication strategy. This involves not only the initial dissemination of information but also ongoing engagement throughout the tendering process. By prioritizing clarity and openness, the geothermal drilling market can foster a more competitive and reliable bidding environment, ultimately leading to more successful project outcomes.
Clear, fair, and transparent payment terms & conditions	Implementing clear, fair, and transparent payment terms and conditions is essential for enhancing market competitiveness in geothermal drilling. This approach can increase confidence in contractors and suppliers, making the market more attractive for both local and international players. The strategy entails developing and clearly communicating payment terms that are equitable	Clear payment terms reduce uncertainty and financial risk for contractors, making bids more competitive and reflective of actual project costs. Transparent and fair payment processes also build trust and credibility in the market, encouraging repeated engagement and long-term relationships with contractors.	One challenge is ensuring that the payment terms are both attractive to contractors and sustainable for the project developers. Balancing prompt payments with the financial management of the project can be complex, particularly in large-scale operations with multiple stakeholders.	A detailed assessment should include evaluating current market standards for payment terms in geothermal drilling, understanding the cash flow requirements of contractors, and aligning them with the project's financial capabilities. Regular reviews and updates to these terms may be necessary to adapt to changing market conditions or project requirements. While setting up clear payment terms is crucial, it is equally important to ensure their consistent application and enforcement. Regular communication regarding payment schedules and prompt resolution of payment-related queries or disputes can further enhance trust and competitiveness in the market. This strategy not only benefits contractors but also aids in maintaining a healthy and competitive market

Strategy	Impact on Market Competitiveness	Benefits	Challenges	Remarks
	and align with industry standards. This includes setting realistic timelines for payment, outlining the process for invoicing, and ensuring that terms are consistent and transparent across all contracts.			environment, fostering growth and innovation in the geothermal drilling sector.

Table 7: Various Options of Increasing Participation of International Drilling Companies

Strategy	Impact on International Participation	Benefits	Challenges	Additional Remarks
Develop Open Access Centralized Integrated Vendor Database (CIVD) for Open Tender Announcement of geothermal drilling project	The establishment of an Open Access Centralized Integrated Vendor Database (CIVD) for announcing open tenders in geothermal drilling projects might be increasing the international participation. This database would serve as a one-stop platform for accessing tender information, making it easier for international companies to identify and compete for opportunities in the geothermal drilling sector. The strategy involves developing a comprehensive, user-friendly, visible, yet easily accessible online database that lists all open tenders related to geothermal drilling projects. This platform should be designed to provide detailed information about each tender, including project specifications, bidding requirements, timelines, and contact details. The database should be regularly updated and made accessible to all potential international bidders.	A centralized vendor database streamlines the tender announcement process, making it more transparent and accessible, especially for international companies unfamiliar with local systems. This can lead to increased competition, potentially resulting in better quality services and cost efficiencies. The platform also serves as a resource for international vendors to understand market needs and tailor their offerings accordingly	Challenges include ensuring the database's security, maintaining up-to-date and accurate information, and promoting the platform to ensure widespread awareness among international companies. Additionally, managing the database requires resources and continuous oversight.	A thorough assessment of the CIVD would involve considering the technical aspects of database management, including data integrity, user interface design, and accessibility. It's also crucial to consider how the platform aligns with international tendering standards and practices to ensure its utility for global vendors. The success of the CIVD hinges on its ability to offer a reliable, comprehensive, and easily navigable source of information. Regular feedback from users, both local and international, can provide insights for continuous improvement, ensuring the database effectively meets the needs of a diverse range of stakeholders. Effective marketing and partnerships with international trade bodies can also help in maximizing its reach and impact, thus boosting international participation in Indonesia's geothermal drilling projects.
Number of wells that will be drilled.	Bundling multiple wells into a single contract can have a significant impact on attracting international drilling companies. Offering contracts for multiple wells can make projects more appealing due to the potential for higher overall profits and more efficient operations. This strategy involves consolidating the drilling of several wells into one contract, rather than tendering each well separately. This can be implemented by outlining a clear plan for the number of wells to be drilled within a specified timeframe and incorporating this into the tendering process.	For drilling contractors, bundled contracts can lead to greater profits as they can optimize resources across multiple wells. From the perspective of the geothermal developer, bundling wells can lead to more competitive unit pricing, as contractors may offer discounts for larger-scale projects. This can result in cost savings and increased efficiency.	The main challenges is ensuring that the contractor has the capacity to handle multiple wells simultaneously. Additionally, managing a larger scale project can be more complex, requiring more robust project management and coordination.	A detailed assessment would include analyzing the capacity of potential contractors to handle multiple wells, assessing the cost benefits of bundling versus individual well contracts, and determining the optimal number of wells to bundle together. This assessment should also consider the logistical and operational implications of drilling multiple wells under one contract. While well bundling can offer financial benefits, it's important for developers to carefully plan and communicate their needs. They should ensure that contractors are fully aware of the scope and scale of the project to avoid any misunderstandings. Additionally, developers should be prepared to manage the complexities that come with larger-scale projects, including increased coordination and resource allocation. The strategy of well bundling can be particularly effective in attracting large international companies that have the capacity and experience to handle extensive projects.
Drilling site location availability and well-prepared	The availability of well-prepared drilling sites and efficient mobilization routes directly impacts the participation of	Well-prepared sites streamline the setup and operations of drilling rigs and services, significantly	One of the primary challenges is the logistical complexity of preparing sites, especially in remote or	A comprehensive assessment would include evaluating the current status of potential drilling sites, identifying the resources needed for preparation, and developing a

Strategy	Impact on International Participation	Benefits	Challenges	Additional Remarks
mobilization route (drilling readiness)	international drilling companies in geothermal projects. Ensuring drilling readiness can make these sites more appealing to international contractors by reducing the likelihood of project delays and logistical challenges. This strategy involves ensuring that the drilling sites, such as well pads, conductors, ponds, etc., are fully prepared before mobilization. It includes developing clear site plans, establishing access routes, and making necessary infrastructural arrangements. This might also entail conducting preliminary assessments to ensure that the sites meet the required standards and are ready for immediate use.	reducing the time and resources needed for mobilization. This efficiency can decrease the likelihood of project delays, making the proposal more attractive to international companies. A ready-to-use site demonstrates project management competence and operational efficiency, essential factors for international contractors.	challenging terrains. Additionally, aligning site preparation with international standards can require significant resources and expertise.	timeline for readiness. It should also involve a detailed analysis of the mobilization requirements specific to different drilling operations and their alignment with international best practices. The more prepared a site is, including the ease of setup for rigs and services, the more attractive it becomes for international contractors. This preparedness not only reduces the risk of delays but also demonstrates a commitment to efficient and effective project management. It's important for developers to understand that the initial investment in site readiness can lead to significant long-term benefits, including attracting reputable international drilling companies.
Job owner safety & enviro record	The safety and environmental record of a job owner (developer) plays a crucial role in attracting international drilling companies. A strong record can significantly enhance a developer's appeal, while a poor history may deter contractors due to concerns over recurring incidents that could damage their reputation and lead to potential blacklisting. This strategy involves maintaining high standards in safety and environmental practices and effectively communicating this track record to potential international contractors. It can include regular safety audits, adherence to international environmental standards, and transparent reporting of safety and environmental performance.	A positive safety and environmental record demonstrates a commitment to best practices, which is highly valued by international contractors. It not only ensures compliance with regulations but also builds trust and credibility, making the developer more attractive to work with.	Maintaining a consistently high safety and environmental standard can be challenging, especially in large-scale and complex geothermal projects. It requires continuous monitoring, investment in safety and environmental management systems, and training for staff.	An in-depth assessment would involve examining the current safety and environmental management practices of the developer, identifying areas for improvement, and benchmarking against international standards. It would also include strategies for effectively communicating these standards to potential international partners. While a strong safety and environmental record can be a significant draw for international contractors, it is important for developers to understand that maintaining these standards is an ongoing process that requires commitment and resources. Developers should also be aware that international companies often have stringent criteria for safety and environmental performance, and meeting these criteria can open up opportunities for collaboration and partnership. It's crucial, therefore, to not only focus on maintaining these standards but also on proactively showcasing them as part of the tendering process to attract the best international talent.
Clear, fair, and transparent payment terms & conditions	Implementing clear, fair, and transparent payment terms and conditions is pivotal in attracting international drilling companies to participate in geothermal drilling projects. This approach assures these companies of financial stability and predictability, which is crucial for their involvement in overseas projects.	Clear payment terms significantly reduce financial uncertainties for international contractors, making them more willing to engage in overseas projects. Consistent and fair payment processes build trust and credibility, making the market more attractive to international	Balancing attractive payment terms for international contractors with the financial realities of the project developers can be challenging. Managing international financial transactions, which may involve different currencies and banking systems, adds another layer of complexity to the process.	An in-depth assessment should consider global best practices for payment terms in the drilling industry, understand the specific financial and cash flow requirements of international companies, and align these with the project's financial planning. It's also important to consider factors such as currency exchange rates, international banking regulations, and potential risks related to international financial transactions.

Strategy	Impact on International Participation	Benefits	Challenges	Additional Remarks
	To ensure effectiveness, the strategy should involve drafting and communicating payment terms that are in line with international standards. This includes specifying payment schedules, defining invoicing procedures, and ensuring contractual terms are transparent and equitable. Regular consultations with international stakeholders can also be beneficial to align these terms with global practices.	players and encouraging long-term business relationships.		Ensuring that payment terms are not only fair but also consistently applied and adhered to is critical. Open communication about payment processes, along with a commitment to resolving any payment issues promptly, will further enhance the attractiveness of the market to international companies. This strategy, while focusing on payment terms, forms part of a broader effort to create a welcoming and reliable business environment for international participants in the geothermal drilling sector.
Job owner payment date record	The payment history of job owners in geothermal drilling projects can impact the willingness of international drilling companies to participate. A track record of timely payments can enhance interest from contractors, while a history of delayed or missed payments may deter them. The strategy involves maintaining a transparent and verifiable record of payment histories for job owners. This could include developing a system for tracking and publicly sharing payment timelines, as well as integrating feedback from contractors on payment experiences. Transparency in payment practices and adherence to contractually agreed terms are key.	A good payment record by the job owner builds trust and confidence among potential contractors, particularly international ones who might be wary of payment risks in foreign markets. Timely payments indicate financial stability and reliability, making the job owner a more attractive partner for future projects.	Challenges include ensuring that all payments are processed on time and in accordance with the terms agreed upon in contracts. Additionally, establishing and maintaining a transparent record system that is accessible and credible can be resource intensive.	An in-depth evaluation of this strategy would consider the existing payment processes and how they can be optimized for transparency and efficiency. It would also look at the potential impacts of payment practices on the reputation of job owners and how this affects their ability to attract international contractors. The assessment should include feedback mechanisms for contractors to report on their payment experiences. While maintaining a positive payment record is crucial, it's equally important for job owners to communicate clearly about any potential delays or issues that might arise. Consistent and open communication regarding payment processes can further bolster the trust of contractors. It's essential for job owners to understand that their payment history not only affects current projects but can also influence their ability to attract skilled contractors for future endeavors. As such, adherence to payment terms is a critical factor in fostering long-term partnerships and ensuring the successful execution of geothermal drilling projects.
Contract Currency	The choice of currency used in contracts can significantly influence the participation of international drilling companies in geothermal projects. Using a widely accepted and stable currency can attract more international players by reducing currency risk and simplifying financial transactions. The strategy involves selecting a currency for contracts that is stable, widely traded, and acceptable to both local and international parties. This could involve using major global currencies like the US Dollar or Euro for international contracts. The decision should be based on current	Using a major global currency reduces the currency risk for international contractors, who may otherwise be hesitant to engage in contracts denominated in a less stable or unfamiliar currency. This also simplifies the financial management for these companies, as they are more likely to have experience dealing in major currencies.	The main challenge is managing the exchange rate fluctuations that can impact project costs and revenues when converting to the local currency. Additionally, there may be legal and regulatory considerations in using foreign currencies for domestic contracts.	A thorough assessment would involve analyzing the potential financial impacts of different currencies, including exchange rate risks and the ease of transaction for international contractors. It would also involve understanding the legal implications and ensuring compliance with local and international financial regulations. While choosing a stable, widely accepted currency can make contracts more attractive to international companies, it's important to continuously monitor global financial markets to understand the implications of using different currencies. Maintaining flexibility in currency choice, while ensuring all parties are comfortable with the arrangement, can be key to successful international partnerships. This strategy, when implemented effectively, can make geothermal drilling projects in the region more accessible and appealing to a global market.

Strategy	Impact on International Participation	Benefits	Challenges	Additional Remarks
	financial trends, currency stability, and the preferences of potential international partners.			
Technology and Knowledge Exchange Programs	Implementing technology and knowledge exchange programs can significantly boost the participation of international drilling companies in geothermal projects. These programs facilitate the sharing of advanced drilling techniques and innovations, making international collaboration more appealing and beneficial. The strategy involves establishing partnerships or agreements with international drilling companies to share technology and expertise. This could include joint ventures, collaborative research projects, workshops, training programs, and conferences. The focus should be on areas where local companies can benefit from international expertise and vice versa.	Such programs enhance the technical capabilities of local geothermal projects, incorporating global best practices and cutting-edge technologies. This mutual exchange fosters an environment of continuous learning and improvement, which is attractive to international companies looking to expand their global footprint. It also strengthens the overall quality and efficiency of geothermal drilling operations.	Challenges include coordinating between different entities with varying operational cultures and technological standards. It also requires significant investment in terms of time and resources to establish and maintain these exchange programs.	A detailed assessment would involve identifying areas where technology and knowledge exchange could be most beneficial. This includes understanding the current gaps in local drilling techniques and the advancements available internationally. The assessment should also include a strategy for implementing these exchange programs in a way that aligns with the goals of both local and international entities. For these programs to be successful, there must be a foundation of mutual trust and a clear understanding of the objectives of both parties. It's important that these exchanges are seen as mutually beneficial, rather than one-sided transfers of knowledge or technology. Effective communication and regular evaluations of the program's impact are crucial to ensure ongoing relevance and value to all stakeholders involved. The ultimate goal is to create a symbiotic relationship that enriches the geothermal drilling sector globally.
Clear Legal and Arbitration Framework	Establishing a clear legal and arbitration framework significantly impacts the participation of international drilling companies in geothermal projects. A well-defined legal structure provides a sense of security and predictability, crucial for international companies considering investment in foreign markets. The strategy involves developing and clearly communicating legal frameworks that govern contracts and dispute resolutions. This includes specifying jurisdictional laws, arbitration procedures, and other legalities in contracts. Ensuring these frameworks align with international legal standards is key.	A clear legal and arbitration framework can reduce perceived risks among international companies, encouraging their involvement. It provides a structured approach to resolving disputes and clarifies legal obligations, leading to a more stable and predictable business environment.	Challenges include ensuring the legal framework is comprehensive yet adaptable to various international legal systems. Balancing the needs of local and international laws and maintaining fairness in legal proceedings can be complex.	A detailed assessment would involve evaluating existing legal frameworks and identifying areas where they might conflict with international standards or fail to provide adequate clarity. This assessment should also consider feedback from international companies on legal barriers they face in foreign markets. While developing a robust legal and arbitration framework, it is crucial to engage with legal experts knowledgeable in both local and international law. Regular reviews and updates to these frameworks may be necessary to keep up with changes in international legal standards. Transparency and clear communication about these legalities are essential to build trust and attract international participants. The objective is to create a legal environment where international companies feel confident to invest and participate in the geothermal drilling market.
Promotion of Local Partnerships (Local-International Hybrid Teams)	Forming local-international hybrid teams can greatly enhance international participation in geothermal drilling projects. This approach promotes a collaborative environment where local knowledge and international expertise converge, making projects more attractive to international companies.	Hybrid teams bring together diverse insights and approaches, leading to more innovative and effective problem-solving. International companies benefit from local knowledge, particularly in navigating regulatory and cultural	The main challenges is managing cultural differences and communication barriers within hybrid teams. It requires a concerted effort to foster an inclusive work culture where all team members feel valued and heard.	A detailed assessment should consider the specific skills and knowledge gaps that can be addressed by international experts. It also involves evaluating the best practices for integrating diverse teams, including training programs, team-building activities, and effective communication strategies.

Strategy	Impact on International Participation	Benefits	Challenges	Additional Remarks
	This strategy involves creating teams that combine the strengths of local and international personnel. This can be achieved through joint ventures, partnerships, or direct hiring. The key is to ensure that these teams are balanced in terms of skills, experience, and cultural perspectives.	landscapes, while local teams gain from the global experience and technical expertise of their international counterparts.		The success of local-international hybrid teams hinges on mutual respect and the willingness to learn from each other. Regular assessments and feedback mechanisms can help identify any issues or areas for improvement. It's also important to establish clear goals and expectations for these teams to ensure they work cohesively towards the project's objectives. By leveraging the strengths of both local and international team members, geothermal drilling projects can achieve higher efficiency, innovation, and success. Hybrid teams, composed of both local and international members, have demonstrated significant success within various geothermal enterprises, including Supreme, Star Energy, and Sarulla Operations Ltd, as well as in service consulting firms such as GRG-Geoenergis, Manvitt-ISOR-Verkis-Rigsis (MVIR group). The primary challenge encountered by these organizations does not pertain to the management of cultural differences but rather to navigating government regulations concerning local content requirements and the acquisition of work permits for foreign personnel.
Global Marketing and Branding of Appeal Reputation of Geothermal Industry in Indonesia	Elevating the global marketing and branding of Indonesia's geothermal industry can significantly influence the participation of international drilling companies. By enhancing the industry's appeal and reputation on a global stage, this strategy can attract more international players seeking lucrative and reputable opportunities. This strategy involves a coordinated marketing effort to highlight Indonesia's geothermal potential, success stories, investment opportunities, and regulatory environment. It could include creating promotional materials, participating in international trade shows, digital marketing campaigns, and fostering media relations to showcase Indonesia's geothermal sector.	Effective global marketing and branding can position Indonesia as a leading destination for geothermal development, attracting international companies with its potential for growth and innovation. It enhances the country's image as a stable, promising market for geothermal investment.	The challenges is creating a marketing campaign that accurately represents the opportunities while addressing any potential concerns of international investors. Additionally, differentiating Indonesia's geothermal market in a competitive global energy sector requires a strategic approach and sustained effort.	A thorough assessment should include analysis of current global perceptions of Indonesia's geothermal industry and identifying key areas for improvement. It should also consider the most effective channels and methods for reaching international audiences, including industry events, digital platforms, and networking opportunities. The global branding and marketing of Indonesia's geothermal industry should not only focus on attracting investment but also on building long-term relationships with international partners. It's important to maintain consistency in messaging and to align marketing efforts with the actual developments and achievements in the sector. Building a strong, appealing brand for the geothermal industry requires collaboration among government bodies, industry players, and marketing experts to ensure a unified and compelling portrayal of Indonesia's geothermal potential on the world stage. The Indonesian government has proactively engaged in the promotion of the country's market advantages at various international platforms, including geothermal conferences and workshops. This effort is aimed at highlighting Indonesia's vast geothermal resources and the potential opportunities for investment and development within this sector.

Strategy	Impact on International Participation	Benefits	Challenges	Additional Remarks
				By doing so, the government not only showcases Indonesia's commitment to renewable energy but also seeks to attract global investors and developers to participate in the exploration and utilization of its geothermal potential. This strategy underscores the government's dedication to fostering sustainable energy resources, contributing to the global transition towards cleaner energy sources while simultaneously stimulating economic growth and development within the country.
R&D Collaboration and Grants	Promoting research and development (R&D) collaboration and offering grants can significantly increase the participation of international drilling companies in geothermal projects. This approach fosters innovation and joint ventures between local and international entities, making the projects more appealing to global companies. The strategy involves setting up collaborative R&D programs and offering grants or incentives for joint research projects between local and international companies. This could include partnerships with universities, research institutions, and industry leaders to develop new technologies or improve existing ones for geothermal drilling.	Collaborative R&D projects bring together diverse expertise, leading to innovative solutions tailored to the unique challenges of geothermal drilling. Grants and incentives make these collaborations financially viable, particularly for international companies looking to invest in new markets. These partnerships can lead to technological advancements, cost reductions, and improved efficiency in drilling operations.	The main challenges include securing funding for R&D initiatives, aligning the interests and goals of different partners, and managing intellectual property rights. Additionally, there may be logistical challenges in coordinating joint projects across different countries.	A detailed assessment should include identifying key areas where R&D could significantly impact geothermal drilling operations. It should also involve evaluating potential partners for collaboration, including their expertise, resources, and compatibility with the project goals. The assessment should consider the financial aspects of such collaborations, including the availability and allocation of grants. While R&D collaboration can lead to significant advancements in the geothermal industry, it requires a long-term commitment and a strategic approach. Transparent communication, clear goal setting, and effective management are crucial for the success of these collaborations. Additionally, promoting these opportunities globally can attract a wider pool of international partners, bringing in fresh perspectives and expertise to the Indonesian geothermal sector.
Enhanced Data Accessibility and Visibility, especially for project tender announcement	Improving data accessibility and visibility, particularly in the context of project tender announcements, can significantly boost the participation of international drilling companies in geothermal projects. Easy access to comprehensive and up-to-date information makes it more convenient for these companies to assess and bid for projects. This strategy involves creating a centralized platform or portal where all relevant data about upcoming tenders and projects are readily available. This includes project specifics, timelines, requirements, and any other pertinent information. Ensuring that this platform is regularly updated and accessible globally is crucial	Enhanced data accessibility allows international companies to make well-informed decisions about participating in tenders. It increases transparency in the tendering process and can lead to more competitive bids from a wider range of international players. Easy access to information also reduces the effort and resources international companies need to invest in preliminary research.	The primary challenge lies in maintaining an up-to-date and comprehensive database, which requires continuous monitoring and updating. Ensuring that the platform is user-friendly and navigable for international users who might not be familiar with local systems or languages is another significant challenge.	A detailed assessment would involve evaluating the current state of data dissemination and identifying gaps in information accessibility. It should also consider the technical requirements for creating and maintaining an international-standard data platform, including language support, user interface design, and data security. While improving data accessibility can significantly aid in attracting international participation, it's important to ensure that the platform complies with international standards of data sharing and privacy. Additionally, promoting this platform through international channels can further increase its visibility, making it an effective tool for drawing global attention to Indonesia's geothermal drilling projects. Regular feedback from users can be invaluable in continuously enhancing the platform's effectiveness.

5. CONCLUSION

Some conclusions that can be drawn from this study can be summarized as follows:

- The analysis reveals substantial growth potential within Indonesia's geothermal drilling market, driven by increasing energy demands and government support for renewable energy. The availability of diverse rig capacities and contractor services highlights a robust infrastructure ready for strategic enhancements.
- Competition with the oil and gas industry for rigs poses a significant challenge, impacting cost and availability. The fluctuating oil prices further exacerbate these issues, necessitating agile and strategic procurement practices.
- Adoption of advanced procurement strategies such as bundled contracts and centralized vendor databases (CIVD) can streamline operations and reduce costs.
- Promoting transparency and fairness in payment terms and conditions is crucial for attracting both local and international competition.
- There's a critical need for fostering local-international partnerships and transparent legal frameworks to attract international drilling companies. Such collaborations can introduce advanced technologies and practices essential for the sector's growth.
- Emphasizing training and development to build local expertise in geothermal drilling will decrease dependence on international talent and strengthen the domestic market's capabilities.

6. RECOMMENDATIONS AND PATH FORWARD

Some recommendations and path forward that can be drawn from this study can be summarized as follows:

1. Enhance Procurement Systems

- Adoption of Centralized Vendor Databases: Streamline the tender process by implementing centralized integrated vendor databases (CIVD), which would improve transparency, reduce procurement times, and lower costs.
- Innovative Contracting Approaches: Encourage the use of bundled contracts and well-bundling strategies to capitalize on economies of scale, potentially lowering costs and enhancing operational efficiency.

2. Foster International Collaboration

- Strengthen International Partnerships: Develop frameworks that facilitate technology transfer and joint ventures with international drilling companies. This can lead to improved technology adoption and innovation in drilling operations.
- Regulatory and Legal Framework Enhancements: Ensure that legal frameworks are conducive to international investment and collaboration, providing clarity and stability that international companies crave.

3. Expand Training and Development

- Invest in Human Capital: Enhance training programs to develop local expertise in advanced geothermal drilling techniques. This investment in human capital will pay dividends in increased operational efficiency and reduced reliance on international expertise.
- Research and Development Focus: Promote R&D collaborations between academia, industry, and government to pioneer advancements in geothermal drilling technologies and practices.

4. Market Dynamics and Competitive Strategies

- Regular Market Surveys: Conduct thorough and regular market surveys to gauge rig availability, service costs, and contractor capabilities, which will aid in timely and effective decision-making.
- Flexibility in Procurement Practices: Adapt procurement strategies in response to market conditions to optimize cost and efficiency, particularly during fluctuations in the oil and gas sector, which impact the geothermal drilling market.

By implementing these recommendations, Indonesia can enhance its position as a leader in geothermal energy, driving both domestic and international investments, while promoting sustainable and economically viable energy solutions. The path forward involves a coordinated effort across multiple facets of the industry to ensure that the potential of Indonesia's geothermal resources is fully realized.

Keywords: EGS, AGS, unconventional, temperature electronics, sensors, drilling

ABSTRACT

Enhanced and advanced geothermal systems (EGS and AGS) are new methods of creating geothermal installations that will potentially increase electric power production by a factor of greater than 10 when compared with more conventional methods. Many such systems are emerging, and they are attracting a lot of funding and excitement. But compared with conventional hydrothermal wells, they are technically challenging to drill. Accurate well positioning, generally including horizontal wells, will be required for the most advanced well designs to succeed. The oil and gas industry can already drill accurate directional wells and this capability is directly transferable to some of the first EGS and AGS wells because they are likely to be drilled at temperatures familiar to oil and gas drillers. But to make EGS and AGS wells more economically interesting, they will need to be drilled at higher temperatures which are currently beyond the capabilities of oil and gas drilling, completions, and production equipment.

Even the claimed 175°C operating capability of oil and gas technologies is challenging for the economics of geothermal drilling because equipment operated at this maximum temperature limit exhibits low main time between failure and/or service. Therefore, the industry needs a step change in its approach to the temperature capabilities of downhole equipment. This presentation will outline just such an approach to the temperature resistance of the electronics and sensors needed.

Showing in detail a new approach to tool design, it will describe how a combination of component selection, a completely reimagined approach to downhole electronics, and multiple cooling strategies will allow measurement and control to be reliably implemented at higher temperatures, initially above 200°C and ultimately as high as 300°C. This will finally make reliable drilling at high temperature a reality and the presentation will conclude by showing results achieved to date during high temperature testing.

1. INTRODUCTION – UNCONVENTIONAL GEOTHERMAL

Although geothermal wells have been drilled for electric power for more than 100 years, since the first power station was built at Lardarello in Italy in 1924 (Clegg and Krase, 2022), the industry has long been associated with hydrothermal reservoirs, whereby hot fluid is found in naturally fractured formations and can be exploited by drilling wells to transport the hot water and/or steam to the surface. Where such reservoirs exist, they can be a very effective source of heat for power generation, but they are not geographically abundant. They tend to be confined to parts of the world where there is heat close to the surface which itself is combined with said fractured formations and water reservoirs. Unless solved, this geographic confinement would prevent the exploitation of geothermal energy for power at a global scale, with only a small number of "lucky" countries benefiting.

Recently, though, the picture has changed. Numerous different styles of enhanced and advanced geothermal systems (EGS and AGS) have been funded, and some have already been demonstrated at pilot scale. Although the design and principle of operation of each style is unique, they all share one binding characteristic: they create an artificial reservoir instead of relying on a natural, hydrothermal one.

Pioneers such as Fervo and Eavor are demonstrating that EGS and AGS can be made to work, with Fervo demonstrating for the first time that electricity can be reliably generated from an EGS well in Nevada in 2023 (Think Geoenergy, 2023).

Although their modes of operation are very different, both companies, and the vast majority of their potential competitors, rely on accurate directional drilling techniques, placing wells a precise distance apart and in some cases connecting them together at the end, many kilometres below the surface. That might seem like an extraordinarily difficult thing to do, but the directional drilling techniques that have been developed by the oil and gas industry over the last 100 years now allow wells to be placed very accurately (Clegg, 2021).

2. UNCONVENTIONAL OIL AND GAS

In a striking parallel with unconventional geothermal, the unconventional oil and gas industry also emerged by creating artificial reservoirs. In this case, the reservoirs were created by fracturing shale, normally thought of as the source rock for conventional oil and gas reservoirs. The most important of the technologies that enabled unconventional oil and gas wells to be drilled at scale were horizontal drilling and hydraulic fracturing. The directional well profiles that will be required to make unconventional geothermal a success are very similar to those used in unconventional oil and gas: increasingly long horizontal sections to maximise exposure of the well to the premium resource. In the case of oil and gas wells, the premium resource is hydrocarbon. In the case of unconventional geothermal wells, the premium resource is heat. Geometrically, the wells look very similar in either case. The most significant difference is temperature, and this will be discussed further in section 5.

The similarity with unconventional oil and gas is important, because of the cost savings that have been made in that industry over the last 15 years. These cost savings should be directly applicable to the unconventional geothermal industry.

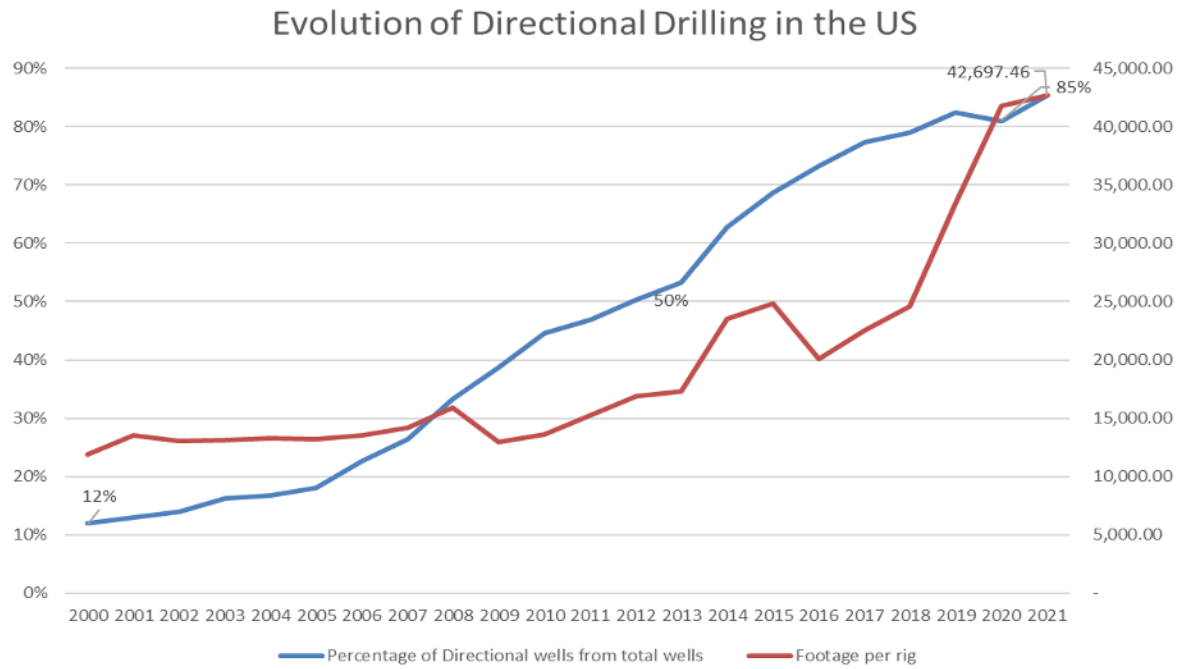

Figure 1: Evolution of the prevalence of directional drilling, and its cost, in the United States.

Figure 1 includes an amalgamation of data from Baker Hughes (bakerhughes.com, n.d.), the United States Energy Information Administration (eia.gov, 2022), and St. Louis Fed (stlouisfed.org, n.d.). It clearly shows how directional drilling has grown from a relatively small niche to the vast majority of wells drilled in the United States during the unconventional shale revolution. It also illustrates how the cost of drilling these wells has come down, with the footage drilled annually per rig increasing by a factor of more than three.

Similar cost savings will be available to the unconventional geothermal industry.

3. TARGETS FOR GEOTHERMAL TO SCALE

In its "Enhanced Geothermal Shot" initiative (energy.gov, n.d.), the United States Department of Energy identified five key areas where technical challenges need to be solved in order to create pathways to a 90% reduction in the cost of EGS by 2035. Two of these are related to subsurface modelling and one to completions and production. The other two are directly related to well construction and include the following specific targets:

- "drill the wellbore at 4X speed"
- "reduce well construction cost by 60%"
- "enable access to 50% more hot rock".

The technology developed for unconventional oil and gas can directly influence these targets. Figure 1 above shows how drilling speed has improved in the unconventional oil and gas industry – the number of feet drilled per rig per year is in inverse proportion to the speed at which the well is drilled. Well construction costs have reduced

in line with this. Additionally, the horizontal drilling techniques pioneered in the unconventional oil and gas industry will allow increasingly long directional or horizontal geothermal wells to be drilled, significantly increasing exposure to hot formations. Based on the progress that the oil and gas industry made over the last 15 years, 50% seems like a very conservative target.

4. UNCONVENTIONAL GEOTHERMAL CASE HISTORIES

There is already evidence that techniques imported from oil and gas drilling are reducing the cost of unconventional geothermal wells.

Results from the Frontier Observatory for Research in Geothermal Energy (FORGE) drilling site in Utah, United States, have shown that drilling speed improved from 14 ft/h to 71 ft/h, a five-fold improvement, between 2017 and 2022, simply by applying oil and gas drilling technologies (US Department of Energy, 2024). The same reference stated that there is still a two-to-three-fold improvement available if the drilling speeds typically achieved in oil and gas can be transferred.

Earlier in 2024 (El-Sadi, *et al*, 2024) Fervo reported significant improvements in drilling performance from their initial wells in Nevada and Utah, United States. Like FORGE, they demonstrated sustained drilling rates of 70 ft/h, resulting from the use of modern drilling techniques imported from the oil and gas industry. Their paper contrasted this with the 25 ft/h baseline estimated by SANDIA (Lowry, et al, 2017) as recently as 2017.

5. THE IMPORTANCE OF TEMPERATURE CAPABILITY

The findings above suggest that the cost targets set by the Department of Energy "Enhanced Geothermal Shot" are very achievable. But as well as reducing the cost of an installation, there are also gains to be found in increasing its value. The leverage of temperature in terms of the value of the well is very high.

A number of scenarios were modelled using the US Department of Energy Geothermal Electricity Technology Evaluation Model (US Department of Energy, 2016). When normalised, they revealed a constant pattern in that the cost of electricity reduces significantly as the temperature of the rock exploited increases. This is clearly shown in Figure 2 below.

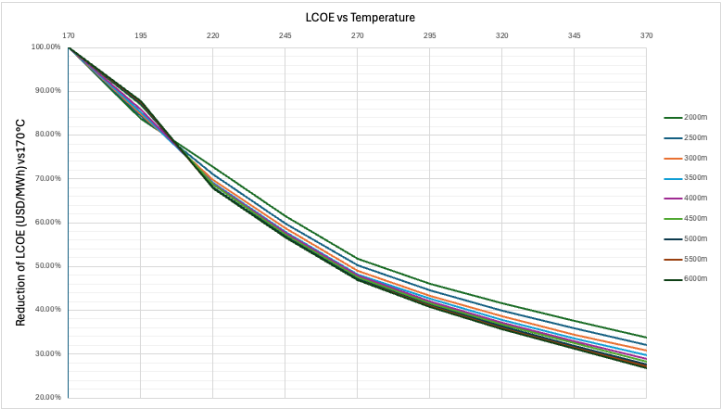

Figure 2: LCOE as a function of reservoir temperature.

The graphs show a consistent and significant reduction in levelized cost of electricity (LCOE) as a result of temperature for EGS systems modelled using GETEM. Results are not shown here for AGS, but increasing temperature has a very similar impact on their economics.

Compared with a baseline (100%) at 170°C, increasing the reservoir temperature to 210°C will reduce the LCOE to approximately 75% of the baseline value. At 300°C, LCOE is only about 30% of baseline. This demonstrates extremely important economic value that will come from deeper and hotter geothermal wells.

170°C was chosen because it is close to the claimed temperature rating of drilling and measurement tools currently used in the oil and gas industry. Typically, this might be 175°C. Occasionally it can be higher, up to 200°C, for a fairly small number of (most likely) expensive tools.

However, this temperature rating is no guarantee that tools will work reliably at such temperatures. The environment in which they are deployed is harsh and difficult, and they often fail prematurely at temperatures lower than their rating.

Research based on drilling a high temperature field in the United States shows a correlation of measurement while drilling (MWD) failures with temperature, but at lower temperatures than would have been expected.

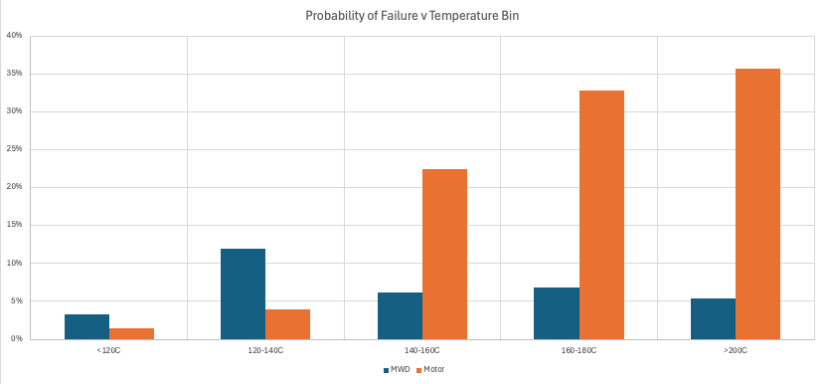

Figure 3: Probability of run terminating failure as a functional temperature.

Rather than working reliably to 175°C, Figure 3 shows that MWD reliability drops off 120°C and 140°C. The picture would probably be worse above 140°C, but for the fact that by then drilling motors, which have a significant elastomeric content in their moulded stators, start to fail even more rapidly than MWD – thereby masking what would otherwise likely be a higher number of run terminating MWD failures at higher temperatures.

This clearly demonstrates the difficulty of drilling at increasingly higher temperatures with equipment directly imported from the oil and gas industry.

6. A HIGH TEMPERATURE DRILLING SYSTEM

Figure 4 shows what a combined high temperature MWD and rotary stable system (RSS) will look like. This drilling system is being developed for operation initially at 210°C, but by 2030 it is anticipated that it will be working reliably at circulating temperatures as high as 300°C.

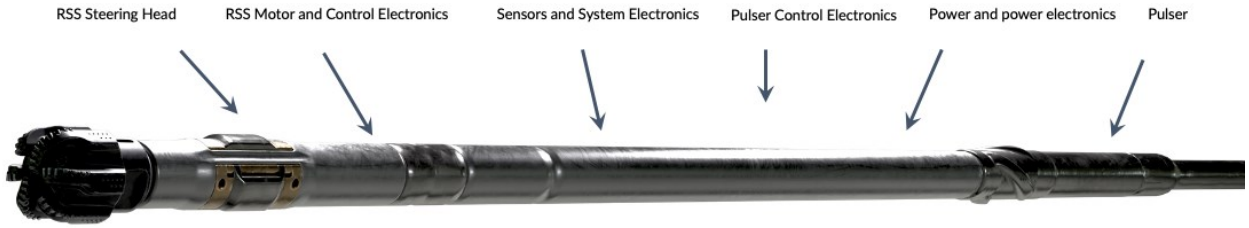

Figure 4: Combined RSS/MWD for high temperature operation.

Closest to the drill bit is the RSS steering head. This can be identical to the type of steering head used in oil and gas wells, with pads and/or pistons that extend once per revolution and urge the bit sideways. However, RSS tools used in oil and gas generally have their own sensor packs and control systems, independent from those used in an adjacent MWD tool – mostly for historic reasons. There is no technical reason why these two set of sensors and electronics cannot be combined. A high temperature drilling tool for geothermal should combine them in order to save on space, cost and technical risk.

Approximately halfway along the tool as illustrated there is a set of sensors and system electronics that is able to measure the direction and inclination of the well, and control a positive mud pulser to send this information to surface. The same sensors can also derive rotational position of the tool and drive electronics that control the steering head. Both the pulser and steering head are controlled with pilot valves that themselves are driven by brushless DC motors.

This drilling assembly can be driven directly from surface, from the top drive, or can be "motorised" in the same way as in oil and gas wells, where a drilling motor is placed above the tool in order to provide additional power downhole. However, conventional mud motors used in oil and gas will suffer at high temperature because of the use of elastomers in their stator assemblies. Options to resolve this include all metal motors (Stefánsson *et al,* 2018) or geared turbines (Jones, Feddema and Sugiura, 2016), both of which can avoid the temperature limitations of the elastomeric stator.

If RSS is not required, the MWD is capable of being used with an oriented directional motor, again very much like oil and gas drilling. As above, the orientation could be of a motor with a metal power section or, again, it could use a geared turbine.

Critical to the success of such a drilling system will be the temperature capability of the sensors and electronics used.

7. A NEW APPROACH TO TEMPERATURE RESILIENCE

Generally, the approach employed to date when attempting to make high temperature drilling and measurement tools has either been to find electronic components that will work at the ambient temperature via a process of screening and selection (Beckwith, 2013) or to try to shield the entire tool from temperature and cool it (Vedum *et al*, 2017 and Stefánsson *et al,* 2018*)*.

Despite many years of trying, the former approach does not appear to capable to get equipment to work reliably above an operating temperature of 200°C. One or two oil and gas manufacturers have managed to get close to 200°C, by using technologies including application specific integrated circuits (ASICs) or multi-chip modules (MCMs). Unfortunately, these approaches suffer from very high non-recurring engineering (NRE) charges, making them unsuitable for products like high temperature drilling tools which are made in low volumes.

A new approach builds on but also modifies these previous attempts. It uses discrete components either selected for or protected from the operating temperature. Discrete components are considered a more cost-effective way of building low volumes of tools. The new approach considers three key requirements:

- Protect the assembly from the external borehole temperature
- Protect components from themselves and efficiently and quickly remove the heat that the components generate internally
- Take the rejected heat from the components to a place where it will do no harm.

This new approach creates a system for mounting boards which allows heat to be removed and rejected quickly. As a first step, it replaces the rectangular printed circuit boards (PCBs) which are ubiquitous in oil and gas drilling and measurement tools, and replaces them with a circular board design. Further, instead of being placed parallel to the axis of the tool, the circular boards are placed normal to the drilling axis in a stack – or perhaps more accurately, in a series of stacks.

The small size of the board means that no component is very far from its edge, and the circular shape tends to promote heat flow, with resistance to radial flow reducing as a function of radial position. The function of the board, and the numerous special materials used in its construction, is to get heat away from vulnerable components as quickly as possible and to the board circumference.

Once at the circumference, the heat can be picked up by a stack of thermally conductive rings which act somewhat like a “thermal superhighway” to take heat away from the board. This “superhighway” could take heat to a pressure vessel which is in contact with drilling fluid flowing past the outside of the tool. This would allow the tool to take advantage of the cooling nature of the drilling fluid, which will almost certainly be at a lower temperature than the formation being drilled. It also allows operation in tandem with technologies like mud chillers and insulated or coated pipe, which can further reduce said temperature of the drilling fluid.

Alternatively, for higher temperature tools, especially as the operating temperature approaches 300°C, the “superhighway “could take heat into a variety of cooling options, which will not be described in this paper. The combination of circular boards and conductive rings lends itself very well to a modular architecture which allows different boards to be treated differently in terms of how they are cooled. By dividing the tool into a small number of stacks of boards, it becomes possible to have very small, compact chambers which can be maintained at different temperatures if necessary. In order for systems to remain cost effective, cooling must be used selectively. Previous projects described above have attempted to cool the whole assembly to the minimum capability of any individual component. This can work for short periods of time, however this approach can be very expensive and power hungry. An alternative approach is to build a series of small chambers and cool each to an appropriate temperature for the weakest component therein. This will avoid cooling a lot of components that do not need it and is much more efficient than maintaining the whole tool at a low temperature.

Figure 5 shows an example of the new generation, high temperature circuit board.

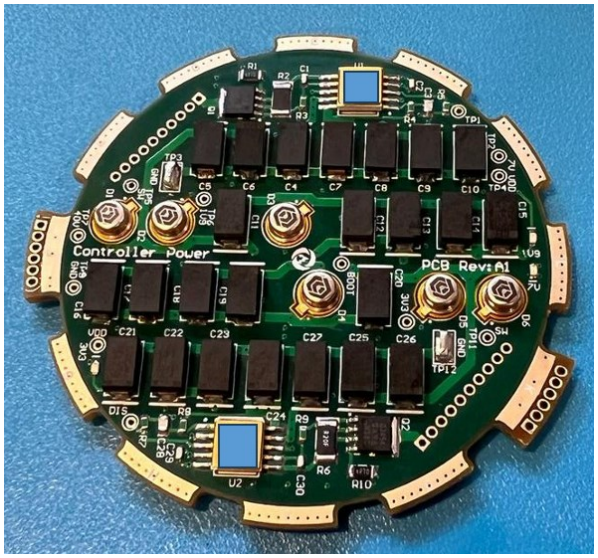

Figure 5: New generation circular PCB.

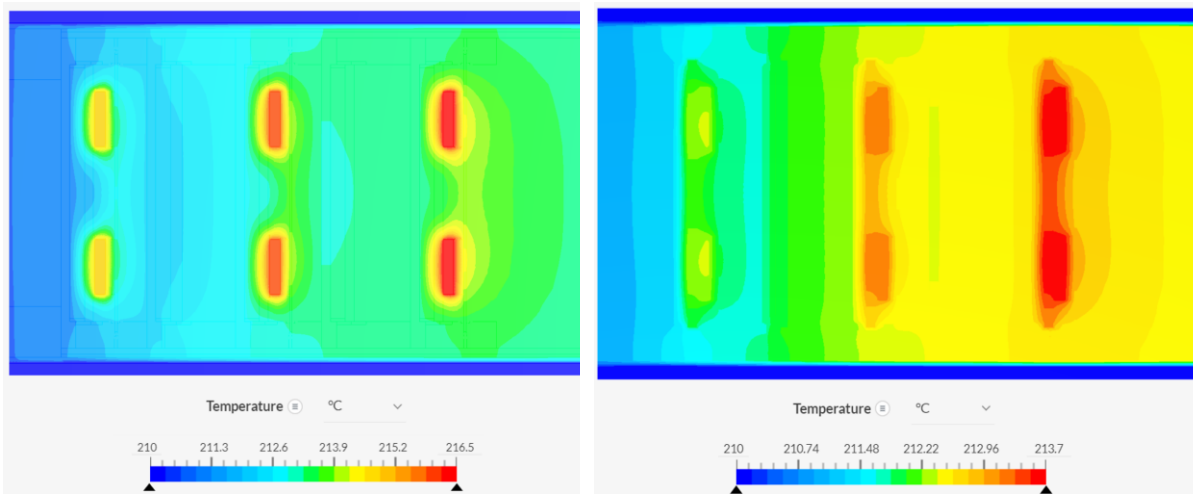
Figure 6 shows one element of the axial stack of PCBs.

Figure 6: One element of axial PCB stack.

Based on the design of multiple stacks as depicted in Figure 6, thermal modelling has been used to optimize the combination of geometric design and materials selection. As can be appreciated from Figure 7, this modelling has shown that it is possible to keep the temperature of components of the board in a multi-stack assembly within 3.7°C or less of the surrounding environment in an optimized PCB assembly and within 6.5ºC or less of the surrounding environment in a conventional PCB assembly.



(a) **(b)**

Figure 7: Thermal modelling of a multi-stack using (a) conventional and (b) optimized PCBs.

8. TEST RESULTS

Initial testing has focused on proving "the physics" for a 210°C drilling tool – that is, heat testing components and boards temperatures between 220°C and 230°C for extended periods to make sure that there are no fundamental issues that will prevent components from working – such as leakage or capacitance issues. This testing has proved successful, with components, prototype boards and downhole ready boards heat soaked at these high temperatures for over 500 hours.

Further work will require highly accelerated life testing (HALT) which combines temperature with shock and vibration to fully replicate the downhole conditions that components and boards will see. However, solving problems that might emerge at this stage is simply an engineering challenge. It does not challenge the physics in the way that initial heat testing has already done.

9. CONCLUSIONS

Unconventional geothermal systems (EGS and AGS) bring exciting new possibilities to the geothermal industry and will allow it to scale globally.

They can leverage techniques including directional and horizontal drilling developed for oil and gas and perfected in the unconventional shale boom in the last 15 years.

Those technologies have demonstrated remarkable cost savings in unconventional shale wells that should be directly transferable to geothermal drilling. But the technologies used in oil and gas do not usually work above 175°C and never above 200°C. In fact, it appears that systems tend to have reliability problems someway below their claimed temperature specification capability.

Temperature has a very strong leverage on the economics of unconventional geothermal systems, with modelled LCOE being very strongly dependent on formation temperature.

A high temperature directional drilling system is being developed which avoids the use of elastomers and incorporates new ways of protecting electronics and sensors from temperature. Instead of using long, rectangular PCBs, the new system will use circular PCBs mounted in stacks where the boards are orthogonal to the drilling axis.

This allows three key requirements for temperature management in high-temperature tools to be addressed

- Protect the assembly from the external borehole temperature
- Protect components from themselves and efficiently and quickly remove the heat that the components generate internally
- Take the rejected heat from the components to a place where it will do no harm.

Cooling may be required for operation at high temperatures, but it is not necessary to cool the entire tool – only those components that need it.

Initial test results are very encouraging, and have already shown that a 210°C tool is feasible, with much higher temperature capabilities to follow.

ACKNOWLEDGEMENT

The authors would like to thank the team at Hephae Energy Technology for their support and inspiration.

Keywords: Geothermal Two-Phase Flow, Pressure Drop, Homogeneous Flow Model, Separated Flow Model, Harrison Method

ABSTRACT

Estimation of pressure drop in two-phase fluid flow is implicitly a more complex process compared to that for single-phase fluids. Empirical correlations proposed for two-phase pressure drop are based on experiments carried out with air-water mixture in small, horizontal pipelines and do not represent large, cross-country, geothermal two-phase fluid conveying pipelines. The analytical procedure followed in the geothermal industry to predict pressure drop in two-phase pipeline is to apply the available methods and then use correction factors, commonly followed as industry practice based on actual field observations.

Two distinct flow models are commonly used to analyse two-phase flow. In homogeneous flow model, a pseudo single-phase fluid is defined and assumed to be uniformly distributed in the pipe, traveling at a uniform velocity. In separated flow model, the gas and liquid phases are assumed to flow separately within the pipe cross-section. Distinct hydrodynamic and thermal parameters for each phase are determined using void fraction and applied to separate energy equations for each phase, in equilibrium with each other.

The pressure drop in two-phase fluid flow comprises of 3 components — a) frictional, b) acceleration component and c) gravity. The pressure loss predicted as per analytical methods is typically found to underestimate the actual pressure drop in geothermal two-phase pipelines and it is common to apply correction factors to the theoretical results to represent real industrial installations.

Traditionally, spreadsheet-based design tools, based on established theories and correlations proposed for two-phase flow analysis, have been used by geothermal design engineers to estimate pressure losses in geothermal two-phase pipelines. This paper discusses the general theory, assumptions and procedures followed to develop such analytical design tools. The correlations and procedures covered in this report are those proposed by R.F.Harrison (1975) , a graduate student at Auckland University, as part of his Masters thesis and experiments carried out in Wairakei geothermal field, with support and sponsorship of the then Ministry of Works, NZ.

1. INTRODUCTION

The outcome of pressure drop analysis and other key process design parameters, forms the basis for selecting the steamfield development options and determining an appropriate generation facility for geothermal.

Estimating pressure drop in a two-phase geothermal fluid flow, however, involves a somewhat more complex procedure compared to pressure drop in a single-phase fluid flow. Over many decades, there has been extensive research and studies conducted on the mechanism of two-phase (gas & liquid) fluid flow and many papers are available proposing correlations to predict the estimated pressure drop. Most detailed studies relating to geothermal fluids were carried out in small (200 mm or smaller dia), near-horizontal pipes, accompanied by heat transfer. With the increase in implementation of centralized separation plants, two-phase conveying pipelines in modern geothermal plants typically comprise of significantly larger pipes (up to 1.3m diameter) along inclined and nonlinear cross-country routes, often running over several kilometers between wellpads and separation plants. As a result, most of the correlations and equations proposed based on published experimental studies are not directly applicable to modern geothermal two-phase conveying systems. To date, there is no unified methodology for accurately determining pressure losses in large geothermal two-phase pipelines, across range of fluid qualities and flow regimes.

The objective of this paper is to present, in a summarised manner, an overview of the analytical procedure commonly followed by geothermal engineers to estimate two-phase pressure drop. Findings specific to the authors' experience are also shared.

2. ANALYSIS MODELS

Two distinct physical model options are mostly used to analyse and estimate pressure drop in two-phase geothermal fluid flow.

2.1 Homogeneous Flow Model

The homogeneous flow model assumes liquid & gas phases are uniformly distributed across pipe cross-section and travelling with the same velocity. The mixture is treated as an equivalent pseudo single-phase fluid, with suitably defined hydrodynamic and thermal properties.

The homogeneous flow model presents the simplest approach for analysis. However, defining effective physical properties for the equivalent single-phase fluid is difficult and the inaccuracies in assuming the void fraction, mean viscosity and similar critical parameters increase as the flow pattern transitions beyond bubble or stratified regimes. The analysis based on homogeneous flow model tends to overestimate the pressure losses, particularly in the higher ranges of pressure drops.

2.2 Separated Flow Model

In this model liquid & gas phases are assumed to flow separately as continuous phases within pipe cross section, as if in 2 separate pipes. In this approach, the most important parameter is void fraction (α), and using it various other two-phase flow parameters, such as individual phase velocities and mean fluid density, a set of equations is applied for each phase to determine the overall pressure drop.

The separated flow model relies on empirical correlations to determine void fraction, flow regime, and interactions between phases. Results vary significantly depending on the correlation followed. The correlation used by the authors is the so-called Harrison-Freeston method. Harrison, a former graduate student at the Geothermal Institute in Auckland, postulated the correlation in his thesis based on his study of test results by Freeston et al in the Wairakei steam field. It is believed that the pressure drop prediction determined as per Harrison's method generally presents results closest to actual field observations. However, not enough field studies have been conducted to substantiate the hypothesis and the discrepancy between theoretical and actual pressure drop can be significant. The margin of error tends to increase as the flow pattern approaches the slug flow regime.

3. COMMONLY USED PRESSURE DROP CALCULATION METHODOLOGIES

From the conservation of energy principle, the total pressure loss in pipe flow is given by:

$$\Delta P_{Total} = \Delta P_{fr} + \Delta P_{mom} + \Delta P_{gr} \quad (1)$$

Where:

ΔP_{fr} = Pressure losses due to frictional effects
ΔP_{mom} = Pressure losses due to acceleration or change in momentum
ΔP_{gr} = Pressure change due to variation in elevation

Analytical computation of each of the components in Equation 1 above are briefly discussed in sections hereinafter.

3.1 Void Fraction

The void fraction, α is defined as the ratio of cross-sectional area occupied by the vapour phase to the pipe cross section.

$$\alpha = \frac{A_v}{A} = \frac{A_v}{A_v + A_l}, \quad (2)$$

Void fraction is one of the most important parameters for two-phase flow analysis, and many empirical correlations are proposed for determining this. It is, however, safe to state that no single correlation seems to accurately predict void fraction that covers geothermal two-phase flows across all fluid conditions, flow regimes, pipeline sizes & geometries.

A well-known method for two-phase pressure drop estimation, used by the author is the correlation proposed by R.F.Harrison (1977). Harrison used the following empirical equation to determine void fraction, which was based on experimental results found by Butterworth (1975) from tests on horizontal pipelines.

$$\alpha = \frac{1}{1 + \frac{(1-x)}{x}^{0.8} + \frac{\rho_g}{\rho_l}^{0.515}} \quad (3)$$

Another correlation for void fraction determination, which is also often used in two-phase flow analysis, was proposed by Zhao, Lee and Freeston (2000) as a refined and more accurate prediction based on 'seventh power law' of velocity distribution. The empirical correlation is given below and can be solved iteratively for α.

$$\frac{1-\alpha}{\alpha^{7/8}} = \left[\left(\frac{1}{x}-1\right)\cdot\left(\frac{\rho_g}{\rho_l}\right)\cdot\left(\frac{\mu_l}{\mu_g}\right)\right]^{7/8} \quad (4)$$

3.2 Pressure Drop due to Friction and Momentum Changes

Frictional pressure losses are dictated by the interactions between individual phases with the pipe wall and the resulting shear force exerted by the pipe opposing the flow.

Pressure drop due to momentum changes is the result of energy dissipated in the form of acceleration of the two-phase fluid velocity, due to flashing of liquid and expansion of the gas phase.

3.2.1 Separated Flow Model

The Harrison method combines pressure drop components due to frictional and momentum components in following correlation:

$$\Delta P_{mom} + \Delta P_{fr} = \frac{4\cdot\tau_w}{D\times(1-AC)} \quad (5)$$

The wall shear stress is given by

$$\tau_w = 1/2\cdot C_f\cdot\rho_l\cdot {V_l}^2 \quad (6)$$

The wall shear stress can also be expressed in terms of mass flow rate and void fraction, as follows

$$\tau_w = 1/2\cdot C_f\cdot\frac{W^2(1-x)^2}{\rho_l\cdot A^2\cdot(1-\alpha)^2} \quad (7)$$

The acceleration component represents energy losses due to changes in momentum flux and is typically much smaller compared to losses due to frictional and static head components. The term AC in Eqn [5] is. given by -

$$AC = \frac{W^2.x^2}{\alpha\cdot A\cdot P\cdot\rho_g} \quad (8)$$

The wall skin factor for two-phase flow was proposed as follows

$$C_f = 1/4\cdot f_T \quad (9)$$

The friction factor f_T can be graphically selected from a Moody chart. The Colebrook-White equation below estimates the friction factor analytically, based on pipe roughness and Reynold's number. The equation requires iterative solution and can be set-up in Excel based spreadsheet in different options.

$$\frac{1}{\sqrt{f_T}} = -2\log_{10}\left(\frac{\varepsilon/_D}{3.7}+\frac{2.51}{R_e\cdot\sqrt{f_T}}\right) \quad (10)$$

There are many alternative empirical formulae proposed to approximately determine friction factor. Serghides's solution below provides a very high degree of accuracy.

$$A = -2\log_{10}\left(\frac{\varepsilon/_D}{3.7}+\frac{12}{R_e}\right)$$
$$B = -2\log_{10}\left(\frac{\varepsilon/_D}{3.7}+\frac{2.51A}{R_e}\right)$$
$$C = -2\log_{10}\left(\frac{\varepsilon/_D}{3.7}+\frac{2.51B}{R_e}\right)$$
$$f_T = \left\{A-\frac{(B-A)^2}{C-2B+A}\right\}^{-2} \quad (11)$$

The Reynolds number used above is based on liquid phase superficial velocity (theoretical velocity if the entire pipe cross section was occupied by the liquid phase alone), using liquid phase fluid properties, where

$$V_l = W\cdot(1-x)/(\rho_l\cdot A)$$

For commercial steel pipes in geothermal two-phase fluid service, a pipe roughness value upto 0.50 mm is generally used, unless specific data is available.

3.2.2 Homogeneous Flow Model

The Homogeneous method for two phase flow pressure drop is simply the application of the Darcy-Weisbach equation to a pseudo single-phase fluid, defined using the two-phase fluid variables. The pressure drop in terms of metres of head is given by

$$h_L = f_T \cdot \frac{L}{D} \cdot \frac{V^2}{2g} \tag{12}$$

The equivalent two-phase fluid parameters, e.g. dynamic viscosity, density, Reynolds number, are calculated using an equation in the following form:

$$TPV = \frac{1}{\left\{\frac{x}{GV} + \frac{(1-x)}{LV}\right\}} \tag{13}$$

where,

TPV = Two-Phase equivalent variable
GV = Gas Phase variable
LV = Liquid Phase variable

The two-phase Reynolds number for a homogeneous fluid is calculated using the equivalent homogeneous fluid properties. The friction factor for the equivalent homogeneous fluid in turn is calculated using Equation 10 or 11 using the two-phase Reynolds number.

The equations for determining the equivalent two-phase fluid parameters, leading to frictional wall shear stress as per homogeneous flow model are listed as follows,

$$\left.\begin{array}{ll} \text{Dynamic viscosity:} & \mu_{TP} = \frac{1}{\frac{x}{\mu_g} + \frac{(1-x)}{\mu_l}} \\ \text{Mean Velocity:} & V_{TP} = \frac{W}{A} = \frac{4 \cdot W}{\pi \cdot d^2} \\ \text{Fluid density:} & \rho_{TP} = \frac{1}{\frac{x}{\rho_g} + \frac{(1-x)}{\rho_l}} \\ \text{Reynold's Number:} & Re_{TP} = \frac{\rho \cdot V_{TP} \cdot d}{\mu_{TP}} \\ \text{Moody friction factor:} & f_{TP} \\ \text{Harrison Friction factor:} & C_{f_{TP}} = \frac{f_{TP}}{4} \end{array}\right\} \tag{14}$$

where subscript *TP* denotes the variable is the homogeneous two-phase fluid equivalent.

3.3 Equivalent Pipe Length

In addition to frictional losses, the pressure drop along a pipeline is influenced by local energy losses in pipe fittings, valves and other appurtenances. Common practice to account for the pressure losses in valves and pipe fittings is to use "equivalent lengths" of straight pipes that would incur same pressure drops.

Some engineers use published tables from handbooks or suppliers' data listings of equivalent lengths of common fittings and valves. In this method the equivalent lengths of all pipe fittings and valves in terms of straight pipes of same size as the main pipe are separately computed and then added to the length of the straight pipe run. A more popular and convenient methodology for incorporating in a spreadsheet based analytical design tool, is to use the "resistance coefficient" for fittings and valves, based on experimental data provided in CRANE Technical paper 410M. The procedure is discussed below.

The local losses in flow appurtenances can be given by –

$$h_l = K \cdot \frac{V^2}{2g} \tag{15}$$

K is a constant for a given type of valve or fitting, independent of friction factor or Reynolds number.

Comparing equation 15 with Darcy equation 13, the resistance factor for valves and fittings can be expressed in terms of friction factor for fully developed turbulent flow and equivalent pipe length, as follows -

$$K = f_T \cdot \frac{L_{Eq}}{D} \quad (16)$$

Appendix-A of Crane handbook lists representative K values for various valves and fittings in terms of f_T. For example, the equivalent length of a 90º LR elbow is $14f_T$. Substituting the calculated value of friction factor for the given flow conditions, equivalent lengths of various pipe appurtenances are determined and added to the straight length of piping to get the equivalent total pipe length. For special pipe appurtenances, specific resistance factors should be provided by the supplier based on experimental data or other means.

It should be noted that the above discussion and methodology for estimating equivalent length of valves and fittings is based on single phase flow, and its use in two-phase fluid pressure drop calculation is only a reasonable approximation. It is valued as it is easy to implement in analytical design tools. Multipliers to these values based on functions of other fluid properties to improve accuracy have been proposed, but they are not yet implemented in the analysis tools used by the authors.

3.4 Pressure Drop due to Static Head

The gravity component, commonly referred to as Static Head Loss (/gain), represents the change in elevations at the start and end of an inclined pipeline. The pressure drop due to change in elevation is a reversible change (unlike frictional loss), and is given by -

$$\Delta P_{gr} = \rho_m \cdot g . \Delta Z \quad (17)$$

The change in elevation is negative for downhill piping and therefore results in a static head 'gain'. The mean density of the two-phase fluid is dependent on dryness fraction and is determined using established correlations for the chosen analysis model, as explained below.

For Separated flow model,

$$\rho_m = \alpha \cdot \rho_g \cdot (1 - \alpha) . \rho_l \quad (18)$$

For Homogeneous flow model,

$$1/\rho_m = {}^{x}/_{\rho_g} + {}^{(1-x)}/_{\rho_l} \quad (19)$$

For low enthalpy two-phase fluid in downhill piping, the static head gain is often ignored or scaled down.

4. DESIGN TOOLS

Spreadsheet-based design tools, based on the analysis methods described in preceding sections, have been traditionally developed and used by engineers to estimate predicted pressure drop in geothermal two-phase fluid pipeline (Figure 1). The results based on generalised procedure for simplified flow models may not, however, exactly tally with the actual field observations. It is, therefore, a common practice by engineers to include certain "contingency factors" or empirical adjustments to the theoretical analysis results.

In recent years, computer based commercial analysis software packages have become available where one can model the piping network accurately, input the thermodynamic and hydraulic parameters and choose specific correlations to be used for flow analysis. The computer programme then performs the iterative analyses and generates the output, following the same methodology as in the manual spreadsheet.

The outcome of the pressure drop analysis is typically captured in PFD's, together with other key process design parameters, which forms the basis for developing the steamfield and the generation facilities in geothermal developments.

5. CORRECTION FACTORS TO CALCULATED RESULTS

Some considerations for adjustment of theoretical results to predict pressure losses more closely are mentioned below. However, such adjustments are empirical in nature, somewhat subjective and based on discretion of experienced engineers. These can vary according to specific knowledge about flow regimes and fluid characteristics. In brown field developments, actual field measurements from existing two-phase lines should be used to calibrate an analysis model for new assets.

Based on some historical field results in DN400 and DN450 lines, taking the average value of Homogeneous and Harrison pressure loss, following correction factors are generally used by the authors to yield reasonable accuracy against field observations. However, it should be noted that this methodology was derived from specific datasets at limited fluid flows and operating parameters. To further refine the modelling, a greater sample of field data would be beneficial.

400	1221	290	6.3	Annular
400	1280	390	9.6	Annular

The Homogeneous flow model typically underestimates the pressure loss, compared to field observation and a contingency factor of upto 50% (scale up by x1.5) is often applied. The Harrison method using the separated flow model seems to result in more accurate pressure drop in most cases and a smaller contingency factor of 5-10% (scale up by x1.05 – 1.1) is common.

Discretising analysis models is an important aspect of two-phase pressure loss modelling. This is done by breaking a pipeline into smaller segments, and evaluating pressures at consecutive nodes, via an iterative calculation process. Typically, a fixed pressure at a terminal point of the pipeline is required as an input. This could be the flowing wellhead pressure, or a known/required pressure at a junction such as a separation plant. The discretisation process is valuable as it can be used to check convergence of results. Modelling a long pipeline using a single

node can result in significant convergence error, as the two-phase analysis formulae rely on variables which are functions of changing properties over the length of the line, such as steam fraction. In high-flow, transient applications such as emergency dump systems for separated geothermal water, a high resolution of nodes is required as fluid properties change rapidly along the pipe length.

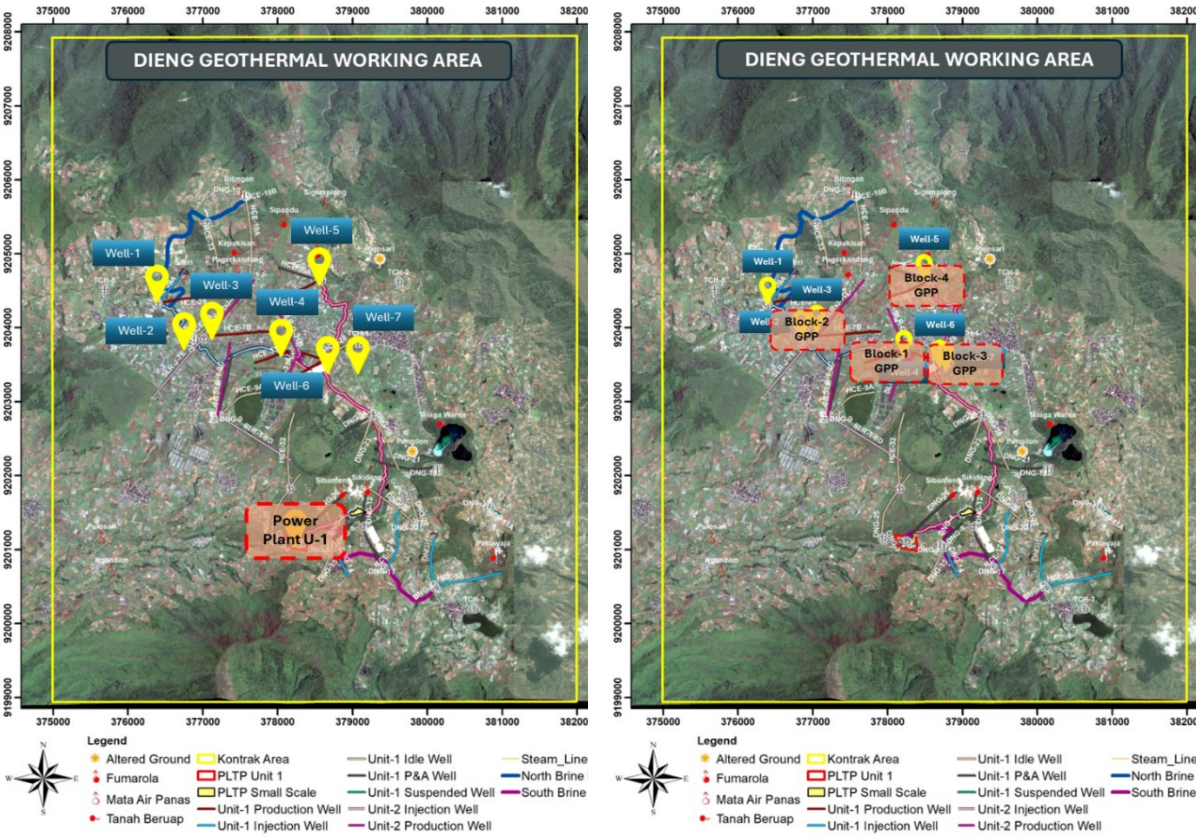
ABSTRACT

Indonesia's Dieng Geothermal Working Area has 200 MW of geothermal and 580 MW of reserve resources. Currently, PT Geo Dipa Energy has an installed capacity of 60 MWe for its Geothermal Power Plant, which applies single flash systems with a total pipe length of about 8.5 km. The authors aim to study the energy loss from the total potential steam from the production well due to pressure and temperature loss. To address these problems, the authors try to engineer the process using block systems in the geothermal power plant, eliminating energy loss along the pipe systems. The research results indicate that the total pressure and temperature loss, using data from maximum capacity in 2020 compared to current conditions, are about 4.5 bara and 22.43°C, and 2.47 bara and 11.19°C, respectively. Furthermore, using ASPEN HYSYS for modeling and simulation of the block geothermal power plant, it was found that the increase in electricity production was 10.12 MWe and 5.91 MWe, equivalent to 17% - 15% of the existing.

1. INTRODUCTION

The Dieng Geothermal Working Area in Dieng, Central Java, has 200 MW of geothermal and 580 MW of reserve resources (Direktorat Panas Bumi & Ditjen EBTKE, 2017). Dieng has been explored with 47 production wells since 1970: 27 production wells under Pertamina from 1977 to 1993 and 20 production wells under Himpurna California Energy (HCE) from 1995 to 1998 (Layman et al., 2002). In 2019, PT Geo Dipa Energi (Persero) (GDE) renewed the geothermal reservoir data model, resulting in a temperature range of 280–330°C (Ashat et al., 2019) and a water-dominated steam characteristic. The Dieng Geothermal Power Plant (GPP) has an installed capacity of 60 MWe and applies single flash systems technology with multiple separator systems at the well field and power plant area. In 2023–2024, gross production was about 40–45 MWe; in 2020, the full capacity of gross production was achieved at 60 MWe. After almost four years of operation, GPP Dieng has decreased by about 20–25 MWe. This has caused a decline in well production and steam loss along the steam pipeline systems.

Figure 1 shows that seven production wells are separated into several areas, with the total length of the pipe to the power plant being approximately 8.5 km from all production wells. The parameters of well production that can generate maximum capacity in the power plant include an average separator pressure of 12.5 bara, a temperature of 187.5°C, and a total steam flow of 438 t/h. The inlet parameters of the power plant systems are about 7.9 bara pressure, a temperature of 169°C, and a steam flow of 432 t/h. Recently, the parameters from the production wells are about 11 bara on average, with a temperature of 187°C and a steam flow of 316.9 t/h. Additionally, the inlet turbine parameters are 8.8 bara, with a temperature of 173°C and a steam flow of 272 t/h. This shows a steam loss in the piping systems of about 44.63 t/h, or 6.3 MWe power equivalent. Steam loss, changes in pressure, and temperature are caused by friction loss, heat loss, and changes in steam parameters at the well production and inlet turbine conditions. Based on the heat loss calculation formula, the effect of thermal insulation conditions in the steam pipeline network was studied in Cerro Prieto Geothermal Field. The total capacity installed is 720 MWe with 13 operating units. Power plants are fed 165 production wells with two high and low-pressure pipeline networks. The pipeline network length is approximately 140 km, with a diameter of 203.2 to 1219.2 mm (8 inches to 48 inches). All pipes were covered by mineral wool and fiberglass insulation with aluminum or galvanized iron as outer protection. From that condition, heat loss resulted as 136 t/h of condensate or equal to 17.57 MWe electricity power. That value represents about 2.44% of the geothermal field capacity installed (Ovando-Castelar et al., 2012).



(a) (b)

Figure 1: Production Well of Dieng Geothermal Power Plant: (a) Existing Systems; (b) Block Systems of Geothermal Power Plant (Source: Author's Documentation)

Based on the problems in the piping systems that can affect the geothermal power plants' electricity generation, the author's point of view is to assess the potential of block system geothermal power plants near the production wells. By designing small-scale systems spread across several areas to reduce energy loss along the central steam piping systems and maximize the utilization of geothermal resources. ASPEN HYSYS modeling and simulation are used to create suitable geothermal block power plant systems. The analysis result is to know the potential of electricity generation is before and after the use of geothermal blocks power plant system with existing parameters of production wells condition.

2. ANALYSIS METHOD

2.1 Thermodynamics Power Plant Analysis

The analysis of geothermal power plants is generally based on the first and second laws of thermodynamics. That principle then developed some parameters that are commonly used to analyze geothermal power plant performance, like overall plant efficiency, Net Plant Heat Rate (NPHR), and Specific Steam Consumption (SSC). That approach was developed to adapt to the operational parameters of the geothermal power plant that the system could monitor.

Overall, the plant efficiency of a geothermal power plant is defined by the first law of thermodynamics, which is defined as energy output divided by energy input. Energy output is defined as generator load (W) because it's the product of a geothermal power plant, and energy input is defined as geothermal steam from the production well that is approached by the total mass flow (m) of steam multiplied by the average enthalpy of production (h).

$$plant\ efficiency = \frac{W}{m\ x\ h}\ x\ 100\% \quad (1)$$

Steam-specific consumption (SSC) is the steam consumed to produce a product. In this scope, steam is consumed to produce 1 kW of electricity (Aziz & Juangsa, 2021).

$$SSC = \frac{m}{W\ nett} \quad (2)$$

Based on the literature, SSC in geothermal power plants ranges from 1.8 – 2.22 kg/s per MWe (Gutiérrez Negrín & Lippmann, 2016). This value also informed the technical cost of electricity production in geothermal power plants.

Net plant heat rate is essentially the same as heat rate, which calculates the heat or energy required to generate a system. In this scope, we see the system as a geothermal power plant. So, the energy used is energy from the total flow rate of steam produced by the production well, and the product is electricity generated by the generator. The equation of this parameter is written as:

$$NPHR = \frac{m\ x\ h}{W\ gen} \tag{3}$$

It's important to specify the scope of the system to analyze the performance of the geothermal power plant since it relates to the product of electricity. The gross power product is defined as the generator that loads electricity. Net power is the gross power minus parasitic load. Parasitic load is the energy used to energize auxiliary equipment in a geothermal power plant ((Ozcan & Gokcen, 2013).

$$W_{netto} = W_{gross} - W_{parasitic\ load} = \left([\dot{m}(h_{in} - h_{isen})]\ x\ \eta_{gen}\right) - W_{parasitic\ load} \tag{4}$$

All these parameters can be determined by plant instrumentation system and thermodynamic properties. Generator efficiency is determined by about 98% (Zarrouk & Moon, 2014).

2.2 Pressure and Temperature Drop

A geothermal power plant uses a piping system to deliver steam from the production well to the power plant and deliver the condensate to the re-injection well. Along the piping system, equipment is installed for different functions like valve, reducer, elbow, loop, condensate drain pod, etc. That equipment gains friction loss from fluid inside the pipe. In saturated steam application, high pressure and temperature drops could lead to condensation, decreasing the amount of steam.

Darcy-Weisbach is used to explain the influence of minor losses against pressure drops in piping systems (Department of Energy Fundamentals, 1992).

$$\Delta_p = (f\frac{L}{D} + \sum K)\frac{pV^2}{2} \tag{5}$$

Where f is the friction factor, L is pipe length in m, D is the diameter of the pipe, K is the fitting coefficient, p is the density of the fluid, and V is flow velocity.

To determine the heat loss of the piping system, we used convection and conduction heat transfer approaches (Wang, 2023).

$$\Delta T = (T_i - T_s)\left[1 - exp\left(-\frac{L}{C_p \dot{m} R}\right)\right] + T_s \tag{6}$$

Where T_i is the temperature of fluid inlet condition, T_s is the temperature of the pipe surrounding/ambient, L is pipe length, C_p is the specific heat capacity of fluid, $\dot{m}$ is the mass flow rate of fluid inside the pipe, and R thermal resistance of the pipe. Then, the thermal resistance of the pipe is formulated using the equation below.

$$R = \frac{\ln(D+\delta)/D}{2\pi\lambda} \tag{7}$$

Where D is the pipe's inner diameter, δ is the thickness of pipe insulation, and λ is the thermal conductivity of pipe insulation, which depends on the insulation material.

Using the mathematical heat transfer model, a study in Indonesia's X Geothermal Power Plant to analyze steam pipeline heat (Pudyastuti & Lie, 2020) concluded an adequate discrepancy of about 1.5 – 5.5 % between the model and measurement.

Recent research has shown that the heat loss of geothermal fluid flow in piping systems is relatively negligible (Zarrouk, 2014). In some cases, the heat loss of 80 t/h of steam at 180 °C flows through a 0.4 m diameter pipe along 2.0 km with 8 cm fiberglass pipe insulation thickness and 20 °C ambient temperature. The energy loss is only 0.6%. The following equation can be derived for the above ambient and piping conditions.

$$\eta_{pipe} = 1 - 0.003L_p \tag{8}$$

Where η_{pipe} is the pipe efficiency based on total geothermal energy and L_p is the pipe length in km.

2.3 Scope and Research Flow Framework

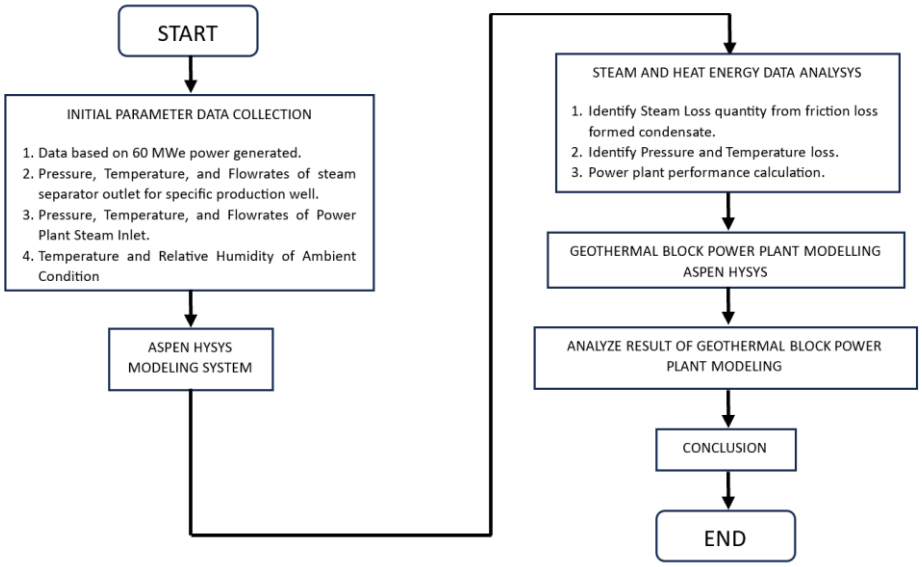


Figure 2: Flow Framework of Research.

Dieng Geothermal Field has seven production wells, and the area is separated from the power plant. Each of them is transported to the Power Plant through a steam pipeline network. This research assesses the potential of geothermal block power plants in block areas of production wells. From the location of the production well and the calculation of pressure drop and heat loss, we divided it into four geothermal blocks. Block-1 (Well-4), Block-2 (Well-1, Well-2, Well-3), Block-3 (Well-6,Well-7), and Block-4 (Well-5). Some research elimination is applied in this research to focus discussion and prevent data bias.

1. Data collected from 2020 operating data parameters at full capacity of production.
2. System scope starts from outlet separator steam until power plant.
3. Subsurface thermal and chemical conditions are neglected.
4. Steady-state condition modeling simulation.
5. The steam dryness of the outlet separator from 2020 data is assumed to be 100%.
6. Turbine efficiency is assumed to be constant at 85% (Zarrouk & Moon, 2014).
7. Pipe insulation condition assumed uniform.
8. The condenser pressure of the geothermal block power plant is assumed to be equal for each block.

First, the researcher collects operational parameters from a Distributed Control System (DCS) for operational parameter data and a Weather Station device for ambient condition data. Operational data collected include pressure, temperature, and mass flow rate of the separator outlet and plant steam inlet. This data is collected based on the full load capacity of the power plant (60 MWe) and current condition. The data was inputted to a Dieng's geothermal power plant system model in ASPEN HYSYS software to simulate the calculation. The simulation results were then collected to identify steam loss, pressure and temperature loss, and power plant calculation. These initial data were then used to model geothermal blocks as specified in the scope of research. The simulation result was used to compare existing plants and identify block geothermal power plant performance.

3. RESULT AND DISCUSSION

The results of performance calculations for the power plant are shown in Table 1. The calculations reveal that the power plant's performance at full capacity conditions (60 MWe) has an NPHR value of 321.25 kJ/kWh higher than the current condition. Furthermore, the total steam usage per 1 MWe of electricity production is also higher by 0.12 t/h or 0.03 kg/s compared to the current condition. The total plant efficiency is lower by about 0.3%, yet both conditions fall within the efficiency range for geothermal power plants worldwide. Additionally, the turbine's isentropic efficiency at both conditions (80.2% and 81.62%) represents the global range for geothermal turbine isentropic efficiency, typically between 60% and 85% (Dickson & Fanelli, 2003). In other words, the performance at full capacity of the power plant and the current conditions still indicate the same plant performance, with no significant decline. The difference in generating power purely comes from the decrease of production wells, parameter conditions at production wells, and the increase in own-use power because of the greater need for supporting equipment.

(b)

The graph in Figure 4 shows a significant drop in pressure and temperature in pipe sections 4, 5, 6, 7, and 8. Significant pressure drop happens at pipe section 4 and pipe section 6 and each value is about 0,81 bara & 1,7 bara. Further, a considerable temperature drop happened at pipe section 6 about 7,53 °C. The pressure and temperature drop at current conditions are almost similar with data at full capacity of production wells and power plants in 2020. Significant pressure and temperature drop happen at pipe section 6 about 0,72 bara and 3,28 °C. These problems occur because steam from several wells combines into one in the main steam pipe refer to Figure 3, resulting in an increase in the friction loss value due to the increased flow rate. The increased flow rate is directly proportional to the increased amount of steam. Meanwhile, the temperature drop is directly proportional to the pressure drop. This temperature drop is corrected by the specific heat value of the fluid flowing inside the

pipe. Each section's pipeline insulation heat loss was compared with the heat flux unit. In this research, all pipelines used Rockwool pipeline insulation with the assumption all of them are in the good condition and the ambient temperature assumed to be uniform in each area of the pipeline section. The ambient temperature is 15.30 °C, this value is based on the average temperature of Dieng when data is collected. As we can see in Figure 4. If we sum up all heat loss through steam pipelines, total heat loss in 2020 is 100.96 kW and in 2024 total heat loss is equal to 50.83 kW. Each value represents 0.17% and 0.13% of the total load generated by the power plant. This result is smaller than a study of pipeline heat loss with varied condition pipe insulation at the Cerro Prieto Geothermal Field (CPGF) power plant, which represents 2.44% of installed capacity (720 MW_e) (Ovando-Castelar et al., 2012). According to Table 2 there are some pressure drop correlations to pipeline geometry, as seen in Figure 4. The pressure drop of pipe Section 6 is the highest among the others since Section 6 has a 1601.18 m length of pipe with total fittings of 38 units. The amount of that condition increases the total length equivalent. It is stated by the Darcy-Weisbach equation. Pressure drops velocity of fluid multiplied by the total pipe segment, so pipe Section 6 has the highest pressure drop. Refer to Figure 3 although pipe section 2 has the same length and number of fittings as section 6, the pressure drop is lower. This is because pipe section 6 accommodates the total amount of steam from all wells, increasing the steam flow rate and fluid flow velocity.

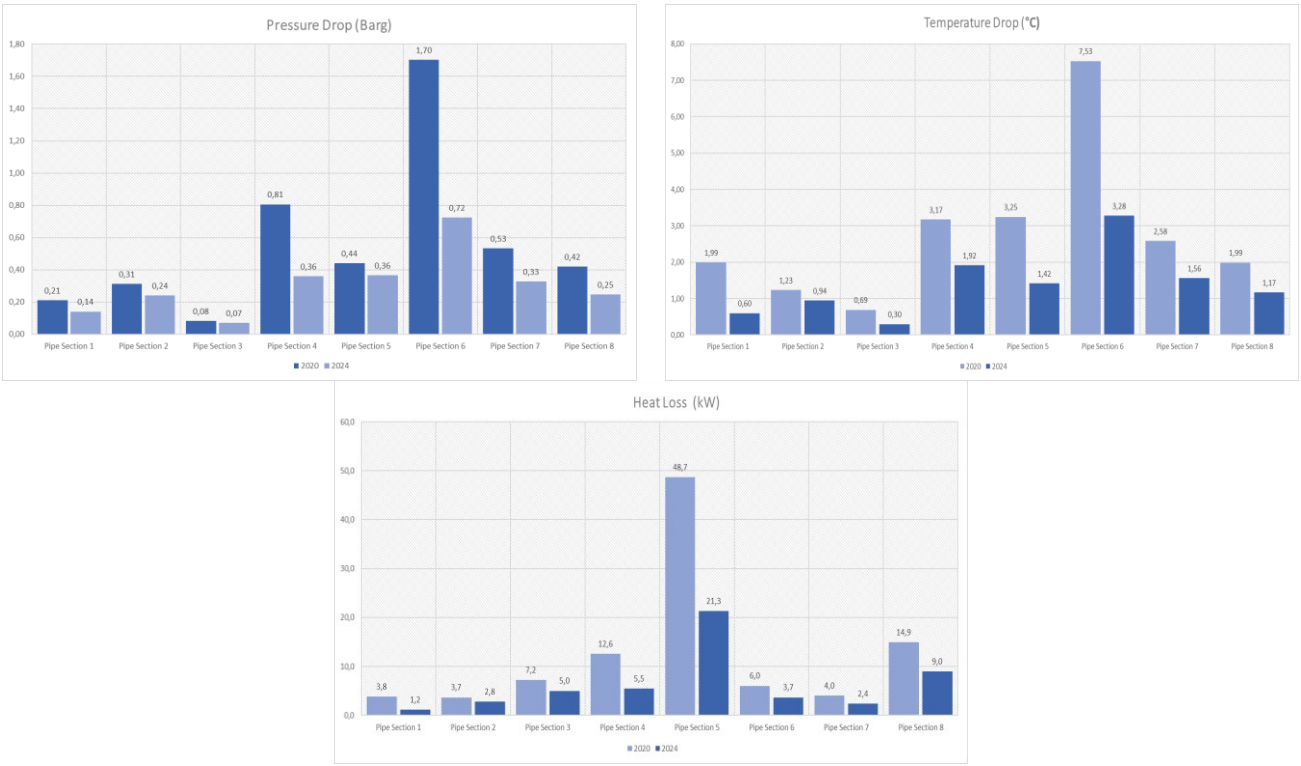

Figure 4: Distribution of Pressure Drop, Temperature Decrease, and Heat Loss.

Table 2: Pipelines Geometry of Existing Geothermal Power Plant.

		Pipe Section 1	Pipe Section 2	Pipe Section 3	Pipe Section 4	Pipe Section 5	Pipe Section 6	Pipe Section 7	Pipe Section 8

Pipe length	m	789.861	1926.11	576.52	1535.123	1031.21	1601.18	579.87	504.57
Total Fitting	Unit	38	38	8	87	22	38	19	15

With modeling using ASPEN HYSYS for the Block Geothermal Systems, as shown in Figure 5, 6, 7, and 8, the pressure and temperature drop is insignificant because the friction and heat loss along the pipe are already unavailable. Transferring the steam out separator through the block geothermal system that is not so far from well production can minimize them. Knowing in Tabel 2 that existing and blocked geothermal power plant systems can reduce the steam loss from the well to the power plant. When using the existing system with long central pipe systems in 2020 and 2024 the number of steam losses is 6,36 t/h and 44,64 t/h. Compared with block geothermal systems in 2020 and 2024, the number of steam losses decreases by about 0,39 t//h and 34,05 t/h. Steam loss at both systems in 2024 is still high because one of the parameters of Well 5 is under the saturation condition at the outlet separator. So steam condensation happens along pipe section 4 due to the output parameters of the separator and the number of loops and fittings.

Steam Inlet Ejector	18,00	2,50	19,60	3,06	17,00	2,40	4,80	0,77

With the modeling and simulation of the block power plant, it was found that electricity production in 2020 was 70.21 MWe and in 2024 was 44.41 MWe. Compared to the existing power plant design, the opportunity for

increased electricity production using the block system can be identified, with increases of 10.12 MWe and 5.91 MWe for each respective year. This increase in opportunity is obtained by converting energy losses along the pipeline to be directly utilized in the block power plant design. The availability of energy from the wells remains relatively high, with energy availability of 165.49 MWe and 128.73 MWe for 2020 and 2024, equivalent to 42% and 34% being utilized to generate electricity. The brine output from the separator still has energy amounts of 95.2 MWe and 78.94 MWe, or 58% and 66% of the energy remains unutilized and can be converted into electricity. In other words, there is an opportunity or potential to use an integrated combined cycle power plant, thereby increasing the thermal efficiency of the geothermal source.

4. CONCLUSION

The research conducted through studying and analyzing the average total pressure and temperature losses during full-capacity generation conditions found them to be 4.5 bara and 22.43°C. In contrast, the current generation conditions are 2.47 bara and 11.19°C. This pressure drop is influenced by the construction of the installed piping system and the amount of steam flowing along the steam pipes to the generator. Increasing the steam flow rate is directly proportional to the fluid or steam flow velocity. Based on the Darcy-Weisbach equation, the flow velocity significantly impacts the pressure drop. The most significant pressure drop occurs in pipe section 6 due to the pipe's construction, which has a length of 1,600 meters and contains 38 fittings.

From the modeling and simulation carried out, the potential for engineering a change in the power generation system to a block geothermal power plant was found, increasing electricity production of 10.12 MWe and 5.91 MWe, or equivalent to 17% - 15% of the existing system, which must transport steam through an 8.5 km long pipe. In other words, using block geothermal power plant technology allows higher electricity production than the existing system.

ACKNOWLEDGEMENT

Keywords: Geothermal drilling, red clay, iron oxide, drilling operation

ABSTRACT

Geothermal drilling activities in Indonesia face many challenges especially comes from the formation. One of the challenges is the presence of iron oxide minerals in the red clay zone. Originating from the decomposition of volcanic rocks enriched with iron minerals, red clay exhibits its distinctive reddish hue owing to the omnipresent iron oxide. Hematite (Fe_2O_3) and Magnetite (Fe_3O_4), the predominant iron oxide minerals in geothermal fields, wield considerable influence over the overall mineral composition of reservoir rocks. Encounters with red clay zone which comprise iron oxide minerals during drilling activities necessitate an understanding of their types and abundance, as they can significantly impact the hardness and abrasiveness of subsurface rocks. Mismanagement can result in formation collapse and stuck pipes, thereby elongating drilling time and escalating project costs.

This study offers insights drawn from operational experiences in the P-Field, a noteworthy geothermal site in Indonesia. The discussion encompasses an overview of general iron oxide mineral characteristics and delves into specific strategies for addressing challenges in drilling operations. Emphasis is placed on mud strategies in production zone, defensive drilling methods, the strategic introduction of slightly underbalance drilling by modified ratio of fluid and aerated in the presence of the red clay zone, modify BHA when experiencing high torque in reservoir zone, and the application of economic reservoir zoning. Implementation of these strategies aims to enhance drilling efficiency, mitigate risks, and optimize project costs.

1. INTRODUCTION

Indonesia is one of the countries in the world with greatest geothermal energy potential. According to ESDM (ESDM, 2020), the geothermal potential in Indonesia reached 23,900 Mega Watt (MW). However, the utilization of geothermal in 2022 was still around 2,360 MW according to International Renewable Energy Agency (IRENA, 2023). In order to harnessing the geothermal utilization which still uncovered, drilling project become one of the way to accelerate this matter. Drilling is the one of the way activity for the respective geothermal operator to enhance their business starting from exploration phase to the development wells. Drilling activity is the main way to gain any new discovered of geothermal potential, despite of there are many challenges during the operation and impact on the high cost needed. Therefore, it is necessary to perform the exploration/development drilling and/or workover operation to sustain and/or escalating their operating capacity.

P-field is one of the biggest geothermal field in Indonesia located in West Java, with one unit operating at 55 MW capacity. In order to accelerate their business, a new geothermal power plant is planned to be built in that area which can covered for an additional 55 MW. To support this, the drilling campaign for 12 development wells have been performed started from September 2021 and ended on the March 2024. During the more than two-year drilling campaign, the drilling team faced many challenges, particularly when drilling in reservoir zone. The red clay zone, which contain Iron Oxide mineral, often to be a root cause of drilling problems after they significantly impact regarding the hardness and abrasiveness. This study will explain some drilling strategies to overcome the problems encountered in the red clay formation, providing valuable lessons for other geothermal operators in Indonesia facing similar challenges.

2. OBJECTIVE AND METHODOLOGY

The objective of this study is to discuss the types and characteristics of Iron oxide Minerals in Red Clay zone in P-field during the campaign. Before delving into the details, the drilling performance in P-Field will be explained, with the rate of the well completion being a key parameter for analysis. Additionally, the representation of drilling challenges/problem in reservoir zone will be illustrated using high torque and/or stuck pipe chart for each well. At the end, the drilling strategies during the campaign namely the transformation of mud strategies during drilling in production zone, perform defensive drilling methods, the application of slightly underbalance drilling when

there is an indication of iron oxide, modify BHA when experiencing high torque in reservoir zone particularly, and also the application of economic reservoir zone, are explained into the detail and eventually become a lesson learn and impact to the overall of the drilling campaign.

3. DRILLING CAMPAIGN SUMMARY

P-Field Drilling Campaign had finished to drill 12 big hole development wells. The drilling campaign was started from the rig demobilization in September 2021 and ended in March 2024 as the rig release for last well. As a summary, the project involves one Mobilization, one Demobilization, four Skidding job, seven Moving inter pad. Majority of the wells drilled in four sections: 26" Surface, 17-1/2" Production, 12-1/4" Production Liner and 9-7/8" Production Liner 2 section. However, there are five wells were needed to be drilled until 7-7/8" Production Liner 3 section as the fifth section as contingency plan in order to reach target depth. The drilling depth wells range start from 1506 mMD to 2107 mMD. In terms of drilling days, the duration range within 26 days to 86 days with 53.9 days average. Figure below shows the rate of well completion in P-Field after the campaign.

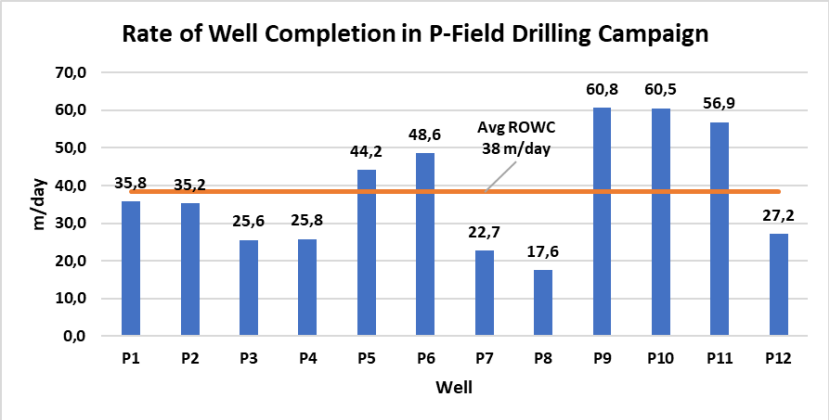

Figure 1: Rate of Well Completion in P-Field.

If looking more detail, there are only five wells which higher than 38 m/day which are P5, P6, P9, P10, and P11. Most of the wells which below average ROWC influenced by hole problem occurred during drilling hence exceed planned days. In addition, drilling campaign generated five wells sidetracked occurred in P3, P4, P7, P8, and P12 which hole problem occurred in these wells specifically. As mentioned above, drilling in Red Clay Zone which contain Iron Oxide mineral generated many drilling problems. The specific explanation of hole problem in Red Clay Zone will discuss in next chapter.

4. RED CLAY FORMATION AND IRON OXIDE MINERALS

Red clay formation is formed by the composition of volcanic rocks that are structured by many of minerals. Iron oxide is one of the mineral composition in red clay formation. Iron Oxide (Fe_2O_3) is composed from the elements between Iron (Fe) and Oxygen (O_2). Hematite/Ferric Oxide (Fe_2O_3) and Magnetite (Fe_3O_4) become the most iron oxide minerals frequently found. Between these types, Hematite/Ferric Oxide is the most iron oxide mineral composition in red clay zone since this kind of mineral has red/brown color which represent the red clay formation. Iron Oxide is a predominant minerals in geothermal fields, wield considerable influence over the overall mineral composition of reservoir rocks in particular. Iron oxide has very unique characteristics with complicated handle. This kind of mineral will react and become rust when meet with oxygen and water. The oxidation process then will occur and cause the solid material, in this case rock, degrade and become brittle. Due to majority of geothermal rocks come from lava which has been deposited from surface over many years, oxidation will occur.

During drilling campaign in P-Field for 3 years, the characteristic of iron oxide minerals have been identified. This type of mineral is reddish and soluble to liquid, particularly when using water in the drilling process. Iron oxide mineral is spreading out in all over P-Field area on two well pads (Pad X & Pad Y) in particular with depth range within 1000 – 1800 m which known as the reservoir zone. Become a soluble and brittle when face the liquid conclude this iron oxide mineral is clearly will affect the hole stability.

5. DRILLING CHALLENGES IN RESERVOIR ZONE

During the drilling campaign in P-Field, stuck pipe incidents accounted for the second highest non-productive time, contributing 699.5 hours or 25.7% of the total NPT. Figure 2 illustrates the high torque and stuck pipe events across all wells in P-Field during drilling campaign.

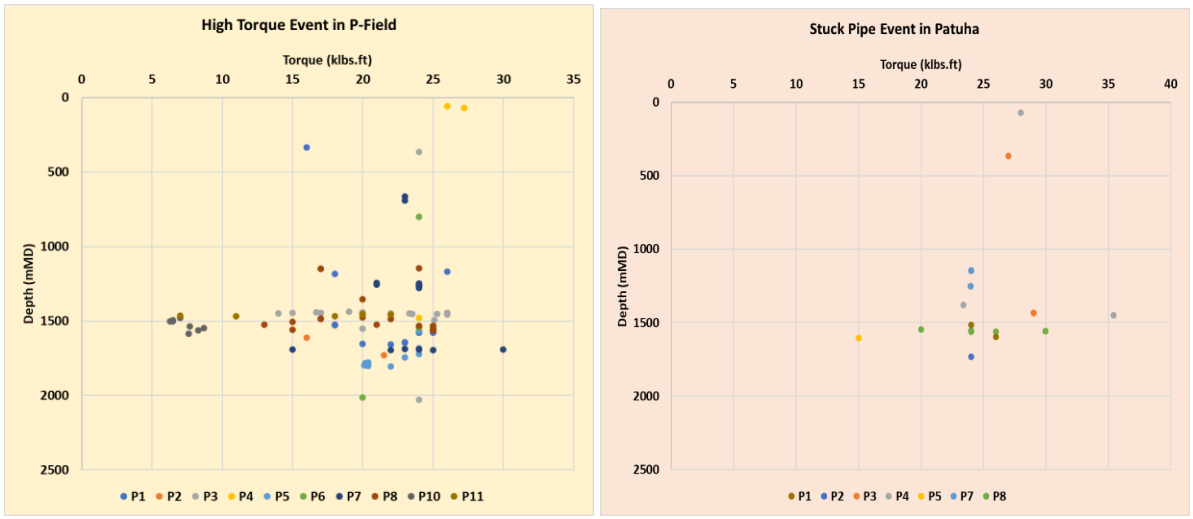

Figure 2: High Torque and Stuck Pipe Distribution in P-Field.

The figure shows that high torque event occurred in all wells with the depth ranging from surface to target depth of 2000 m. However, events most frequent between 1200 m to 2000 m depth, which corresponds to the reservoir zone. High torque events arise due to cuttings and/or formations, which most composed by iron oxide minerals, are not properly circulated to the surface and eventually accumulate below the hole. In addition, since the P-Field reservoir zone does not have a large fault zone to accommodate the cuttings when loss circulation, makes the high torque during drilling happen and stuck pipe then occurred.

Moreover, stuck pipes happen influenced by hole pack off from the formation in most wells. This is particularly problematic in the P-Field reservoir zone, which is composed of red clay formations containing iron oxide minerals that significantly impact formation pack-off. As discussed in the previous chapter, iron oxide minerals fall into three categories, all of which affect formation stability in P-Field. The drilling strategies to optimize handling of iron oxide minerals will be detailed in the following chapter.

6. DRILLING STRATEGIES

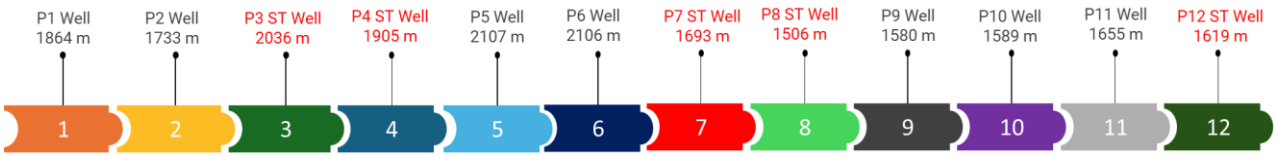

Figure 3: Drilling Journey in P-Field.

Presence of iron oxide mineral in red clay zone become one of the reason hole problem occurred in P-Field. Figure 3 showing the drilling journey in P-Field. Along the campaign, the drilling team continuously learned how the best practice to do the drilling operation since the first and second sidetrack well occurred in P3 & P4 well. The different approaches in terms of drilling operation had been taken to drill in P5 and P6 well. Slightly underbalance drilling and defensive drilling method were applied for the first time and resulting these wells into TD target. However, in the next drilling in P7 and P8 well, since the return condition was PLC and the pad location close to the crater, there was limitation to applied underbalance method, made hole pack off problem occurred suspected by presence of iron oxide in red clay formation. The continuation of drilling problems despite different approaches taken necessitated drilling team to thoroughly review the drilling program. Drilling team concluded that changing mud strategies in production zone, modify drilling BHA when experiencing high torque, maintaining defensive and slightly underbalanced drilling method, and apply the economic reservoir zoning were the best strategies to be applied. The detail of drilling strategies are explained in below.

6.1 Mud Strategies During Drilling in Production Zone

KCl Polymer is the most often mud type used when drilling for 26” section and 17-1/2” section due to these sections possess swelling clay and sticky clay as the drilling hazard. KCl (Potassium Chloride) is effectively used to inhibit clay hydration and generally KCl levels within 3-5%. Moreover, KCl polymer produce sufficient Plastic Viscosity (PV) and Yield Point (YP) as the mud properties which present the ability to lift the cuttings to the surface. Since the drilling in 26” and 17-1/2” are in full return condition mostly and rarely on partial loss event to total loss, this mud system is suitable.

After drilling in 4-5 first well, the team observed that flow return condition when drilling in reservoir zone was partial loss – full return condition instead of total loss. This indicates that the fault in reservoir zone is not large enough. And the presence of iron oxide which soluble and brittle when face the water only and still contain clay washout, can produce more cutting and lead to hole problems. Therefore, drilling team initiate to continue utilized the KCl Polymer mud when drilling in 12-1/4" and 9-7/8" hole section. Nevertheless, it is really noteworthy that KCl polymer mud type is only utilized when the partial loss – full return is still occurred. When encountered partial loss – total loss and the ability of mud mixing is not sufficient, then aerated mud + viscous water be applied. Moreover, in order to prevent high torque, lubricant additives need to be added within 1-2% range either KCl polymer or aerated water + viscous water mud type. Figure 4 explain the decision scheme of mud system in reservoir zone.

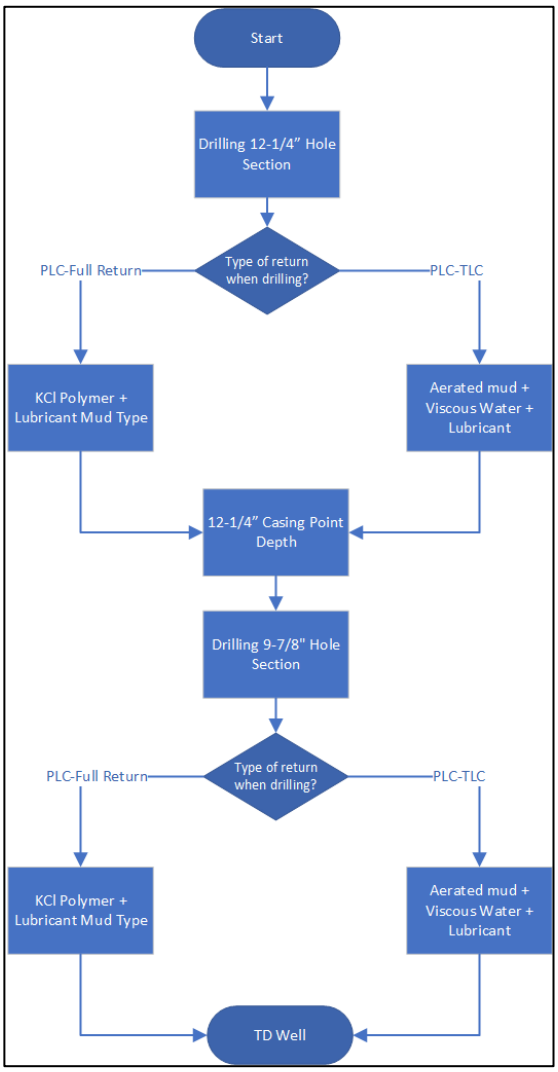

Figure 4: Mud System Selection Scheme.

6.2 Defensive Drilling Method Application

Defensive drilling is another drilling strategies applied in P-Field during the campaign. This method was applied firstly in P5 well and continuously maintained to the last well in P12. The principal of this method is perform drilling along 3-5 m progress. Afterwards, drill string picked up full stand while working pipe and circulate hole. This method is to ensure the wellbore in clean condition after drilled and will not lead to high torque, hence the drilling can reached target as per program. Defensive drilling method generally applied when face the iron oxide minerals. However normal drilling condition was conducted if there is no presence of iron oxide.

6.3 Application of Slightly Underbalance Drilling

As the terms, slightly underbalance drilling is modify the ratio between liquid (water/mud) and aerated mud which makes the mud flowrate lower than air rate in order to prevent iron oxide face the water/liquid. Moreover, since the mud flowrate was reduce, the borehole temperature become slightly hotter and iron oxide minerals is expected to be stable. Since the slightly underbalance drilling influence the pressure in wellbore keep lower than formation

pressure, this make allows cuttings to the surface and keep wellbore in clean condition. The application of aerated mud in slightly underbalance drilling was within 1800-2800 SCFM and influence the foam rate utilization between 8-20 gph. Meanwhile, the liquid ration was keep in 300-500 gpm during drilling.

6.4 Modify BHA in Reservoir Zone

Drilling BHA plays another important role when drilling in P-Field. In the first 4 wells, the directional BHA was always applied from the first to last section. However, stuck pipe occurred in P3 and P4 wells in 12-1/4" section and left the important part of directional BHA in hole which impact on drilling cost. The drilling team, after reviewed the drilling program, agreed to consider the utilization of rotary BHA instead of directional BHA when drilling in reservoir zone. In this case, directional BHA was still become a priority after this type of BHA cand adjust and correct the direction of the well as of reservoir target plan. However, when drilling encountered high torque zone, the replacement from directional BHA to rotary should be performed. From the operation, torque was considered as high when the drill string became difficult to rotate – stalled with the maximum torque was limited into 25 klbs.ft. In addition, since slightly underbalance method was applied in reservoir zone in order to maximize allowing on cuttings to the surface, directional BHA could not accommodate after there was a minimum liquid flowrate requirement from the mud motor and also influence to the temperature. The other objective to utilized rotary BHA in production zone was reduce cost fish and reduce large size of BHA component which impact to the release drill string when stuck. Moreover, even after the high torque and other considerations still occurred during drilling with rotary BHA, decision to utilize slick rotary BHA was conducted.

6.5 Economic reservoir zone

At the time after all drilling strategies had been conducted in reservoir zone (change mud strategies in production zone, defensive drilling method, slightly underbalance drilling, and modify BHA) did not help, then the application of economic reservoir zone become the last option. Economic reservoir zone was applied during the campaign in P-Field start from the P9 to P12 well. This method was conducted during drilling in reservoir zone by set casing shallower in order to prevent hole pack off if the well going deeper particularly when the iron oxide was appear. In this regard, after the well had been set casing using 8-5/8" perforated liner 2, a well completion test then carried out to assess whether the well can produce geothermal fluid. If the well completion test results are good, drilling then will be stopped and that depth. However, if the results are not satisfactory, going deeper the well using 7-7/8" hole section as contingency plan will be continued. Figure 5 shows the detail of drilling strategies during drilling campaign with the results.

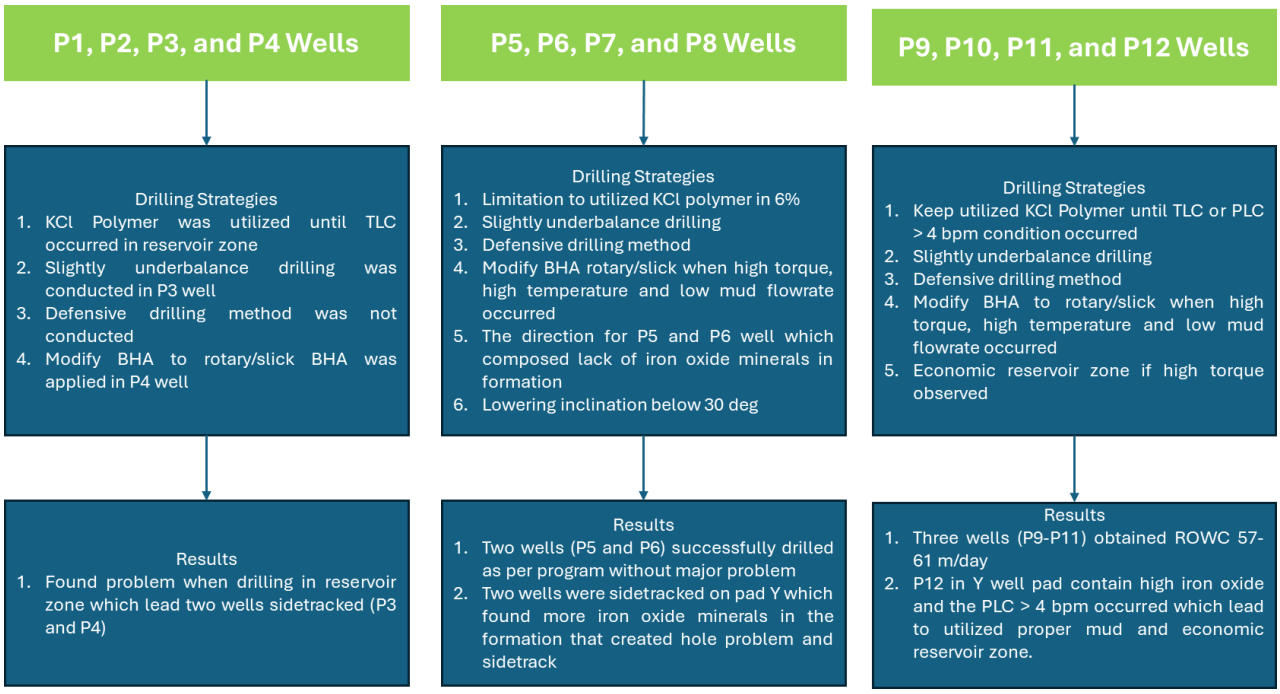

Figure 5: Drilling Strategies with the Result.

As we can see, different drilling approaches were always performed in each of the four wells, resulting in better outcomes. In the first four wells, all wells exceeded the drilling days based on the program, with two wells were sidetracked. Then, in the next four wells, when the defensive drilling method and slightly underbalanced drilling were applied, two wells successfully reached TD (total depth), however P7 and P8 wells experienced sidetrack due to the return condition was PLC and the pad location close to the crater enforced limitation to applied

underbalance method. The peak was in wells P9 to P12, where after a review of the drilling program, only one well exceeded the drilling days and performed a sidetrack.

7. CONCLUSION

Drilling campaign in P-Field resulting 12 development wells had been finished, started from 2021 to 2024. Through three years, many lessons learn were obtained during the campaign, particularly in the drilling operation. The presence of iron oxide minerals in the red clay formation within the reservoir zone presents a challenge for the drilling team to execute the entire well to reach the total depth target. Based on drilling operation, the characteristic of iron oxide minerals have been identified. This type of mineral is reddish and soluble to liquid, particularly when using water in the drilling process, predominantly found in two well pads (Pad X & Pad Y) within the depth range of 1000 – 1800 meters. Consequently, during operations, stuck pipe incidents became one of the largest (NPT) contributor during the drilling campaign, accounting for 699.5 hours or 25.7% of the total NPT. This is understandable as high torque and stuck pipe events mostly occur at depths of 1200 to 2000 meters, which correspond to the reservoir zone. This depth range is also where the red clay zone containing iron oxide is distributed.

During the operation, especially after completing the first four wells, the drilling team then applied another approach, namely Slightly Underbalanced Drilling and Defensive Drilling Method. Both methods successfully brought wells P5 and P6 to reach the expected TD target at depths of 2107 and 2106 meters. However, in the next drilling in P7 and P8 well since the return condition was PLC and the pad location close to the crater, there was limitation to applied underbalance method, made hole pack off problem occurred suspected by presence of iron oxide in red clay formation. The continuation of drilling problems despite different approaches taken necessitated drilling team to thoroughly review the drilling program. Drilling team concluded that changing prudent mud composition and/or system, modify drilling BHA when experiencing high torque, maintaining defensive and slightly underbalanced drilling method, and apply the economic reservoir zoning were the best strategies to be applied.

In terms of applying a mud strategies during drilling in the reservoir under partial loss-full return conditions, a KCl polymer will be used as the mud system to ensure that the cuttings can allow to the surface. A defensive drilling method will also be employed by circulate hole clean and working pipe after drilling 3-5 meters to ensure the wellbore is clean after drilling and to avoid high torque. Slightly underbalanced drilling will also be conducted alongside the defensive drilling method, where the ratio of aerated mud is higher than the liquid. The application of aerated mud in slightly underbalanced drilling ranges from 1800-2800 SCFM, influencing the foam rate utilization between 8-20 gph. Meanwhile, the liquid ratio will be maintained at 300-500 gpm. Modifying the BHA will also be done when high torque is encountered and applied slightly underbalance drilling which influence minimum mud flowrate, by switching from directional to rotary BHA. Moreover, reduce fish cost and reduce large size of BHA component are other objectives to utilized the rotary BHA. However, if this persists, a slick BHA will be used. The economic reservoir zone becomes the last method of the drilling strategy implemented in the P-Field by setting casing shallower to prevent hole packing if the well goes deeper, particularly when iron oxide appears. If the well completion test results are unsatisfactory, then continuing the well deeper using a 7-7/8” hole section as a contingency plan will proceed. The strategies proved successful in the last four wells, which only one well exceeded the drilling days.

Keywords: production operations, optimization, well head pressure, trim valve

ABSTRACT

Production operations optimization means various experimental implementation in the field which consider any aspects that might intervene the system in the purpose of obtaining the most optimum operations production. In Patuha Geothermal Field, there is X-7 Well that always gets a spotlight. The well shows an unstable production behavior with the well head pressure declines rapidly. X-7 Well also has calcite scaling problem in wellbore. Well washing usually executed to bring back the performance of X-7 Well before the campaign of well intervention. Well washing is implemented periodically by injecting condensate water for a certain period then shut-in the well until reach its maximum of stable well head pressure then the well online to main system. However, even after the well washing, the well head pressure still declines rapidly. As the result, well washing often forcefully done until the well head pressure equal to main steam line pressure. Due to this condition, the production operations optimization must be implemented. The set of well head pressure and trim valve to steam-in the X-7 well to the main system considering the operations constraint. These will be determined by an upper and a lower limit considering the known data from the well to the main system. The purpose of this optimization is to obtain the most optimal trim-valve opening then the production days getting longer and achieve the most efficient steam production. A 10% trim-valve opening is recommended because it shows the most optimal results in addressing the issues present at X-7 Well.

1. INTRODUCTION

The Patuha Geothermal Field, located southeast of Bandung in West Java, Indonesia, has been in commercial operation since 2014 by producing electricity from vapor dominated steam. Patuha Geothermal Power Plant operates twelve (12) production wells with steam dryness levels ranging from 95% to 98%. The X-7 Well is one of the production wells that contribute to Patuha Unit 1. X-7 Well was drilled in 1997-1998 then subsequently idle due to Indonesia's economic crisis.

During the production process, X-7 Well has exhibited unstable production behavior leading to scaling issues that impact production rates. The ability of the geothermal reservoir to deliver fluids is a success factor in geothermal energy utilization while scaling at pipe connected to production well determines the efficiency of power production. Most common scale in geothermal field are silica and calcite. For example, the serious decline in steam production well in Maori geothermal field is caused by calcite deposit and scale inhibitor is used to prevent precipitation of calcite in the well successfully (Sigfusson and Gunnarson, 2011; Fukoda et.al, 2011; Thorhallsson, 2012). When productions well not perform properly, various well intervention has been implemented such as well head water injection that often conducted at high pressure, intermittent cold-water injection, and well heating up in order to open up the hydrological path to permeable zone (Axelsson et.al, 2006).

In Patuha Geothermal Field, workover and well intervention using Coiled Tubing Unit were conducted multiple times to clean the wellbore from scale and remove any remaining fish with the intention to maintain the production performance of the well, thus minimizing the needs for future well-washing. Well washing is performed at X-7 Well when the well-head pressure almost equal to the main-steam-line pressure and plans for workover or well intervention still scheduled for a later time. Well washing implemented periodically as short-term effort to sustain steam production.

2. METHODOLOGY

Optimization is a time-consuming process that needs numerous stages and considerations from any aspect, often requires repeated efforts to achieve the desired optimum result. Optimization is necessary due to the production behavior of X-7 Well that is being quite unstable. To start, the problem has to clearly defined. Next, literature study is done to gather necessary data and explore the potential solutions. Data collection includes piping specifications to define constraint in this optimization process and historical event data of the well to mapped any

program that has been done previously in the well. Well production data correlate to piping specifications data and historical event data with the output optimization method will be executed in the field, typically through a field trial.

In the field-trial process, data are collected for analysis and evaluation of the field-trial result. It is not always possible to immediately get the right or even the best method. The method needs to be modified or changed if the result is deemed ineffective of implementation in the production operations. The effectiveness of this field-trial process should be carefully and wisely analyzed by comparing it with initial data and previous field-trial data. Geochemical data is essential to corroborate the results of the effectiveness in each field-trial. The end of this optimization is to obtain the most optimal methodology that can be applied to the production operations process in the field, as shown in Figure 1.

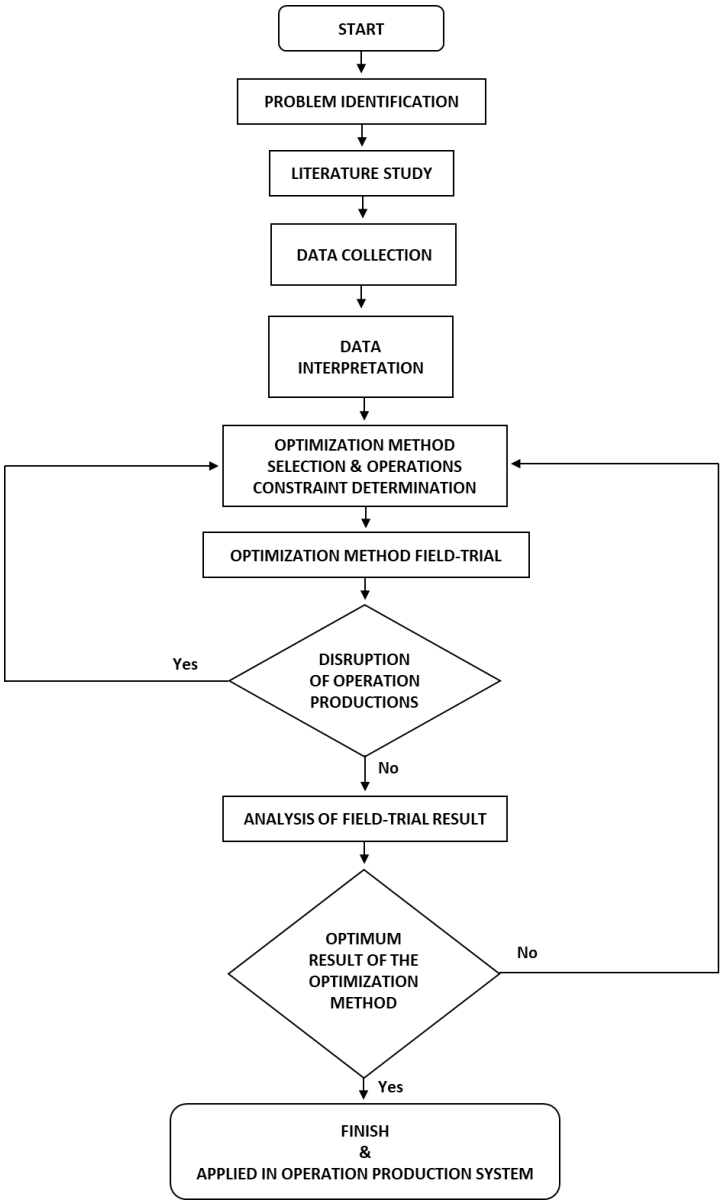

Figure 1: Methodology of the study.

3. CASE STUDY

Workover for X-7 Well was conducted in November 2020, the results were sufficient to supply the steam production. The operation of X-7 was return to normal and the well head pressure declined gradually for about 2.4%/month until it nearly equal to main steam line pressure by January 2022. Well head pressure will equivalent to main steam line pressure unless measures are taken to prevent flow disruption such as blockage or back-pressure. Before this occurrence might happen, the X-7 Well should be out from the main system followed by well washing to restore its performance. After completing the well washing, X-7 Well will be online to the main

system. However, despite the well washing has been done, X-7 Well shows a rapid decline in well-head pressure, approximately 24% per month, eventually almost equal with the main-steam-line pressure. Within less than a month, another well washing is required due to the average monthly decline in well-head pressure of about 40% as shown in Figure 2.

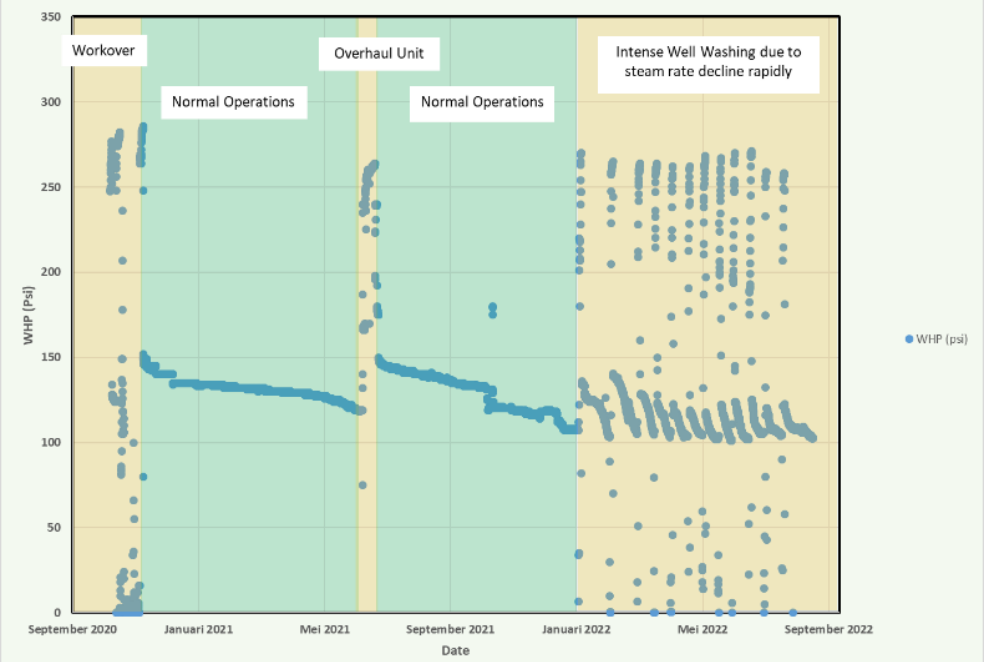

Figure 2: Well Head Pressure X-7 Well Trend after Workover 2020.

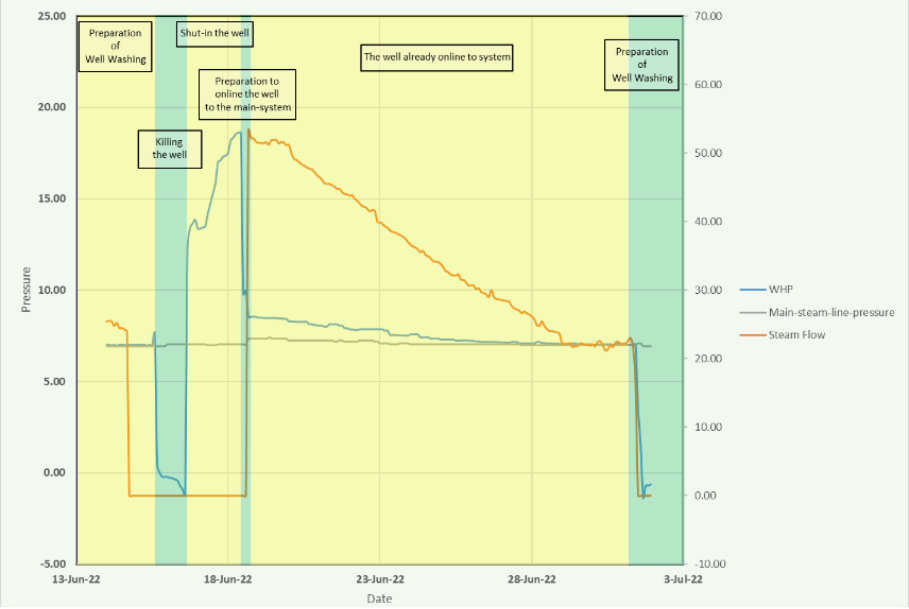

Figure 3: WHP vs Main-Steam-Line-Pressure vs Steam Flow during Well Washing.

3.1 Well Washing

Well washing is the short-term action when the well head pressure declines below the differential pressure restraint to the main steam line pressure with the intention of recovering the performance of the well. Well washing is implemented periodically, conducted by injecting condensate water for a specified duration as part of the program then shut in the well as the program until reaches its maximum shut in well head pressure. Before the well is online to the main system, the steam quality should be checked by using a brass target plate and geochemical analysis as required. If the quality of steam meets the range of its requirement, then the well will be online to the main system.

Well washing is conducted in five stages as shown by Figure 3. The first stage is preparation, since the well head pressure is close to the main steam line pressure, preparation means the pump for killing is in a good condition to

operate and the well will be offline from the system to the silencer. After that, killing the well by condensate water until a vacuum is achieved then condensate water continues to be injected for a certain period and shut-in the well until it reaches its maximum pressure for a certain duration. Next, focuses on preparing to online the well to the main system takes an important role because the steam quality should be checked to ensure it meets the requirements before online to the main system. Finally, the well will be online to the main system to supply the steam production by adjusting the trim valve opening. In every stage of well washing, continuous monitoring is conducted on the wellhead assembly to ensure that there is no leakage during this process. Additionally, monitoring is performed on the casing & wellhead temperatures also wellhead movement.

Table 1: Result of Well Washing after Workover 2020.

Well Wash	Period	WHP DECLINE		Production Days	Trim Valve Opening (%)
		% /day	% /month		
1	Jan-22	0,8%	24%	26,8	40%
2	Feb-22	1,3%	38%	22,9	32%
3	Mar-22	2,3%	68%	12,9	32%
4	Apr-22	2,4%	71%	12,8	34%
5	Apr-22	1,2%	36%	13,8	35%
6	May-22	1,2%	36%	11,8	33%
7	May-22	1,1%	33%	11,8	33%
8	Jun-22	1,9%	57%	9,9	32%
9	Jun-22	1,5%	46%	12,8	32%
10	Jul-22	1,2%	36%	11,7	32%
11	Jul-22	0,8%	24%	14,5	32%
12	Aug-22	0,4%	12%	27,0	32%

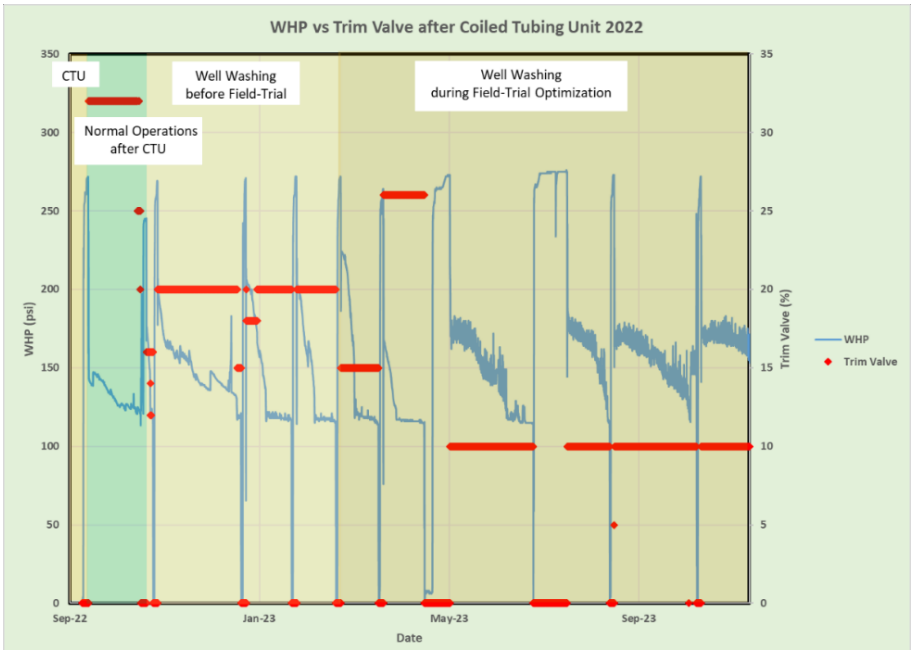

Figure 4: WHP vs Trim Valve after Coiled Tubing Unit 2022.

3.2 Well Head Pressure Decline

After 413 days since the last workover passed and the operation of X-7 Well without conducting any well washing, then the first well washing was finally carried out in January 2022. After the initial well washing, refer to Table 1, the X-7 Well came back online to the main-system with a trim valve opening 40%. However, it only contributes to supply the steam production for 26 days due to a well-head pressure decline of approximately 24% per month, nearly reaching the main-steam-line pressure. After that, a second well washing was necessary, and the well returned online with a trim valve opening 32%, but contributed only 23 days with a well head pressure decline of about 38% per month. Then, well washing was conducted routinely and forcefully at regular intervals. Data shown in Table 1 indicates that the second period well wash with a smaller trim valve opening resulted in shorter production days. Even in the third period, with the same trim valve opening of 32%, production days were further reduced to only 13 days before another well washing was needed. Furthermore, maintaining a relatively constant trim valve opening in subsequent periods around 32%-35% continued to reduce production days, with some

periods lasting only 10 days before requiring another well washing. The X-7 Well demonstrates that increasing the trim valve opening after well washing actually shortens production days, and maintaining a constant trim valve opening leads a continual decrease in production days in each period. This indicates that there is an issue with the X-7 Well, specifically scale growth inside the wellbore that impedes well productivity (Sujarmaitanto, H. et al. 2022). It necessitates a workover or well intervention on this well as a long-term action, similar to the 2020's workover that was previously conducted.

In September 2022, a well intervention using Coiled Tubing Unit was carried out to clean the wellbore of the X-7 Well. After the well intervention was finished, the well was online to the main system for about 32 days. It has to undergo another well washing due to the well head pressure closely equivalent to the main steam line pressure. Then well washing was executed periodically as shown in Figure 4.

4. RESULT AND DISCUSSION

An optimization for X-7 Well is necessary to maximize the production days. Adjusting the trim valve opening is the method to optimize the operations production of X-7 Well so the well washing intensity becomes less frequent and the well can reach its optimal steam production.

4.1 Operations Constraint

The setting of trim valve opening to steam-in the well into the main system must consider operation parameters from the well head, well steam line then main steam line, known as Operations Constraint. These will be determined by upper and lower limit by considering the known data of the wells and the operating parameter correlated to the main system (Donoso, 2022). Well steam line is a line that directly connected from the wellhead to accommodates fluids from a single well before gather to the main steam line. Main steam line is a line that gather all well steam line, thus becoming the main line that transport geothermal fluids to the power plant. Well head pressure and main-steam-line pressure are considered as the limitation in this production optimization. Increasing the trim-valve opening reduces the well head pressure, if this parameter is not carefully managed and exceeds its limits, it can lead to blockage or back-pressure issues. On the other hand, decreasing the trim valve opening increases the well head pressure, which potentially triggers the safety system protection (pressure safety valve and rupture disc) or more serious safety issues if it's not controlled. The maximum well head pressure as the upper limit will be defined lower than the Maximum Allowable Pressure of the well steam line, as shown in Equation 1. The minimum well head pressure as the lower limit will be defined higher than the main steam line's pressure as shown in Equation 2. When reducing the trim-valve opening followed by the increase of well head pressure, it is obligatory to ensure the main steam line pressure does not exceed its maximum design pressure for Pressure Safety Valve, as shown in Equation 4. The minimum main steam line pressure as the lower limit will be defined higher than the well head operating pressure, as shown in Equation 5. The well head operating pressure is defined by a value that is lower than the maximum well head pressure and higher than the minimum well head pressure. These parameters play an important role in the optimization decision making. Any action has to be taken when the well head pressure is near the lower limit or almost equal to the main-steam-line-pressure as well as the upper limit. Specially, the upper limit is beneficial as a guidance to adjust the trim valve when the well has to be online after shut in, to ensure it does not exceed its Maximum Allowable Working Pressure in the well steam line also the design pressure for safety pressure valve in the main steam line.

$$MAWP_{well-steam-line} > WHP_{max} \quad (1)$$

$$P_{operating\ main-steam-line} < WHP_{min} \quad (2)$$

$$MAWP_{well-steam-line} > WHP_{max} \geq WHP_{operating} \geq WHP_{min} > P_{operating\ main-steam-line} \quad (3)$$

$$P_{design\ for\ PSV} > P_{max\ main-steam-line} \quad (4)$$

$$WHP_{operating} > P_{min\ main-steam-line} \quad (5)$$

$$P_{design\ for\ PSV} > P_{max\ main-steam-line} \geq P_{operating\ main-steam-line} \geq P_{min\ main-steam-line} < WHP_{operating} \quad (6)$$

In order to determine the maximum pressure and temperatures as operation constraints, piping design and specification in the steam line have to be considered. Table 2 shows the steam line piping specifications. The constraint set in this optimization is easily illustrated in Figure 5.

Table 2: Steam Line Piping Specification.

Rating	Well Steam Line CLASS 300	PSV at Main Steam Line
Design Pressure	36 barg	11.5 barg (PSV)
Design Temperature Max	250°C	-
Design Temperature Min	15.2°C	-
Operating Flow Temp Max	184.6°C	-
Operating Flow Temp Min	175.5°C	-

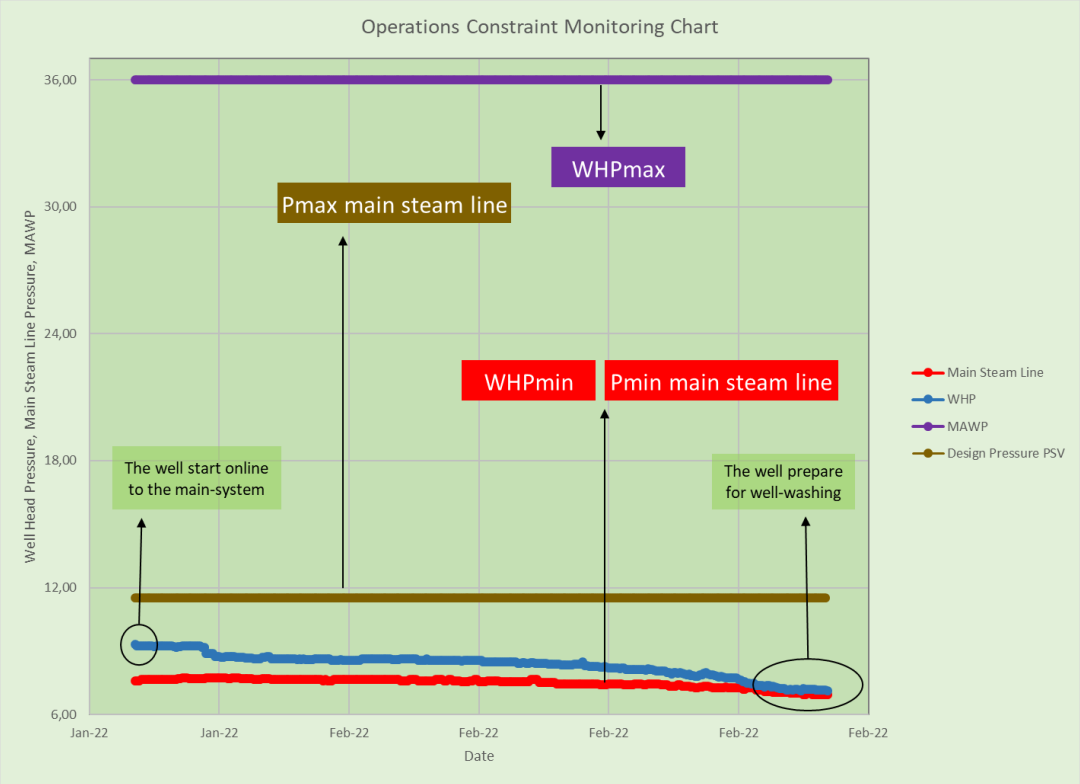

Figure 5: Operations Constraint Monitoring Chart.

4.2 Trim Valve Adjustment

The upper and lower limit in trim valve adjustment cannot be ignored since that are the most important parameters. Adjusting the trim valve opening above 20% requires full attention to the allowable working pressure of the pipe as the upper limit and vice versa.

Table 3: Result of Well Washing after Coiled Tubing Unit. Before Optimization, and During Field-Trial for Optimization.

Well Wash	Period	Trim Valve Opening (%)	WHP Starting (bar)	WHP DECLINE		Production Days	Steam Prod Avg (Tn/hr)	Cum. Steam Prod (Tn)
				% /day	% /month			
13	Nov-22	20%	14.21	0.7%	21%	52.7	26.24	33,114
14	Jan-23	20%	13.76	3.4%	103%	28.7	19.78	13,567
15	Feb-23	20%	15.06	4.2%	125%	24.7	20.57	12,133
16	Mar-23	15%	15.31	4.7%	140%	23.8	16.41	9,255
17	Apr-23	26%	11.63	3.9%	116%	25.8	20.48	12,656

Field-Trial for Optimzation

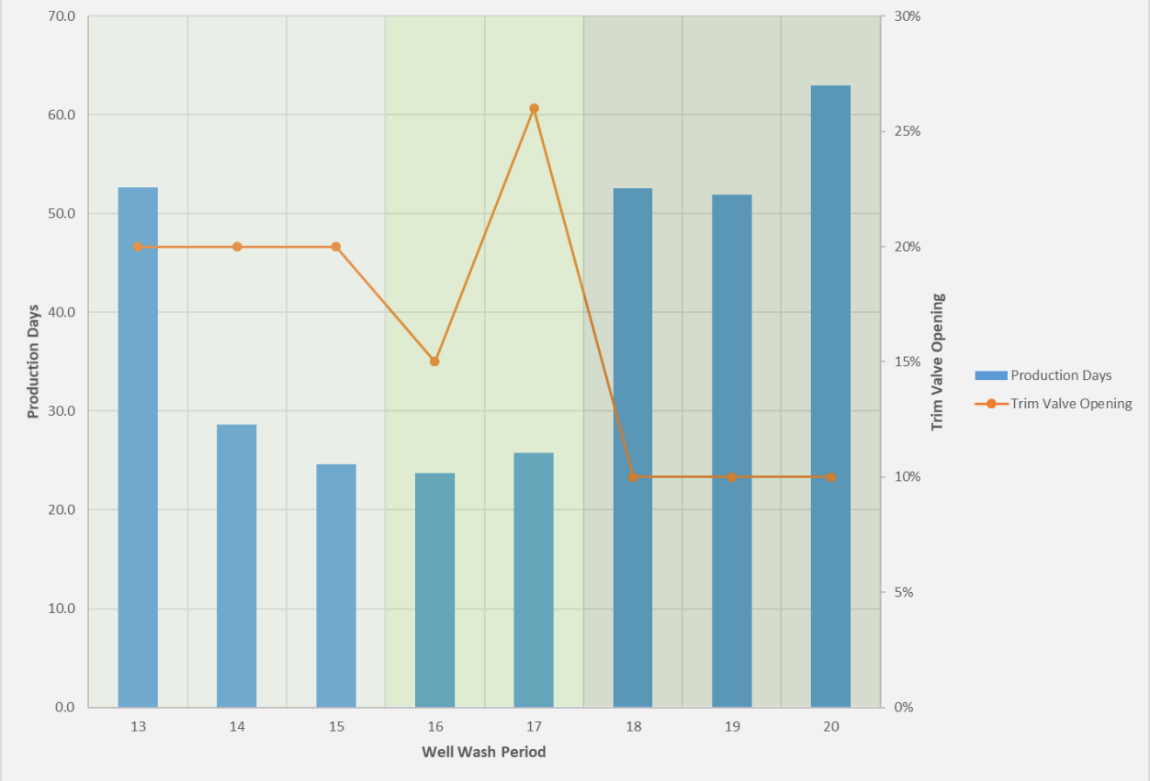

Figure 6: Production Days vs Trim Valve Opening.

The field-trial optimization was executed several times by adjusting trim valve opening with 15% (lower than 20%) and 26% (higher than 20%). The result of these adjustments is shown by Table 3. The trim valve opening at 15% led to shorter production days compared to the trim valve opening at 20% due to higher well head pressure decline with a cumulative steam production falling below expectations. The trim valve opening at 26% resulted in production days and cumulative steam production almost similar to trim valve opening at 20%. In addition, geochemical analysis data as shown in Table 4, indicates several geochemical parameters are sufficiently high and pose a risk of calcite deposition along the wellbore, which may lead to a rapid decline in steam production over a short period of time. Based on the trial result shown in Figure 7, there is no significant difference between 15% and 26% trim valve openings, thus another field trial will be conducted on different trim-valve opening in order to obtain the optimal setting.

Table 4: Geochemical Analysis for X-7 Well.

Well Wash	Period	Trim Valve Opening (%)	pH	Ca (ppm)	HCO3 (ppm)	TDS (ppm)	CSI
13	Nov-22	20%					
14	Jan-23	20%	8.51	5.56	26.93	160.38	0.72
15	Feb-23	20%	7.58	17.7	24.35	183.54	0.75
16	Mar-23	15%	6.52	42.2	29.2	79.79	0.89
17	Apr-23	26%	6.97	21	27.92	228.91	1.2

Before Optimization
Field-Trial for Optimization
Field-Trial for Optimzation

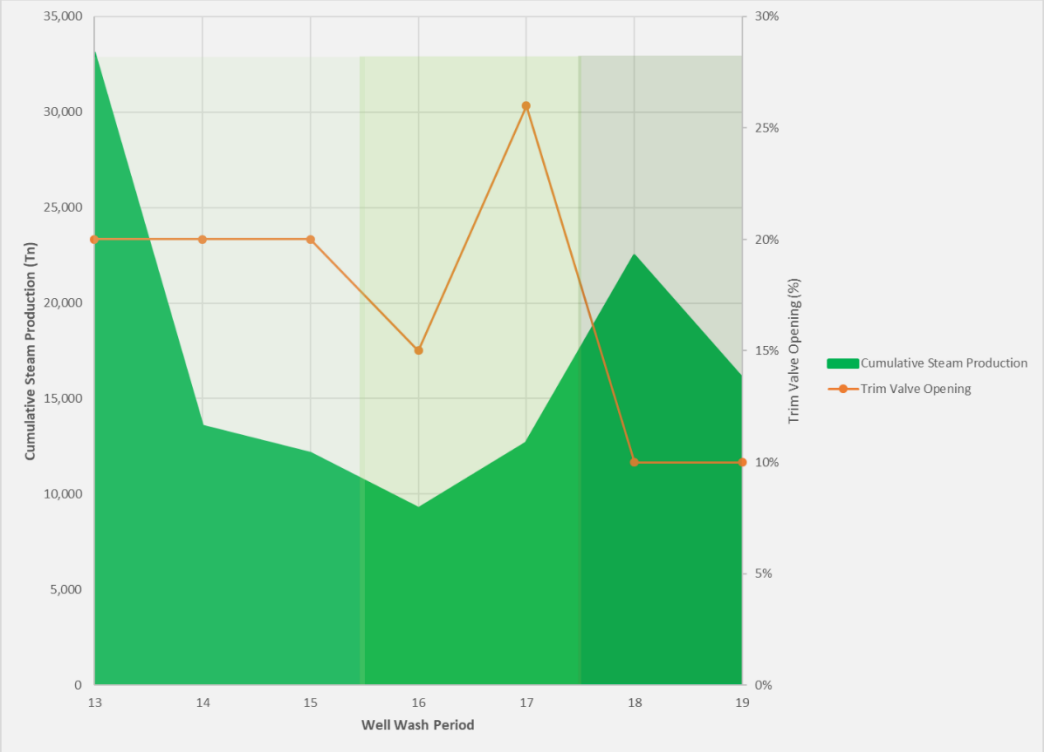

Figure 7: Cumulative Steam Production vs Trim Valve Opening.

The next field-trial was performed by adjusting trim-valve opening at 10%. By adjusting trim valve opening at 10% shows promising result. Thus the 10% trim-valve opening has been decided for next well washing to validate the consistent positive outcomes. Based on the geochemical analysis, the calcite saturation index (CSI) values are negative, indicating a significantly lower risk of calcite deposition. These geochemistry data taken from separated water sample from the well steam line at the top and bottom port sampling points, providing insights into conditions within the wellbore and at the surface. It is also confirmed by the production days which is two times longer and the cumulative steam production increased during that period, the significant results are shown in Table 3 and Table 4 for well wash 18-20.

4.3 Comprehensive Analysis of Field Trial Effectiveness

The result of the field trial has been comprehensively analyzed, encompassing the well production performance throughout its life time or production days and steam production, also geochemical analysis.

Table 5: Optimization Parameters Effectivity Comparison.

Well Wash	Trim Valve Opening (%)	Production Days	Effectiveness by Production Days (%)	Cum. Steam Prod (Ton)	Effectiveness by Cum. Steam Prod (%)	Remarks
13	20%	52.7		33,114		First well wash after Coiled Tubing Unit in 2022
14 & 15	20%	26.67		12,850		
16	15%	23.8	-10.94%	9,255	-19.13%	First field-trial optimization
17	26%	25.8	-3.44%	12,656	2.00%	Second field-trial optimization
18, 19 & 20	10%	55.83	109.38%	19,102	-29.00%	Third field-tial optimization

Before Optimization
Field-Trial for Optimization
Field-Trial for Optimzation

To obtain the most optimum trim valve opening, an effectiveness of production days and cumulative steam production is a crucial parameter that must be considered to formulate recommendations for this problem, as well as the geochemical data as the confirmatory parameters.

Based on the production days for each trim valve opening, the effectiveness that assessed by comparing the data before optimization shows that the result after adjusting trim-valve opening at 10% is up to two times better than trim valve opening at 15% and 26% as shown in Table 5. Therefore, it can be concluded that by comparing to a larger trim-valve opening, a 10% trim-valve opening is recommended because it results in the longest production days that leads to minimize the downtime production of X-7 well. Furthermore, the result of optimizing the production operations of X-7 Well, specifically by reducing the frequency of well washing is crucial to maintain casing integrity. This is because of the high cyclic loads of temperature and pressure changes during well washing can lead to casing damage (Kaldal, S. G. et al, 2012).

Refer to Table 5, on cumulative steam production data, the effectiveness by cumulative steam production is assessed similarly to the calculation for production days. By comparing the effectiveness of cumulative steam production between each trial, a trim-valve opening of 10% shows a slightly lower cumulative production effectiveness compared to larger trim-valve openings, but the difference is not significantly seen when considering its effectiveness in production days.

Based on the geochemical analysis shown on Table 4, a trim-valve opening of 10% indicates relatively low-value geochemical parameters and a CSI value of less than null which indicate a lower risk of calcite scale precipitation. Trim-valve opening of 10% is recommended for X-7 Well production optimization by considering the longer production days, lower well washing frequency, and higher cumulative steam production. The lower risk of calcite precipitation compared to other trim-valve openings and the casing integrity can be more maintained due to less frequent well washing as an additional reason to strengthen the recommendation to solve the issue present in the X-7 well.

5. CONCLUSION

In Patuha Geothermal Field, X-7 Well faced scale growth problem in the wellbore which caused a significant decline in well head pressure. That condition needs periodic well washing to maintain the well performance. The trim-valve opening needs to be controlled at the time X-7 Well needs to be online after well washing shut in. Optimization for this well is an absolute need in order to extend the production lifespan while ensuring optimal output. The optimization was carried out by conducting field trials with various trim-valve openings after completing the well washing by considering operations constraints. Through the analysis & calculations in the field-trial process, trim-valve opening at 10% gives the optimal result and is recommended for X-7 Well operation.

6. RECOMMENDATION

Workover or well intervention is a long-term solution to address this scale growth issue which causes an extreme well-head pressure decline. However, optimization of the production operation is necessary. The optimization processes that were discussed in this paper are possible to be considered as a reference, but need an adjustment to suit both subsurface and surface conditions for each field then the limitation will be identified to conducting the optimization.

Keywords: Geothermal, Silica Scaling, CaSil Technology, Calcium Silicate, Silica Extraction, Direct-Use, Reinjection

ABSTRACT

Silica scaling continues to pose a worldwide challenge in the full exploitation of geothermal reservoirs. As dissolved silica precipitates during cooling and steam production, it forms an intractable scale that blocks pipework, heat exchangers and reinjection wells. These deposits significantly lower the efficiency of heat exchangers, resulting in a direct reduction in electricity and revenue generation over time. Regular and costly maintenance is required which leads to plant downtime. Conventional silica scale mitigation techniques are not wholly successful and come with drawbacks such as high cost or corrosion risks.

The innovative and proprietary CaSil technology introduces a disruptive method of transforming dissolved silica entities into a novel calcium silicate (CaSil) product, forming discrete particles that remain suspended and do not adhere to metal surfaces. This process achieves a significant reduction in the silica saturation index to well below 1 within seconds. The robust technology is adaptable to a wide range of brine compositions, regardless of the initial silica concentration, ensuring dependable elimination of silica scaling. Moreover, the CaSil technology facilitates the safe reduction of brine temperatures beyond current limits without inducing any silica scaling. This presents novel business prospects for utilising additional process heat in sectors like greenhouses, aquaculture, or milk powder production, supporting the efforts to decarbonise industrial processes. The CaSil technology can seamlessly integrate with existing geothermal operations, or greenfield plants, offering a versatile solution.

This paper presents updated data from our development plant which was successfully operated across four different geothermal resources in New Zealand. The effectiveness and robustness of the technology which can unlock the full potential of geothermal resources are highlighted. Additionally, data based on laboratory experiments are discussed, addressing the applicability of the technology to high silica, hypersaline geothermal brines such as the Dieng field in Indonesia.

1. INTRODUCTION

1.1 Silica Scaling

The earth's core holds practically inexhaustible amounts of thermal energy. This energy can be extracted to produce electricity in geothermal power stations, particularly in tectonic plate boundary areas with volcanic activity such as the Ring of Fire. Hot water, steam, or a mixture of both is extracted from a natural or artificially created geothermal reservoir. The sourced fluid typically contains a mixture of different minerals in solution, such as chloride-based salts, carbonates, base and precious metals and silica. The specific composition is dependent on the pressure, temperature and rock structure of the resource and varies from location to location. However, steam is required for the technical utilisation, which is produced by reducing the pressure of sourced water in a flash vessel. This causes a portion of the liquid to boil off as steam that can then be used to drive a turbine and produce electricity.

The mass reduction of the liquid phase causes the dissolved chemical species to concentrate in the brine. Additionally, the water temperature decreases to the respective pressure-dependent boiling point. This causes the silica solubility to decrease which is dependent on the fluid temperature. Typically, silica becomes supersaturated after a flashing stage due to the two simultaneously occurring effects and leads to unwanted scaling. The ensuing silica polymerisation process is dependent on the brine pH, salt content and degree of supersaturation. Hypersaline brines in particular suffer from a further significant reduction in silica solubility due to the dissolved salt species. This is a well-documented problem in geothermal resource utilisation and a world-wide challenge (García et al. 2005; Iler 1979; Makrides et al. 1980).

As the silica polymerisation process advances, intractable scale is formed in all process equipment such as pipes, valves, heat exchangers and reinjection wells. This significantly lowers the efficiency of a power plant over time and necessitates costly maintenance and plant downtime. Several mitigation methods have been developed by industry and are used worldwide such as hot reinjection, acid dosing or sequestering agents. However, they can come with significant drawbacks such as a very limited degree of resource usage, corrosion issues or high

operating cost. Additionally, no currently used mitigation technique can fully prevent silica scaling, making regular cleaning and maintenance still a necessity (Gunnarsson and Arnórsson 2005; Thorhallsson 2011; Richardson et al. 2014).

1.2 The CaSil Technology

The Calcium Silicate (CaSil) technology has been developed to address the shortcomings of currently utilised silica scaling mitigation efforts. The technology offers a novel and disruptive solution which can wholly eliminate silica scaling in geothermal resource utilisation. Additionally, significantly lower brine temperatures are possible after the CaSil technology treatment without inducing silica scaling, than with any other commercially available and economical technology. This unlocks the full potential of geothermal resource utilisation for power generation and direct-heat applications. Figure 1 shows a schematic diagram of an exemplary integration of the CaSil technology with a typical geothermal power station. Different implementation methods of the technology are possible depending on the needs of the individual plant.

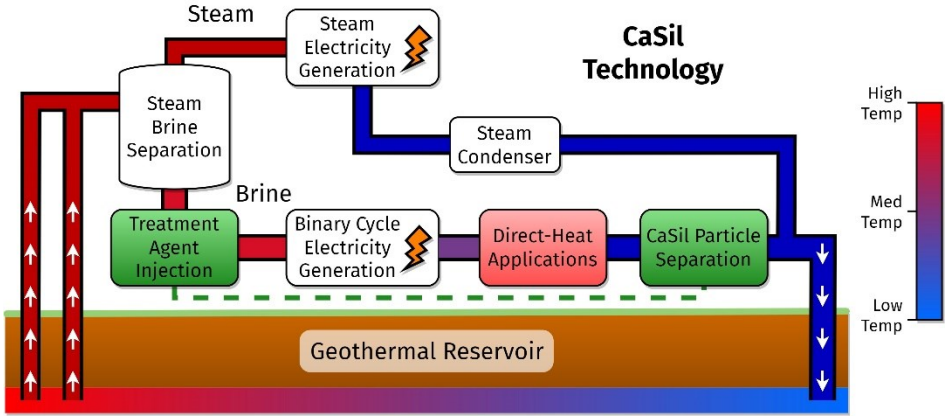

Figure 1: Schematic diagram on an exemplary integration of the CaSil technology in a geothermal power plant with flash and binary cycle.

A treatment agent is injected into the geothermal brine as soon as silica reaches a supersaturated state, which typically occurs after the flashing process. The dissolved silica is rapidly transformed into a novel nanostructured calcium silicate (CaSil) material which does not stick to metal surfaces and has unique chemical and structural properties. The chemical reaction is completed within seconds and forms a colloidal suspension with discrete particles. The suspension can easily flow through pipework and heat exchangers used in a binary cycle plant or for direct-heat applications. Little turbulence is needed to keep all CaSil particles in suspension. Finally, the CaSil is separated as a useful material before brine reinjection.

By transforming the silica, the residual silica concentration in the treated brine is actively lowered which leads to a reduction in the Silica Saturation Index (SSI) to significantly below 1. Silica scaling is effectively prevented at currently common discharge temperatures of geothermal power stations (140-100 °C). This means no scaling can occur after the treatment agent dosing point so all pipework, binary plant heat exchangers and reinjection wells stay clean and fit for purpose. Naturally, this boosts the electricity output of binary plants over time as scaling is eliminated (see section 2.1). Additionally, more heat energy can be extracted safely from the medium temperature brine before an SSI of 1 is re-established, increasing the sales revenue from binary cycle power production. This can be done in additional downstream binary cycle plants or through heat supply to direct-heat applications (see sections 2.2.2 and 2.2.3).

The CaSil technology can be readily installed into existing geothermal power stations or greenfield projects to offer a comprehensive silica scaling prevention technology as well as enable the full utilisation of a geothermal resource.

2. FULLY UNLOCKING GEOTHERMAL RESOURCES THROUGH CASIL

As mentioned before, the CaSil technology significantly lowers the SSI of a given brine well below 1. This enables additional downstream heat utilisation in an economical manner that is currently not possible by any other means. Significantly more value can be created from a geothermal resource by implementing the CaSil technology, depending on the individual resource conditions and site requirements. This can be achieved through additional electricity generation assets, the availability of excess heat for direct-use applications, mineral extraction or the production of environmentally friendly products based on the generated CaSil material.

Through the CaSil technology, the revenue streams of a geothermal power plant can be diversified from just one product (electricity) to a multifaceted industry hub. Each of the individual possible benefits are explained in the following subsections.

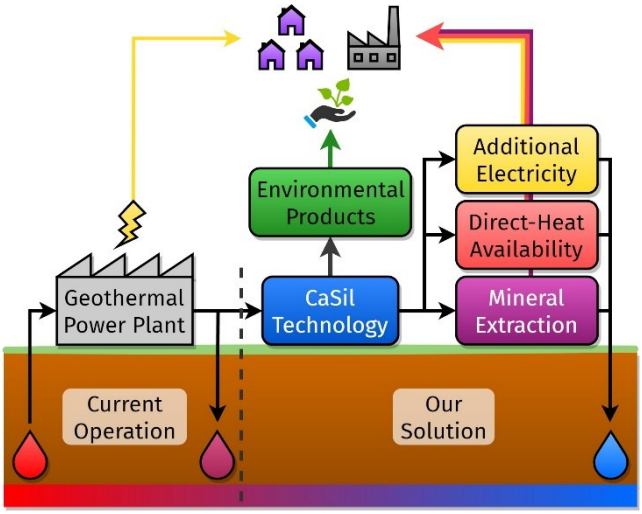

Figure 2: Schematic diagram of the CaSil Technology outputs and possible benefits.

2.1 Enhanced Electricity Generation in Existing Binary Plants

In current operations, binary cycle units experience silica scaling. The mineral deposits reduce the effective heat transfer coefficient and significantly raise the pressure drop across the affected heat exchangers. This results in a gradual reduction in generated power from the unit over time as depicted in Figure 3 (red line). The scaling rate is dependent on the silica concentration and degree of supersaturation. In the example above, a 20 % reduction in power output of a given unit is assumed over a period of 6 months. Once the power output drops below a chosen value (in this case 80 %), the unit is taken out of service and laboriously cleaned. Typically, this includes high pressure water blasting, strong acids or bases, or a combination thereof. Afterwards, the power output returns to 100 %, however, silica scaling will start again immediately and the cycle restarts. Valuable production capacity and revenue is being lost due to this saw-tooth power production profile caused by silica scaling. Additional cost is incurred by the necessary heat exchanger cleaning and plant downtime.

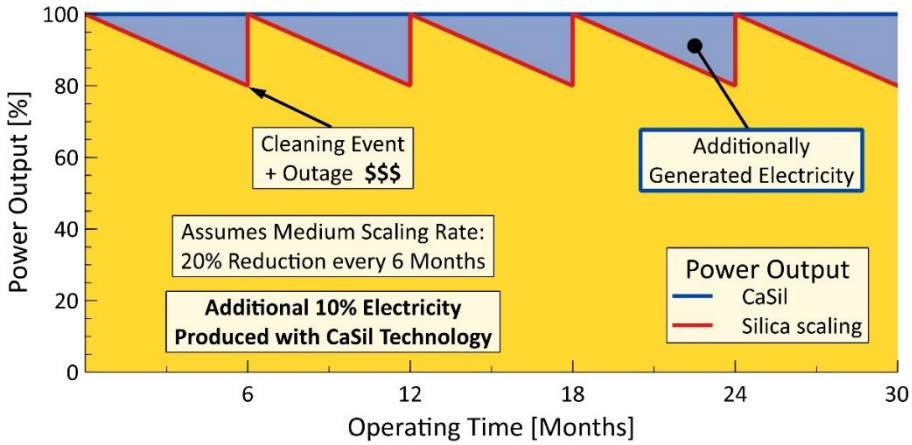

Figure 3: Model power output curve of a typical binary plant affected by silica scaling and enhanced electricity generation enabled by the CaSil technology.

With the CaSil technology, the SSI drops significantly below 1 at common geothermal process temperatures (see also Figure 4). This means that no silica scaling occurs and heat exchangers stay free of depositions. Binary plants can therefore continuously deliver their full power output over time (Figure 3, blue line). This means, that more electricity is generated over time compared to the saw-tooth production profile of a binary unit operating under current conditions. In the depicted example, an additional 10 % of electricity, and therefore revenue, is generated from the same existing asset over time by including the CaSil technology. The amount of additionally generated electricity depends on the individual scaling rate. For severe scaling rates, the amount of additionally generated electricity is estimated to be up to 25 %. Additional benefits are the elimination of strong acids or bases for

cleaning which incur H&S risks around transport, handling and disposal. Furthermore, the financial burden of cleaning services and plant downtime can be eliminated.

2.2 New Downstream Opportunities for Electricity and Direct-Heat Applications

2.2.1 Field Results from CaSil Development Plant

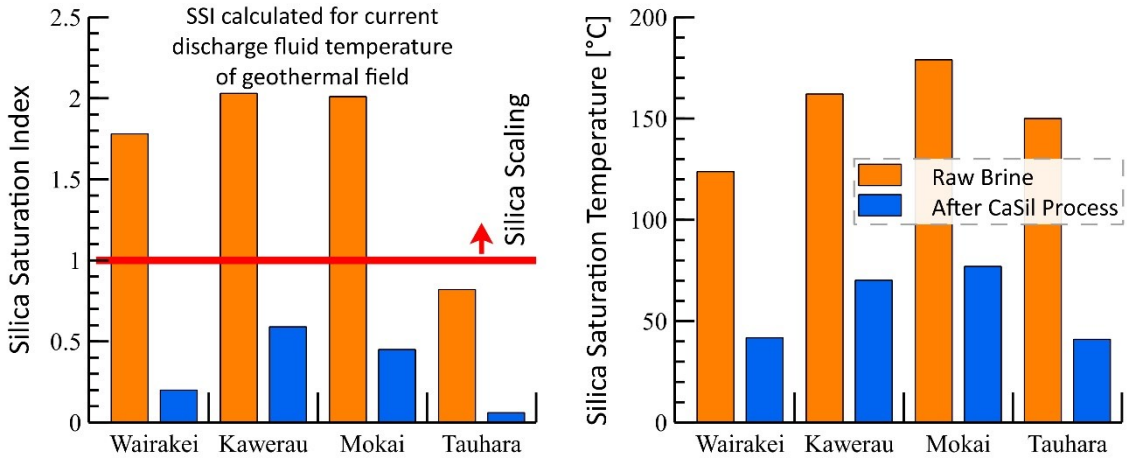

Figure 4: Silica Saturation Index at field discharge temperature and Silica Saturation Temperature for Wairakei, Kawerau, Mokai and Tauhara geothermal fields in New Zealand for sampled raw brine and CaSil treated brine.

The CaSil technology has been successfully proven and demonstrated in different geothermal fields across New Zealand. A continuously operating and fully automated development plant has been designed, built and improved over a number of years which reached its current state of development in 2023, processing up to 3 t/h of geothermal fluid and demonstrating all unit-operations of the technology. The plant was installed at the Wairakei, Kawerau and Mokai geothermal resource for research and development of the technology at the respective fields. Currently, the plant is located at the He Ahi – Eco Business Park near Taupo, New Zealand, which is located on the Tauhara geothermal resource. Field data from the development plant is presented in Figure 4.

The SSI of all fluids is calculated for the current reinjection temperature of each field (left side). In the Wairakei, Kawerau and Mokai fields the sourced raw brines were already supersaturated in silica (SSI > 1) at their respective reinjection temperatures. This means, silica is polymerising and scale formation occurs. At the Tauhara field the fluid is exclusively used for direct-heat applications and currently reinjected at high temperatures. This means the SSI is still below 1. However, as more direct-heat customers establish their presence at the Eco Business Park, more heat will be extracted from the geothermal brine, inevitably leading to an SSI below 1.

After the CaSil treatment the SSI could be significantly reduced below 1 in all these geothermal resources. This means, no more silica scaling occurs at the current reinjection temperatures for each field. In Wairakei, a reduction in SSI from 1.78 to 0.2 was achieved. Similarly, in Kawerau and Mokai the SSI decreased from 2 to 0.6 and 0.45 respectively. The reason for the higher SSI after treatment in Kawerau and Mokai is the significantly more acidic nature of the brines which affects the process chemistry. However, the SSI was still reduced significantly below 1, which cannot be economically achieved by any other means. Changes in the process chemistry are possible to reduce the SSI further if required. In Tauhara, the SSI decreased from 0.8 to 0.06 at the comparatively high current reinjection temperature.

The same results can be seen for the Silica Saturation Temperature (right) which is the fluid temperature at which an SSI = 1 occurs. Significant reductions in the SST after treatment were recorded. In Wairakei, the fluid could be cooled to 42 °C after treatment before silica polymerisation starts again. In Kawerau and Mokai the SST is 70 °C and 77 °C respectively, after the CaSil treatment. At the direct-heat park in Tauhara, the scaling temperature was reduced from 150 °C to 41 °C. For this specific site, the available saleable heat capacity of the park can be increased by up to 60 % by the inclusion of the CaSil technology.

The significant reduction in SST demonstrates the substantial opportunities for geothermal resources for enhanced electricity generation and direct-heat availability for industrial or residential purposes.

2.2.2 Electricity Generation

As detailed in section 2.1, existing binary plants can experience an uplift in power output over time by elimination of the silica scaling problem. However, geothermal resources with severe silica concentrations and scaling rates are unlikely to currently be able to use binary technology. The significant reduction in SSI by the CaSil technology

as detailed in section 2.2.1 allows such power plants to include downstream power production facilities without inducing further silica scaling. Depending on the individual process parameters, this could be a second flash cycle or binary plant unit.

Table 1: Additional electricity that can be produced by a downstream binary plant for exemplary flow rates and current reinjection temperatures. Outlet temperature = 80 °C, c_p = 4.2 kJ/kg*K and η = 12 % assumed.

	Current Reinjection Temperature = Inlet Temperature		
Brine Flow Rate	180 °C	150 °C	130 °C
400 t/h	5.6 MW_{el}	3.9 MW_{el}	2.8 MW_{el}
800 t/h	11.2 MW_{el}	7.8 MW_{el}	5.6 MW_{el}
1200 t/h	16.8 MW_{el}	11.7 MW_{el}	8.4 MW_{el}
2000 t/h	28 MW_{el}	19.6 MW_{el}	14 MW_{el}

Table 1 lists the additional electricity that could be generated by a downstream binary plant for exemplary flow rates and reinjection temperatures, which would be the downstream binary inlet temperature. An outlet temperature of 80 °C and efficiency of 12 % is assumed. Should an additional steam cycle be used instead, the efficiency may be higher accordingly.

Significant uplifts in the overall power generation can be achieved by additional downstream steam cycles or binary plants. Medium sized power plants with 1200 t/h of brine which might currently reinject at 150 °C could generate 11.7 MW_{el} more from the same brine source. For an industry example the Dieng I power plant can be utilised, which is a single flash plant producing 26.9 MW_{el}. Approximately 398 t/h of hot geothermal brine at 182 °C are flashed to atmospheric pressure. Due to the severe silica scaling rates the brine cannot be cooled further in the power generation process. A pond is utilised to precipitate silica before fluid reinjection (Pambudi et al. 2015). Initial laboratory experiments with synthetic and acidified brine from Dieng I confirmed that the CaSil technology can successfully lower the SSI of the brine significantly below 1 (Borrmann et al. 2024). Therefore, approximately 5.7 MW_{el} could be generated from the same resource utilising a downstream binary plant. This assumes an efficiency of 12 % which in an actual plant would likely be higher given the high input temperature of 182 °C. Alternatively, a secondary flash cycle could be used which has a higher efficiency than a binary unit. This combination of CaSil technology and downstream generation asset would boost the power output of Dieng I by at least 21 % simply by utilising the currently unused geothermal brine.

2.2.3 Direct-Heat Uses

Lower temperature brines might not be suitable anymore for further heat extraction (e.g. below 110 °C), or other reasons might exclude the opportunities for the generation of additional electricity detailed in section 2.2.2. In these cases, the supply of direct-heat to industrial or residential customers could be attractive. Naturally, a mix of electricity generation and direct-heat supply can be designed as well, depending on the individual circumstances.

Table 2: Available heat energy for direct-use applications for exemplary flow rates and current reinjection temperatures. Outlet temperature = 80 °C and c_p = 4.2 kJ/kg*K assumed.

	Current Reinjection Temperature		
Brine Flow Rate	150 °C	130 °C	110 °C
200 t/h	16.3 MW_{th}	11.6 MW_{th}	7 MW_{th}
400 t/h	32.6 MW_{th}	23.3 MW_{th}	14 MW_{th}
800 t/h	65.3 MW_{th}	46.6 MW_{th}	28 MW_{th}
1200 t/h	98 MW_{th}	70 MW_{th}	42 MW_{th}

The available heat energy for direct-use applications for exemplary brine flow rates and current reinjection temperatures is presented in Table 2. Even small geothermal plants with only 200 t/h brine flow can supply significant amounts of heat energy for direct-heat applications with medium temperature brines (e.g. 130 °C, 11.6 MW_{th}). Alternatively, larger plants can utilise a portion of their flow for dedicated direct-heat use if the full flow is not required or desired. These opportunities are opened up by the CaSil technology.

Selected examples of direct-heat uses are shown in Figure 5. Additionally, the typically required process temperatures for each application are depicted. For example, horticultural green housing requires process heat in the range of 30-80 °C. Depending on the geographical location of the green house a heat consumption of approximately 1-3 MW_{th}/ha is common (Mertoglu et al. 2003). However, consumption rates larger than 2 MW_{th}/ha occur predominantly in very cold locations. A small geothermal plant with 11.6 MW_{th} dedicated to direct-heat use

could therefore support approximately 5-11 ha of green houses, depending on the geographical location, diversifying the revenue portfolio.

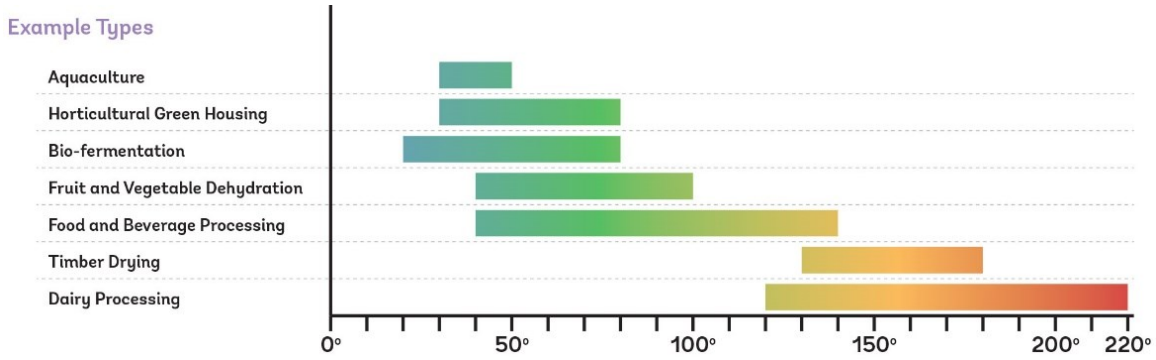

Figure 5: Selected examples of direct-heat uses and required process temperature ranges in °C (Climo et al. 2022).

Process heat from geothermal resources is also low in carbon emissions, with approximately 13 % of the carbon factor compared to natural gas and 7.5 % compared to coal (Climo et al. 2022). This means geothermal can play an important role in the decarbonisation of industry by supplying affordable, clean and always available process heat to industrial or even residential applications. Additionally, direct-heat customers can lower their expenditures by switching to geothermal heat through the lower operating cost compared to coal or gas as well as the reduced carbon emissions for which, depending on location, carbon credits may have to be purchased or a levy paid.

2.3 Mineral Extraction

Geothermal brines contain a cocktail of different species. This includes precious minerals which, if present in sufficient quantity, become financially attractive to extract and process. However, conventional extraction processes typically rely on membranes to concentrate and filter the desired species. In current geothermal plants silica is in a supersaturated state at the point of flashing. Silica polymerises at this point in the process and would consequently severely scale any membranes used for mineral extraction. Therefore, mineral extraction from raw geothermal brines is typically not financially viable due to the high cost incurred through ongoing maintenance and regular capital-intensive replacement of membranes.

Figure 4 showed the significant reduction by the CaSil technology in SSI in the treated brines. This means silica is in a severely undersaturated state. In these process conditions conventional mineral extraction processes can work without membrane fouling from silica and an economical operation is viable.

Laboratory tests were conducted to assess the compatibility of brine mining with the CaSil technology. Most species (e.g. Lithium, Boron, etc.) are not affected by the CaSil treatment, remain in solution and can be extracted downstream of the CaSil process. Other species (e.g. Copper, Zinc, Manganese) are adsorbed by the CaSil material during particle formation and are extracted with the CaSil material in the separation process. The desired minerals can then be further processed.

2.4 Environmental Products

The CaSil material also provides a platform for the development of environmentally beneficial product applications of which a number of applications are in the research and development stage. This is afforded by the unique surface chemistry of the CaSil particles which can be altered by the process chemistry to suit different product application needs.

An attractive application for the CaSil material is the recovery of base metals from waste mining and industrial process streams. As discussed in section 2.3, CaSil adsorbs certain metal ions and is therefore a suitable addition to mining and processing operations to mitigate environmental pollution through mine tailings. Also, the overall efficiency of metal recovery is increased.

2.5 Benefits for Fluid Reinjection

The CaSil technology allows the fluid to be cooled significantly more than is currently possible without inducing any silica scaling. The colder fluid has a higher density which will increase the downhole pressure of the water column, while maintaining the same wellhead pressure. The higher pressure can force more fluid through the porous rock strata, therefore increasing injectivity of the reinjection wells.

Colder fluid is also slightly cooling down the immediate rock strata around the reinjection well. This causes the rock to naturally contract and open more pores and fissures. Analogue, this causes an increase in injectivity of the

wells due to the reduced pressure losses from fluid-rock interactions. This effect can also be observed in well workovers where cooler condensate is injected for prolonged periods of time (Coutts et al. 2018).

Naturally, the reinjection of cooler fluid requires careful field management so no cold spots can develop in the reservoir or breakthroughs occur.

3. CONCLUSION

Silica scaling is the single largest hinderance worldwide in the full utilisation of geothermal resources. The intractable scale blocks pipework, heat exchangers and reinjection wells, lowering the efficiency of the plant, reducing the electricity output and necessitating costly maintenance. Current mitigation efforts fall significantly short of providing a definitive long-term solution to silica scaling. All of them require a trade-off between energy production and required maintenance. Additionally, significant amounts of heat energy are left in the brine and must be discarded due to severe scaling rates at low temperatures.

The CaSil technology is a novel and disruptive technique that uniquely provides a comprehensive silica scale elimination plan for a wide range of geothermal resources. Additionally, the full potential of geothermal energy is unlocked by significantly lowering the silica saturation temperature to unprecedented levels in an economical way. The technology can be readily interfaced with existing geothermal plants or greenfield developments.

Our CaSil development plant has clearly proven the viability and effectiveness of the technology at the Wairakei, Kawerau, Mokai and Tauhara geothermal resources in New Zealand. Silica saturation temperatures as low as 41 °C were achieved in the field.

Geothermal power plants with severe scaling rates which are forced to discharge brine at very high temperatures can benefit significantly from the CaSil technology as the opportunity to use downstream binary plants is unlocked. This can boost the overall electricity generation significantly from the same amount of sourced brine, which is hitherto unobtainable. Electricity generation plants with less severe scaling problems achieve an uplift in performance by eliminating the typical saw-tooth production profile from binary plants due to progressive silica scaling.

Also, significant new business opportunities are unlocked with the sales of heat energy for direct-heat applications such as greenhouses, aquaculture or food product drying. This desirably contributes to the decarbonisation of industry, where geothermal energy can have a significant impact as well. The reduction in SSI also opens the possibility of extracting valuable minerals from the geothermal fluid as conventional membrane extraction processes now become economically viable due to the elimination of scaling/fouling.

Furthermore, benefits for the reinjection system can be achieved by boosting the injectivity of reinjection wells. This is accomplished through the low SSI value of brines and colder fluid temperatures for reinjection. This leads to a denser fluid with higher downhole reinjection pressures as well as a contraction of the rock strata around the well which decreases pressure losses.

ACKNOWLEDGEMENT

The authors would like to acknowledge the New Zealand Ministry of Business, Immigration and Employment for research funding (RTVU2205).

Also, MB Century Ltd for the considerable in-kind support in the pilot scale development of the CaSil technology at Wairakei, Ngati Tuwharetoa Geothermal Assets, the Tuaropaki Trust and Contact Energy Ltd for the opportunity to site the development plant and use of the geothermal brine from the Kawerau, Mokai and Tauhara fields.

ABSTRACT

The CaSil technology is a proprietary innovative new technology that eliminates silica deposition and scaling from geothermal brine, supersaturated in silica. The technology has been developed and successfully demonstrated at development plant scale operation over six years in four New Zealand geothermal fields.

This paper reports an initial study on the application of the CaSil technology to the silica supersaturated, hyper-saline brine from the Dieng geothermal field, Indonesia. Problematic dissolved silica is rapidly captured as a nanostructured calcium silicate material before silica deposition and scaling can occur. This yields a treated brine that can be cooled to unprecedented low temperatures without silica scaling, thereby enabling more heat energy to be accessed and electricity generated from the same brine flow than is currently possible.

Samples of brine from the from the Dieng-1 well that had been acidified after collection were provided by Geo Dipa Energi to CaSil Technologies for analyses and an initial assessment of the suitability of the CaSil technology to prevent silica scaling. Using atomic absorption and UV visible spectroscopies, electrochemistry, and titrations the main constituents of the brine were identified. Based on this, a simulated brine was generated and used to test and identify the potential of the proprietary CaSil technology to reduce silica levels and the Silica Saturation Index, SSI, of this high silica, hyper-saline brine accordingly.

Another intention of these trials was to explore effects from the borate buffer system due to the high boron content of the brine, on the CaSil technology and the reduction of the Silica Saturation Index (SSI) to levels where additional heat can be harnessed and electricity generated without inducing silica scaling. Autoclave reactions were used to simulate field specific high temperature and pressure reaction conditions.

The successful laboratory trials using the simulated brine were confirmed using the Dieng brine samples provided in further experiments. These show the pathway for possible field trials, which promise that by incorporating the CaSil technology, additional heat recovery and electricity generation from the Dieng resource can be achieved without silica scale formation, thereby unlocking the full energy potential and utilisation of this geothermal resource.

1. INTRODUCTION

Geothermal energy is an attractive natural renewable energy resource which can provide large quantities of heat energy for electricity generation and/or direct heating applications. In water dominated high enthalpy fields, the geothermal water (brine) in the subsurface reservoir that is typically about 200-300 ˚C, dissolves rock and sediment minerals in the reservoir rocks releasing silica mainly as the $H_3SiO_4^-$ ion, alkali and alkaline earth metal cations, and anions such as chloride and carbonate into the hot brine.

The superheated brine is piped to the surface where through the steam/water flashing process, about 1/3 of the mass flow is flashed into steam that is used to drive a turbine and generate electricity. The residual 2/3 of the mass flow of the now cooler brine can be used for binary cycle electricity generation or direct heating. The resulting cooling and concentration of the brine leads to silica supersaturation where the solubility of dissolved silica is exceeded, leading to silica polymerisation and problematic silica scaling. The scale undesirably blocks pipes, valves, heat exchangers, other process equipment and reinjection wells. (Borrmann et al 2009, Brown 2011).

Silica scaling severely limits the extent to which the separated brine can be cooled in the binary heat exchangers which in turn limits the amount of electricity generated from the resource. This is a major impediment to the

efficient utilisation of the geothermal resource. Much of the heat energy contained in the separated brine is wastefully reinjected to the reservoir.

Current methods to address silica scaling include acid dosing to lower the pH which slows the silica polymerisation reaction, and the use of sequestering agents to bind the dissolved silica entities. However both these approaches are not particularly effective and silica still scaling persists. Frequent cleaning of heat exchangers and the periodic cleaning of existing reinjection wells or drilling new wells is a common practice (Gunnarsson and Arnórsson 2005).

For higher enthalpy geothermal resources where the brine is heated to higher temperatures in the reservoir, the levels of dissolved silica in the brine are similarly higher. The problem of silica scaling is further increased, and the amount of electricity generated by the binary plant is decreased accordingly. This is particularly the case for the Dieng resource.

1.1 The CaSil Technology

The proprietary CaSil technology, developed by the authors Johnston, Borrmann Schweig and Fraser and owned by CaSil Technologies Ltd, eliminates the world-wide problem of silica scaling and unlocks the full energy potential of a geothermal resource. This is achieved by rapidly capturing the problematic silica species dissolved at supersaturated levels in the separated brine, as a unique proprietary nanostructured calcium silicate (CaSil) product, before silica polymerisation and scaling can occur. The Silica Saturation Index is reduced substantially. The CaSil product is separated continuously from the treated brine and used in various environmentally beneficial applications.

The temperature of the treated brine with this significantly reduced Silica Saturation Index, can be lowered much further than is currently possible with existing practices. This enables significantly more heat energy to be recovered for direct heating applications and more electricity to be generated by the binary cycle process accordingly. In addition, the necessity for cleaning silica scale and associated maintenance requirements is similarly reduced considerably, as is the need for drilling new reinjection wells.

The technology has been developed and successfully demonstrated at pilot plant scale operation over six years in four New Zealand geothermal fields, Wairakei, Kawerau, Mokai and Tauhara, each with different brine compositions and temperatures. This clearly demonstrated the robustness and the wide scale applicability of the technology to different geothermal resources (Johnston et al 2006, Johnston and Borrmann 2017, Schweig et al 2023, 2024)

The CaSil technology is therefore ideally suited for application at the Dieng geothermal resource, Indonesia, where the temperature of the separated brine can currently only be lowered to about 182 ˚C before silica scaling takes place. The CaSil technology reduces the SSI considerably and offers the ability to cool the treated brine to substantially lower temperatures and to enable more electricity to be generated accordingly. This is not possible by the use of acid dosing or sequestering agents.

This paper presents the results of an initial laboratory study on the application of the CaSil technology to prevent silica scaling in the Dieng geothermal brines, using a simulated brine with a composition typical of the high silica, hyper-saline geothermal brine from the Dieng geothermal resource. Also a sample of Dieng-1 brine is included. This work opens up the opportunity for a much wider and in depth field study, using actual Dieng brines.

1.2 The Dieng Geothermal Field

The Dieng geothermal field is one of the most prospected geothermal fields in the Central Java Province, Indonesia, located about 120 km from the province capital Semarang. The area of 63 km^2 in size is located along the Java Trench of the Indo-Australian Plate below the South-East Asian Plate in the volcanic arc, corresponding to the active andesitic volcanism related to the plate subduction. The Dieng area has an estimated field development potential of 400 MWe (Ministry of Energy and Mineral Resources, 2017). It is a high-temperature, hyper-saline field with surface manifestations such as fumaroles, hot springs, and acidic mud pools. These are distributed in the areas of Sileri, Sikidang and Pakuwaja. Sileri is located to the northwest with fluid temperatures around 300 ˚C and acid-sulphate-chloride type hot springs. In the central Sikidang area, fluids at depth are around 300 °C hot and contain high amounts of non-condensable gases (NCGs), mostly CO_2. Sileri and Sikidang are craters that consist of old Dieng volcanic rocks. The upflow areas of the hydrothermal systems are believed to be around Sileri and Sikidang where the fluid flows northeast, and southwest along faults. These faults are the drilling targets for future production wells.

Since 1975, 52 wells have been drilled in Dieng, 27 wells by Pertamina, 20 wells by Himpurna California Energy (HCE) and 5 slim holes for coring. 5 production wells and 4 injection wells are operating for power plant Unit 1. Samples discussed in this article relate to wells HCE 7 and HCE 30. The installed capacity of Unit 1 is 60 MWe and current production is around 55 MWe. In July 1998, this power plant was commissioned by Himpurna

California Energy Limited. After the project was shelved for a while, in 2002, Geo Dipa Energi, a joint venture between PT Perusahaan Listrik Negara (PT PLN) and PT Pertamina, took over the ownership of the Dieng geothermal field. Since 2011, Geo Dipa Energi is a designated state-owned enterprise by Government Regulation no. 62/201.

At Dieng-1, Geo Dipa Energi operates one unit of a single-flash cycle with a capacity of 60 MWe (Ministry of Energy and Mineral Resources, 2017; Kamila et al., 2020). The resource of Dieng-1 is characterized by a water-dominated hyper-saline reservoir with temperatures ranging from 240 to 333 °C (Ministry of Energy and Mineral Resources, 2017; Sudarman and Hochstein, 2017; Nasruddin et al., 2016; Mohammadzadeh et al., 2018). Special attention is paid to the highly problematic issue of silica scaling in the production systems, turbines, and the reinjection system. Deposition of silica scale has been identified widely in Fluid Collection and Reinjection Systems (FCRS), such as in two-phase flow lines, i.e., the separator and the brine line to the reinjection site. These significant scaling problems limit the extent of cooling and the amount of electricity generated, and also adversely affect the operational cost of the Dieng Unit 1 plant. Therefore, a more effective and reliable scaling prevention method is required to ensure future operation, increased resource utilisation efficiency, the and future development of the Dieng geothermal field.

The CaSil Technology is ideally suited to prevent silica scaling in the FCRS to protect the current Geo Dipa Energi assets, enable significantly more electricity to be generated by the binary cycle technology and provide a useful CaSil product for environmentally beneficial applications. This will allow more efficient energy utilisation of the resource and its further expansion.

The chemistry of brines is very field and well specific. The CaSil technology has been shown to prevent silica scaling in four different New Zealand geothermal resources. Building on this success, some preliminary laboratory scale trials using simulated geothermal brines with a composition typical of the Dieng geothermal resource, together with samples of the Dieng brine, have been carried out. The results are presented here.

2. RESULTS AND DISCUSSION

Four acidified samples of brine from the Dieng-1 field were provided by Geo Dipa Energi, Indonesia. These were analysed using the facilities at Victoria University of Wellington, New Zealand (VUW), and also at GNS Science, Taupo, New Zealand for confirmation. The main components (>10 ppm) detected in the brine samples were silica, boron, calcium, arsenic, sodium, potassium, lithium, and chloride. Minor (1 to 10 ppm) elements were manganese, iron, and aluminium. Traces of magnesium, strontium, indium, and germanium were also detected. The samples of brine contained flakes of solid material, which upon digestion released further potassium, silica, and sodium into the brine. These were likely to be mineral fragments from the reservoir rocks. Historically, the brine of the Dieng geothermal field is known to also contain sulfur (measured as sulfate), hydrogen carbonate (bicarbonate), and ammonia. Due to the acidification of the samples, these species were not detected. The acidification step is necessary to reduce the extent to which silica polymerisation takes place following sampling and cooling of the brine, and transportation.

2.1 Analysis of Brine and Preparation of Simulated Brine

Table 1 provides an overview of the range of the major constituents from the historical data, the actual levels measured in the Dieng-1 brine at Victoria University of Wellington, and in the two samples of the simulated brine, Sim 1 and Sim 2.

Table 1: Major constituents of brine collected from the Dieng geothermal field.

	Silica	**Na**	**K**	**Cl**	**B**	**Ca**	**HCO_3^-**	**Li**	**pH**
	ppm	ppm	ppm	ppm	ppm	ppm	ppm	ppm	
Historical data	650 to 950	7k to 11k	2k to 3k	16k to 20k	450 to 700	600 to 900	25 to 45	35 to 65	6 to 6.8
VUW	1175	9000	2542	18k	352	624	n/a	45	<2
Sim 1	1000	8000	2500	18k	450	600	40	45	6.5
Sim 2	1200	8000	2500	18k	450	600	40		6.5

For the following study and the preparation of a simulated brine from Dieng, only the major constituents were considered. Sim 1 and Sim 2 differ in their silica and lithium contents.

Particulates of solid material were also present in the acidified samples from the Dieng field. These were analysed and found to contain silica, borate, potassium, and chloride and were omitted from the simulation. Ammonia, and sulfide were not considered due to their volatile and noxious nature, but will be included in future studies.

The brine simulation faced several challenges: At high pH (>9.5) borate species can precipitate out, and silica and calcium can react to form calcium silicates. Furthermore, at the pH value chosen, silica is supersaturated and will

form silica gel. As discussed below, these challenges were successfully overcome and stable simulated brines were prepared using the constituents in table 2.

Table 2: Stock solutions as source of various elements/species.

	NaCl	KCl	LiCl	As_2O_3 in NaOH	$CaCl_2$	$Na_2B_4O_{17}•10H_2O$	"Na_2SiO_3"	$NaHCO_3$
Target	Na	K	Li	As	Ca	B	Silica	HCO_3^-
Also adds	Cl	Cl	Cl	Na	Cl	Na	Na	Na

Hydrochloric acid was used to adjust the pH, which also adds chloride ions to the solutions thereby assisting in establishing the intended chloride concentrations. Sodium silicate is basic and provided the starting point of the simulated brines. With silica being the main target species of this study, greater care was taken in matching the intended silica levels. The other components were added rapidly to enable speedy processing of the brine due to its tendency to form silica gel. The alkali chlorides, arsenic, and bicarbonate solutions and water were added to the sodium silicate solution first. Then the pH was adjusted to below 9. The borax solution was added, and the pH adjusted to about 6.8. The calcium chloride solution required slight acidification to stabilize it. This slightly acidic solution was added last, and the pH of the final solution adjusted to 6.5 to represent that of Dieng-1 brine. In total 8 brines were prepared. These synthetic brines were analysed to determine the closeness of them to the actual Dieng-1 brine composition.

An overview of how closely the composition of these brines adhered to the planned two simulations is shown in Figure 1. Brines 1 to 3, 7 and 8 were following the Sim 1 composition and brines 4 to 6 of Sim 2. All brines prepared could be used to prepare 2 to 4 samples that were used in the CaSil technology application experiments in parallel, before deposits started to form, with the rest of the brine needing to be discarded. The compositions achieved were mostly within 10 percent of the desired values with some deviating about 20 percent. Lithium was only added to 1 brine, due to limited availability of the source material. Overall, the brines were representative of the compositions targeted and the Dieng-1 brines. Hence, application of the CaSil technology under different operating conditions was attempted for all these brines.

Samples of these prepared brines were taken rapidly and the CaSil agent added. The resulting slurry was stirred for another minute as the CaSil reaction is very rapid, allowed to settle for 2 minutes, and filtered under vacuum. The filtrate was recovered for analysis. The filter cakes were dried at 120 ˚C overnight and weighed to establish yields. Treatments were carried out at room temperature and 70 ˚C at a litre scale, and at 150 and 180˚C in a scaled down approach (250 mL) in an autoclave. The autoclaved samples were cooled down rapidly and quenched to obtain temperature dependent data.

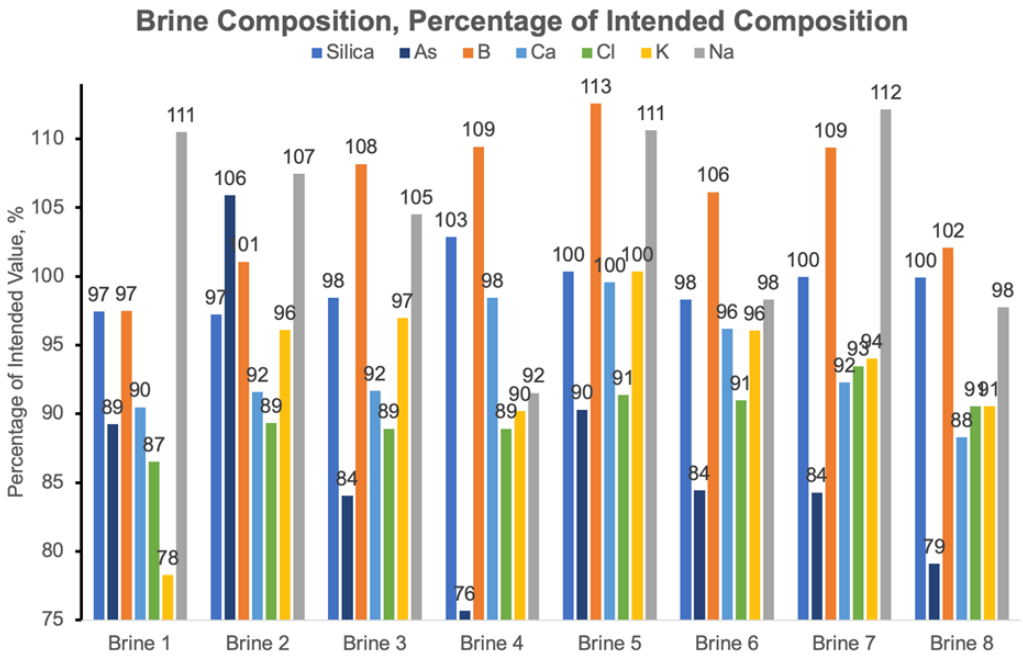

Figure 1: The deviation in the respective compositions of simulated brines from their intended values.

As stated above, the CaSil treatment substantially lowers the Silica Saturation Index (SSI) of geothermal waters by removing silica as a unique nanostructured calcium silicate (CaSil) material. Thereby the CaSil technology enables use of geothermal waters at lower temperatures than currently possible. This laboratory scale work was carried out to ascertain if the CaSil treatment is applicable to the high silica, hyper-saline brines from the Dieng geothermal resource, and any adverse effects of the high levels of borate in the brine. The results presented in Figure 2 show that the residual silica concentration in the treated brine is lowered from the respective initial values of 1000 and 1200 ppm silica to about 150 ppm at room temperature and to about 350 to 450 ppm at 180˚C. The increase in residual silica content with increasing temperature is consistent with the temperature dependent solubility of silica. In all cases the SSI is substantially reduced, allowing the brine to be cooled to much lower temperatures that is currently possible. This desirably confirms the applicability of the CaSil technology to prevent silica scaling at Dieng and thereby enable more electricity to be generated from the existing brine flow (Figure 3).

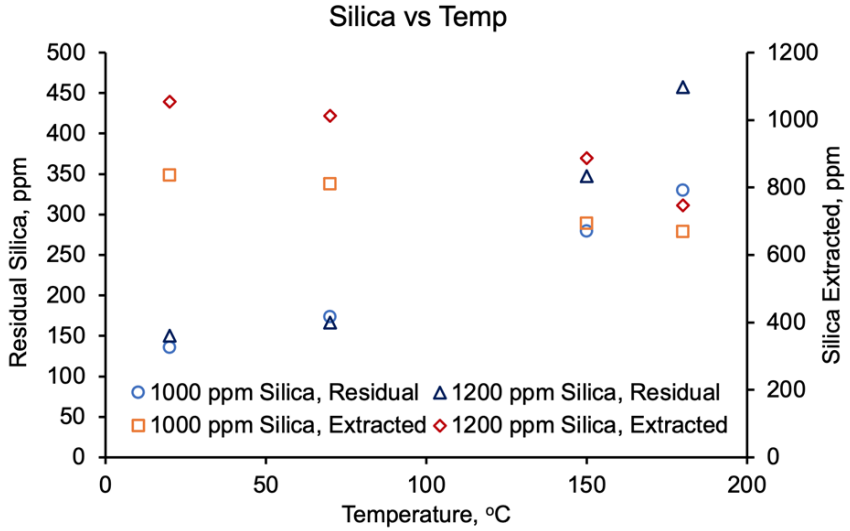

Figure 2: Residual and extracted silica at different temperatures by the CaSil technology.

As the Dieng brines contain high levels of borate, the effect of the borate buffer system on the CaSil technology was investigated. For the simulated Dieng brines, the pH values increased to between 7.7 and 9. It was considered that the presence of the borate in the brine governed this increase in pH, as borate is commonly used in buffer systems (Dubin, 1984). The work here shows that this level of pH increase in the simulated Dieng brines does not affect the CaSil technology.

Using the values for the residual silica concentrations and the pH of the treated brines, the SSI was calculated using the formula published by Brown (2011). Due to the buffering of the pH value, the SSI at room temperature was about 1. However, with increasing temperature the SSI reduced considerably, and very desirably it was as low as 0.3 for the experiments carried out at 180 ˚C. The calculated values of the SSI for following CaSil treatment at different temperatures are shown in Figure 3. These low values of the SSI cannot be achieved by the other methods currently used to address silica scaling. Also pleasingly, no formation of silica gel was observed on cooling of the treated brines to room temperature, even after several days.

The effect of the borate in buffering the pH likely leads to the very low amount of calcium carbonate present in the CaSil product, despite the carbonate/bicarbonate species being present in the simulated brine (see XRD study below). The equilibrium between bicarbonate and carbonate is on the lower side of bicarbonate ($pKa_2 = 10.33$). Therefore, by keeping the pH lower, borate buffer effectively prevents the formation of carbonate ions. This is an interesting finding and invites further investigation.

The application of the CaSil technology in preventing silica scaling as demonstrated here, desirably provides a treated Dieng brine with a very low SSI, that can now be used in downstream recovery of other dissolved minerals including lithium. For these recoveries it needs to be established, if the CaSil technology interferes with any of these species for the Dieng brine. As expected, there was no significant change in the level of lithium before and after the CaSil treatment (less than 1% change which is within the experimental measurement uncertainty). Further work will be carried out in the future to confirm this on actual Dieng brines.

The X-ray diffraction patterns of the CaSil products formed in the process (Figure 4), show the presence of sodium and potassium chlorides. These species could readily be removed from the CaSil products by washing the filter cakes with water, confirming that they originate from trapped pore water in the CaSil filter cakes.

The broad hump in the XRD pattern centered at about 23 °2θ is typical of CaSil, which is amorphous/polycrystalline in nature. Very minor amounts of calcium carbonate in the form of calcite are shown by its main peak at about 30 °2θ. No other calcite peaks are observable. This is a common species that gets trapped in CaSil particulates and is removed with them accordingly. The bicarbonate added to the simulated brine formed this calcite. As, the amount of bicarbonate in the original brine and in the brine following CaSil treatment were very similar, as indicated by titration with acid, the amount of calcite formed was similarly very small. This is a consequence of the borate buffer system detailed above.

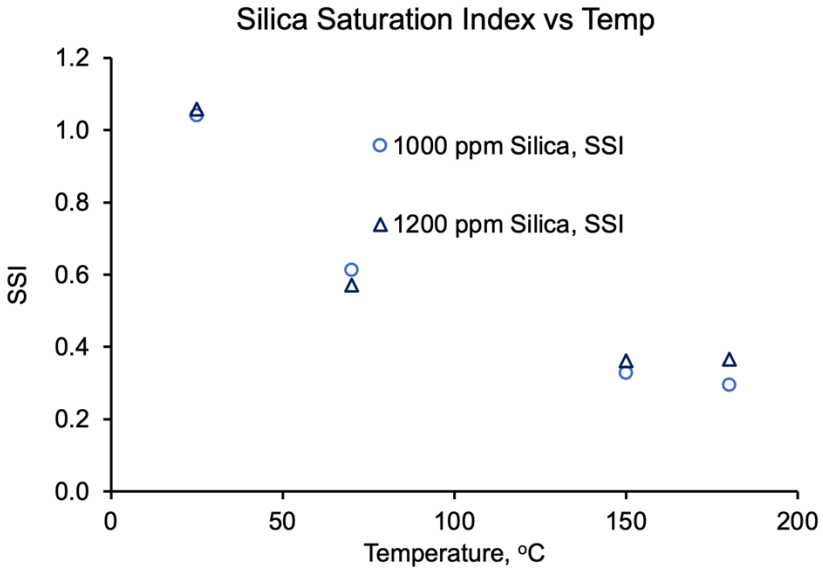

Figure 3: SSI vs temperature for treatment of simulated brines.

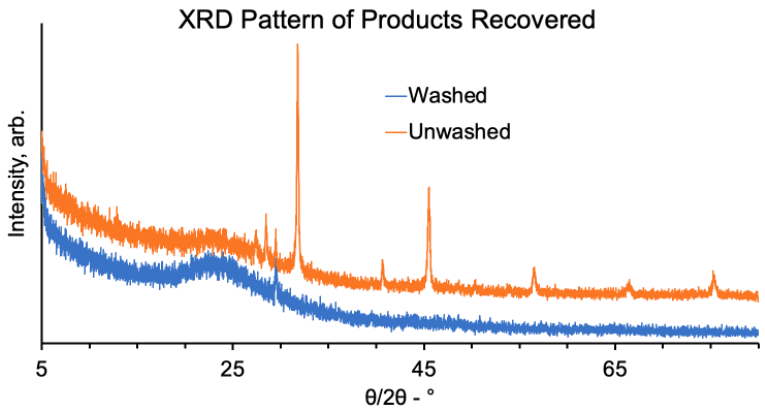

Figure 4: Evidence of salt trapped in the pore water of products.

2.2 Treating Actual Dieng-1 Brine

Encouraged by the findings from the study of simulated brine, a sample from Dieng-1, HCE 7c FA, was treated with the CaSil technology. Prior to treatment, the pH value of the brine sample had to be raised to levels (pH 6.5) comparable to untreated brine. This was accomplished by addition of sodium hydroxide. The supernatant and CaSil product from the treatment of HCE 7c were recovered and analysed. While the CaSil product from the simulated brine was white in color, the HCE 7c CaSil sample was cream colored, which is probably due to the presence of iron and manganese, as they were minor constituents and not incorporated into the simulated brine. Similar discolorations in the presence of iron and manganese have been observed in our previous work. The analysis of the untreated and treated brine from HCE 7c is presented in Table 3.

The most notable and very desirable feature is the substantial removal of silica from Dieng-1 brine, raising of the pH, and consequently substantially lowering the SSI from 9.75 to 0.6. This very clearly demonstrates the effectiveness of the CaSil technology in removing the problematic silica and reducing the SSI to below 1, thereby preventing silica scaling.

Table 3: Comparison of untreated and CaSil treated brine form Dieng-1 HCE 7c.

	Silica	Na	K	Cl	B	Ca	Li	As	pH	SSI
	ppm	ppm	ppm	ppm	ppm	ppm	ppm	ppm		
Untreated	1141	9345	2193	8420	304	514	42	23	6.50	9.75
Treated	77	9528	2117	8200	305	658	43	20	8.83	0.6
Change	-1064	+183	+76	+220	-1	+144	-1	3	+2.33	-9.15

The values for arsenic, boron, chlorine, lithium, potassium, and sodium essentially remained unchanged within the margin of uncertainty. The amount of calcium increased, as is expected from to the CaSil treatment.

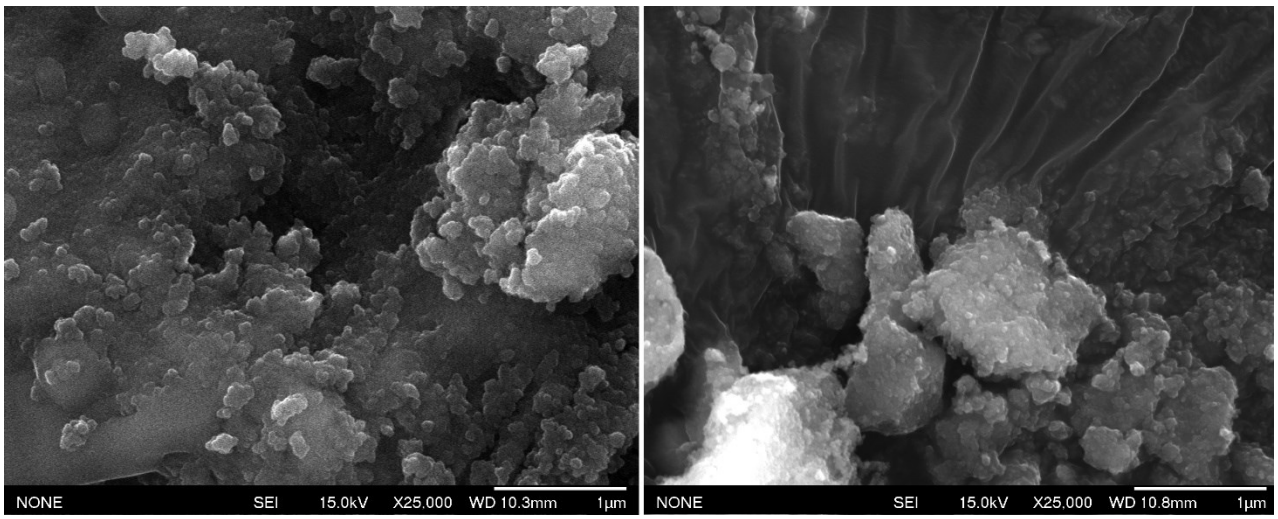

Figure 5: Scanning electron microscope images of simulated CaSil (left) and CaSil recovered from treated HCE 7c (right).

The scanning electronmicroscope images of the CaSil products generated from the simulated brine and the HCE 7c brine (Figure 5) show the products are very similar, and indeed comparable to CaSil products we have generated from many other brines (Borrmann 2009). This result further demonstrates the successful application of the CaSil technology to prevent silica scaling in Dieng brine and to provide a useful CaSil product.

3. CONCLUSIONS

Samples from Dieng-1 brine were provided by Geo Dipa Energi to CaSil Technologies to assess the applicability of the CaSil technology in preventing silica scaling from the brine. The samples and historical data provided by Geo Dipa Energi formed the basis of preparing a simulated brine that was used to carry out the preliminary study presented here. The results clearly show that the CaSil technology substantially reduces the silica content of the simulated brines and also the Dieng-1 brine, thereby lowering the SSI, which in turn prevents silica scaling.

The study also showed that borate present in the brine forms a buffer system that influences the pH change in a way that has not been observed prior to this study. As the Silica Saturation Index is also dependent on the pH, the effect of borate needs to be taken into account in implementing the CaSil technology. However overall, it does not adversely affect the CaSil technology. In the actual brine sample, the effect of borate on the pH was not as pronounced as in the simulated brine samples.

Very little carbonate was captured in the CaSil product despite this species being present in the simulated brine. This could also be due to the presence of the borate buffer. The equilibrium between bicarbonate and carbonate would be on the side of bicarbonate ($pKa_2 = 10.33$). Therefore, by keeping the pH at levels lower than observed for other brines, the borate effectively prevents the formation of carbonate ions, which appears to be necessary to form the usual calcite impurity on the surface of CaSil particles. This is an interesting finding and invites further investigation.

Based on the success of the work using the simulated brines, one of the samples studied in the analysis of Dieng-1 brine was treated by the CaSil technology. This similarly showed the treatment was successful and a CaSil product was produced. The residual silica concentration and pH value meant that the Silica Saturation Index was desirably lowered to 0.6. This low SSI value and the extent of removal of problematic silica from the geothermal brine cannot be achieved by any of the practices currently used to address silica scaling. The distinct advantages of the CaSil technology in preventing silica scaling are clearly demonstrated here.

ACKNOWLEDGEMENTS

This research has been funded by the New Zealand Ministry of Business Innovation and Employment Research (RTVU2205). Also, to Geo Dipa Energi for providing the Dieng-1 samples and allowing us to present this study and results at the IIGCE 2024.

Keywords: geothermal power plants, steam flow measurement, flowmeter selection, performance optimization

ABSTRACT

Accurate steam flow measurement is crucial for optimizing geothermal power plant performance. This paper delves into the selection of steam flowmeters for geothermal applications, providing a comprehensive comparison of various flowmeter types based on technical parameters such as measurement accuracy, pressure drop, maintenance needs, installation complexity, fluid compatibility, and scaling potential. The discussion covers understanding steam flow conditions, specific challenges encountered in geothermal environments, and the latest advancements in flowmeter technologies tailored to the unique demands of geothermal processes.

Through comprehensive analysis and comparative studies, this paper offers valuable insights into the factors to consider when choosing the optimal flowmeter for enhancing the performance and reliability of steam flow measurement systems in geothermal power plants. Venturi, Orifice and Annubar flowmeters offer simplicity and more cost-effective but have limitations in accuracy and involve pressure drop impacts. Vortex flowmeters propose several advantages over traditional differential pressure flowmeters, particularly in applications involving wet steam or fluctuating flow rates. Coriolis flowmeters provide high accuracy, but they are more expensive and sensitive to vibrations. Ultrasonic and Magnetic flowmeters offer non-intrusive measurement, but their accuracy can be affected by steam properties and flow conditions. Additionally, this paper explores the advantages and limitations of other flowmeter types, providing a comprehensive overview of the available options for geothermal steam flow measurement.

The selection of a steam flowmeter should be based on a thorough evaluation of the plant's requirements, considering factors like flowmeter specifications, such as measurement accuracy, pressure drop, maintenance requirement, installation complexity, fluid compatibility, scaling risk and other potential considerations. This paper provides a valuable framework for selecting the most suitable steam flowmeter to optimize geothermal power plant performance and ensure reliable operation.

1. INTRODUCTION

Indonesia is a country with geothermal resources accounting for 40% of the world's total geothermal energy, showcasing significant potential for renewable energy sources. Despite this vast potential, the utilization of geothermal energy began only 20 years ago, and as of now, Indonesia has tapped into just 4-5% of its geothermal capacity. The country, particularly in non-Java islands, is facing a substantial increase in electricity demand, necessitating additional power generation each year. Currently, the installed capacity of geothermal power plants is approximately 2.3 GW out of a total national capacity of around 83.8 GW. The Government of Indonesia expects geothermal to play an increasingly important role as a renewable energy source.

In partnership with two state-owned companies, Pertamina and Perusahaan Listrik Nasional (PLN), Star Energy Geothermal (SEG) operates three geothermal power plant assets in West Java with a total capacity of 886 MW. The Darajat geothermal power plant in Garut Regency generates 274.5 MW, consisting of Unit 2 (97.5 MW), Unit 3 (122 MW), and supplying steam to Unit 1 PLN to produce 55 MW of electricity. The Salak geothermal power plant in Sukabumi Regency generates 381 MW, consisting of Units 4, 5, and 6 (each producing 67 MW) and supplying steam to Units 1, 2, and 3 PLN (each producing 60 MW of electricity). The Wayang Windu geothermal power plant in Pengalengan Regency generates 230.5 MW, consisting of Unit 1 (113.5 MW) and Unit 2 (117 MW).

To support the safe, reliable, and efficient operation of all its geothermal power plant assets, SEG currently employs steam flowmeters in both the Resource Production Facility (RPF) and the Power Generation Facility (PGF). At Darajat, which features steam-dominated resources, venturi tubes and orifice plates are used for steam flow measurement. The venturi flowmeters are installed in the main steam system within the PGF, while orifice flowmeters are commonly implemented in the auxiliary steam systems of the PGF and also in the RPF. Meanwhile, at Salak and Wayang Windu, where wet geothermal resources are prevalent, venturi tubes and

annubar flowmeters are more commonly used. Venturi flowmeters are utilized for steam measurement in the main steam systems of the PGF, while annubar flowmeters are installed in both the main steam and auxiliary steam systems within the PGF, as well as in the RPF, particularly downstream of the separators.

SEG is actively expanding its geothermal power generation capacity. To optimize existing plants and extend their operational life, the company is retrofitting existing units at Darajat, Wayang Windu, and Salak with advanced steam turbine equipment and Balance of Plant (BOP) technologies. Additionally, several new plants are under development, including the Salak Binary Plant (15 MW), expected to be operational this year, with Wayang Windu Unit 3 and Salak Unit 7 following in the next few years. SEG is also exploring new geothermal areas, such as in South Sekincau and Hamiding. These combined efforts aim to achieve the 1,200 MW generation target by 2028 through a mix of new plants, exploration endeavors, and implementing advanced technology in existing facilities to optimize performance and ensure continued safe and reliable operations.

This technology deployment of various flowmeters ensures that each type of geothermal resource and facility setup is accurately monitored and managed, contributing to the overall operational excellence of the plants. Through these efforts, SEG is not only expanding its capacity but also enhancing the reliability and performance of its geothermal power generation, aligning with the national goal of increasing the role of renewable energy in Indonesia's power sector.

2. SIGNIFICANCE OF STEAM FLOWMETERS IN GEOTHERMAL APPLICATIONS

This paper delves into the critical role of accurate steam flow measurement in optimizing performance and ensuring safety within geothermal power plants. It presents a comparison of various steam flowmeter technologies employed in geothermal applications. By understanding the significance of steam flowmeters, the diverse measurement techniques available, and the challenges encountered in geothermal environments, plant operators can make informed decisions when selecting the most suitable flowmeter technology for their specific needs.

Steam flowmeters are instrumental in ensuring efficient and reliable operation of geothermal power plants by providing real-time data on steam flow rates. This information is critical for three primary functions:

- **Optimizing Power Generation:** Precise steam flow measurements enable plant operators to fine-tune turbine operation. This allows for maximizing power output while minimizing energy losses through efficient steam utilization.
- **Ensuring Plant Reliability:** Flowmeters act as integral reliability components by continuously monitoring steam flow rates. Real-time data allows for detection of anomalies and potential process changes, such as unexpected pressure drops or flow fluctuations, enabling operators to take immediate action.
- **Improving Plant Efficiency:** By tracking steam flow through different stages of the power generation process, plant managers can identify areas for efficiency enhancement. This can lead to reduced operational costs and minimized sub-surface resources impact through optimized steam supply utilization.

2.1 Challenges in Steam Flow Measurement for Geothermal Applications

Measuring steam flow in geothermal environments presents unique challenges:

- **Steam Conditions:** Unlike traditional steam applications, geothermal steam often contains liquid droplets and impurities. Not all flowmeters are capable of handling this fluid process flow accurately. The chosen technology must be suitable for measuring this special steam conditions.
- **Harsh Environment:** Geothermal fluids can be highly corrosive due to the presence of dissolved minerals, and steam flow can reach high velocities, leading to potential erosion. Flowmeters must be constructed from materials that are both corrosion-resistant and suitable for withstanding high-velocity flow to ensure long-term reliable performance and maintain measurement accuracy.
- **Varying Flow Rates:** Geothermal steam flow rates can fluctuate significantly depending on reservoir conditions and power generation demands. The chosen flowmeter technology must have a wide dynamic range to accommodate these variations and provide accurate measurements across the entire operating spectrum.
- **Steam Temperatures and Pressures:** Flowmeters must be constructed from robust and temperature-resistant materials suitable for these conditions to ensure long-term reliable performance

2.2 Diverse Steam Flowmeter Technologies

Geothermal power plants utilize a variety of steam flowmeter technologies as follows:

- **Differential Pressure (DP) Flowmeters:** These are the most common type due to their simplicity and affordability. They measure the pressure difference across a restriction (orifice plate, venturi tube, or annubar) in the steam flow path. This pressure difference is proportional to the flow rate, providing a reliable and relatively inexpensive measurement method. Including to this flowmeter type is annubar flowmeters, also known as averaging pitot tubes.
- **Vortex Flowmeters:** These flowmeters employ vortices generated by a bluff body (typically a triangular prism) placed in the flow stream. As steam flows past the bluff body, vortices are shed at a frequency proportional to the flow rate. This non-intrusive measurement technique offers high accuracy and a wide flow range, making it suitable for diverse geothermal applications.
- **Coriolis Flowmeters:** These flowmeters utilize the Coriolis force to measure mass flow rate. As steam flows through a vibrating tube, the Coriolis force causes the tube to twist slightly. The frequency of this twisting motion is directly proportional to the mass flow rate. While offering high accuracy and direct mass flow measurement, Coriolis flowmeters are generally more expensive and more sensitive to vibrations compared to other technologies.
- **Ultrasonic Flowmeters:** These flowmeters employ ultrasonic waves to measure the transit time of the waves across the steam flow path. The difference in transit time between upstream and downstream measurements is proportional to the flow velocity. This non-intrusive technique offers high accuracy and is well-suited for wet steam conditions.
- **Magnetic Flowmeters:** These measurement devices are also known as electromagnetic flowmeters, operate based on the principle of electromagnetic induction. As conductive steam flows through a magnetic field, a voltage is generated proportional to the flow velocity.

By understanding the significance of steam flowmeters, the diverse measurement techniques available, and the challenges encountered in geothermal environments, this paper equips plant operators and engineers with the knowledge necessary to select the optimal flowmeter technology for their specific geothermal power plant application. Several sections below will discuss various steam flowmeter options suitable for geothermal power plant applications. Each section will also examine the specifications of the flowmeters, including measurement accuracy, pressure drop, maintenance requirement, installation complexity, fluid compatibility, scaling risk and other potential considerations.

3. DIFFERENTIAL PRESSURE (DP) FLOWMETERS

Differential pressure (DP) flowmeters operate based on Bernoulli's principle, which relates fluid velocity to pressure. As steam flows through a restriction its velocity increases as it passes through the narrowed section, causing a corresponding decrease in pressure. The pressure difference (ΔP) is measured across the restriction and is proportional to the square root of the flow rate. This section discusses the different types, operating principles, installation considerations, advantages, and drawbacks of DP flowmeters for steam flow measurement in geothermal applications. DP flowmeters encompass a variety of designs, each tailored to specific applications. Below are the most widely used type of flowmeter in geothermal power plant applications:

- **Orifice Plates:** These are the most common DP flowmeters, featuring a thin plate with a central orifice that creates a pressure differential proportional to flow rate.
- **Venturi Tubes:** These devices utilize a tapered throat section to induce a pressure differential, offering better accuracy compared to orifice plates.
- **Annubar:** These flowmeter also known as averaging pitot tubes. They offer several advantages over traditional DP flowmeters, particularly in applications requiring very low pressure-drop or involving fluctuated flow rates.

3.1 Orifice Plates

Orifice flowmeters are widely used devices for measuring fluid flow rates in various industries, including geothermal power plants. They operate based on the principle of differential pressure, where a restriction (orifice plate) is inserted into the flow stream, causing a pressure drop that is proportional to the flow rate.

3.1.1 Orifice Plate Specifications

The accuracy of orifice meters is influenced by several factors, including fluid properties, pipe configuration, orifice dimensions (beta ratio), Reynolds number, and correction factors. Optimal performance is typically

achieved with beta ratios between 0.35 and 0.6. However, under specific conditions, beta ratios outside this range may be used, though they come with increased measurement uncertainty. The overall accuracy ranges from ±0.5 to ±5%.

Orifice plate specifications are detailed in standards such as API MPMS Chapter 14.3 and include several key aspects. The thickness of the orifice plate is crucial and depends on the line size, with a minimum thickness of 1/8 inch for lines under 10 inches and 1/4 inch for larger lines. The flatness of the plate is also critical, with the maximum deviation from flatness calculated based on the orifice and pipe diameters. Additionally, the surface roughness of the plate should not exceed 50 micro inches to ensure accurate measurements. The upstream edge of the plate must be a sharp square-edge that does not have any burrs, as these imperfections can increase measurement uncertainty. Proper centering of the orifice bore within the pipe is essential, especially for custody measurement applications, where stricter tolerances are required.

The materials used for orifice plates are typically corrosion-resistant, such as stainless steel (304SS, 316SS), Monel, or other alloys, depending on the service conditions. The location of pressure taps, which can be flange, corner, or radius taps, is another important factor influenced by flow conditions, pipe size, cost, and required accuracy. For piping specifications, the latest revisions of standards like ISO 5167 outline the requirements for the design of the pipe section preceding and following an orifice plate, known as the meter run. This section of the piping system must establish a stable and predictable flow profile before the fluid encounters the orifice. Key factors influencing meter run design include pipe diameter, fluid properties, flow rate, and desired accuracy.

Generally, a minimum of ten pipe diameters of straight pipe is recommended upstream of the orifice, with an optimal length of 25 to 30 diameters. Downstream, a minimum of five pipe diameters is typically required, but eight to ten diameters are preferred for better accuracy. However, these are just guidelines, and the actual requirements can vary based on specific conditions. Factors such as the presence of valves, elbows, or other fittings near the orifice can influence the necessary straight pipe lengths. Additionally, fluids with high viscosity or those containing suspended solids may necessitate longer meter runs. To further enhance the flow profile and reduce required straight pipe lengths, flow conditioners like straightener vanes can be employed.

Installing an orifice flowmeter can be relatively straightforward, but precise alignment and adherence to piping specifications are crucial. The corrosive nature of geothermal fluids necessitates the use of compatible materials for the orifice plate and other components. While orifice flowmeters generally require minimal maintenance, regular inspections are essential to identify potential issues such as erosion, corrosion, or blockage. The orifice plate, pressure taps, and sensing lines should be checked for any abnormalities. In geothermal applications, where scaling is a common problem, additional cleaning or chemical treatment might be necessary to maintain meter performance.

Although orifice flowmeters are commonly used to measure steam flow rates in geothermal power plants, their application presents specific challenges. A primary concern is the pressure drop induced by the orifice, which can reduce system efficiency. To ensure accurate measurements, careful installation and adherence to piping guidelines are crucial. The corrosive nature of geothermal fluids necessitates the use of corrosion-resistant materials and regular inspection to prevent scaling and maintain performance. Additionally, factors such as flow profile, cavitation, and velocity can impact the accuracy of orifice flowmeters in geothermal environments.

3.1.2 Orifice Bores

Orifice plates come in various configurations of orifice bores, including concentric, eccentric, multi-hole and segmental designs, each suited for specific fluid conditions and applications. The concentric bore design is the most common and is ideal for measuring clean fluids like steam, gas, water, air, and clean liquids. The eccentric bore design is used for liquids containing gas, allowing the gas to pass through the orifice bore located at the top of the pipe. The segmental bore design is suited for liquids with solids, with an opening that allows solids to pass freely. Segmental bore orifice plates are often preferred over eccentric plates for measuring suspended solids in liquids and gases. Recently, multi-hole bore orifice plates have been developed, offering a wider range of applicable Reynolds numbers and requiring shorter meter run lengths compared to eccentric and segmental designs. However, data for eccentric and segmental plates is limited and outdated, with concentric orifice meters generally providing more accurate measurements. Figure 1 provides the picture of orifice bores.

For geothermal steam measurement, the concentric design is generally the most widely used type of orifice plate. The primary reasons for selecting the concentric design include:

1. Simplicity: Its simple and symmetrical design makes it easier to manufacture, install, and calibrate.
2. Accuracy: Available data and research indicate that the concentric design provides better accuracy compared to other designs, especially for single-phase fluids like steam.
3. Standardization: The concentric design is widely adopted, leading to more established industry standards and practices.

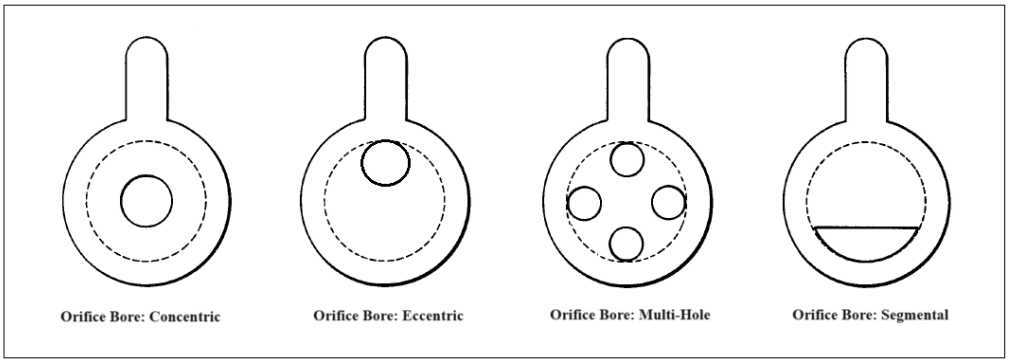

Figure 1: Various Orifice Bores.

Other orifice plate designs, such as eccentric, segmental, and multi-hole, are typically better suited for fluids containing solid particles or multiphase mixtures. For relatively clean steam, the concentric design is often sufficient. While other factors such as fluid conditions, required accuracy, and cost should be considered, the concentric design remains the preferred choice for most geothermal steam measurement applications.

3.2 Venturi Tubes

Venturi flowmeters are widely utilized in various industries including geothermal power plants, operated based on the principle of differential pressure. As the fluid passes through a narrowed section of the tube, its velocity increases while pressure drops. This pressure difference is then used to calculate the flow rate. Compared to orifice meters, venturi flowmeters typically offer a broader flow range and better measurement accuracy. This is primarily due to the carefully designed converging and diverging sections of the venturi tube, which help to maintain a stable and predictable flow profile, thus reducing the chances of measurement errors. The accuracy of venturi meters usually ranges from ±0.5% to ±3% of the actual flow rate, depending on factors such as the Reynolds number, fluid properties, and adherence to manufacturing tolerances. Figure 2 provides the schematic of venturi tube.

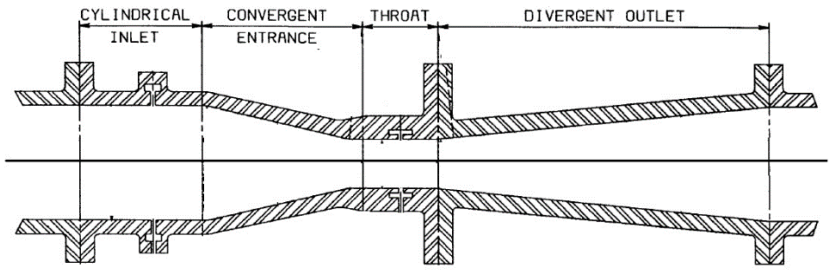

Figure 2: Venturi Tube.

One of the key advantages of venturi flowmeters is their relatively low pressure-drop. The gradual expansion of the fluid through the diverging section of the venturi tube minimizes energy losses, resulting in a permanent head loss that typically ranges from 10% to 14% of the measured differential pressure. This characteristic makes venturi flowmeters particularly appealing for geothermal applications, where maintaining system pressure is critical for efficiency. Additionally, the reduced pressure-drop compared to other differential pressure devices, like orifice plates, contributes to overall system energy savings, making venturi meters a more energy-efficient choice. Figure 3 compares the overall pressure loss through several DP flowmeter primary elements.

In terms of fluid compatibility, venturi flowmeters are versatile and can handle a wide range of fluids, including gases, liquids, and slurries. This makes them suitable for the challenging conditions found in geothermal power plants, where fluids can be highly corrosive or contain suspended solids. To ensure long-term durability and performance, materials like stainless steel, high-strength alloys, and ceramic coatings are often used in the fabrication of venturi tubes. Although the potential for scaling is lower in venturi meters due to their smooth flow path and larger cross-sectional area, it remains a concern in geothermal applications with high mineral content. Regular inspections and cleaning are recommended to prevent scaling, particularly in the throat area, which is more susceptible to build-up.

The installation of venturi flowmeters requires careful consideration of space and pipe configuration. While they generally require shorter upstream and downstream straight runs compared to orifice meters, typically 5 to 10 pipe

diameters upstream and 2 to 5 diameters downstream. The larger physical size of venturi tubes means that they take up more space and can be more complex to install. Proper alignment and adherence to these installation guidelines are essential to ensure accurate measurements. Despite the initial complexity, venturi flowmeters are known for their low maintenance needs, making them a cost-effective choice in the long run. Regular maintenance, including inspections for erosion, corrosion, or scaling, is crucial to maintain optimal performance, especially in harsh geothermal environments.

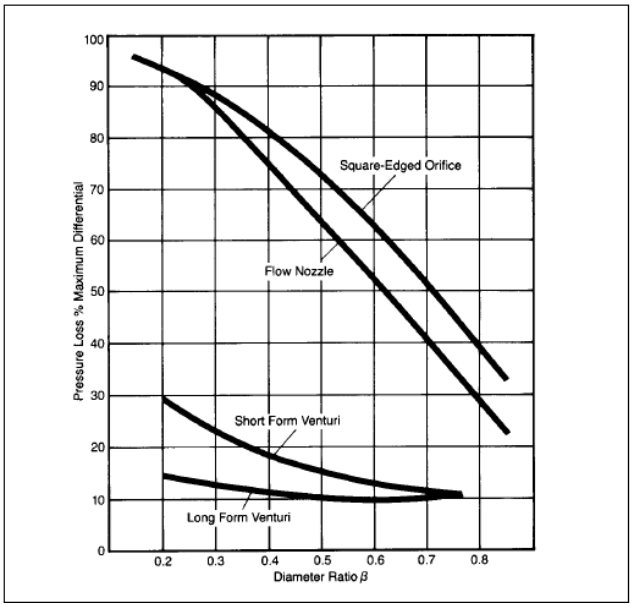

Figure 3: Pressure Loss vs. Diameter Ratio (Beta).

In conclusion, venturi flowmeters offer a robust and reliable solution for measuring flow rates in geothermal power plants. Their high accuracy, low pressure-drops, and minimal maintenance requirements make them well-suited to the demanding conditions of geothermal applications. While they may come with a higher initial cost and installation complexity compared to other flowmeter types, the benefits they provide in terms of durability, energy efficiency, and long-term reliability often justify the investment. By carefully considering factors such as fluid compatibility, scaling risk, and installation requirements, venturi flowmeters can significantly contribute to the efficient operation of geothermal power plants.

3.3 Annubar

Annubar steam flowmeters, also known as averaging Pitot tubes, are a type of differential pressure flowmeter designed to measure the flow of steam and other fluids in various industrial applications, including geothermal power plants. These flowmeters operate on the principle of differential pressure, where the flow velocity is determined by measuring the difference in pressure between the upstream and downstream sides of the sensor. The annubar design features multiple pressure-sensing ports along the length of the tube, which average the flow profile across the pipe, resulting in a more accurate measurement of the flow rate. Figure 4 provides the measurement principles of annubar flowmeters.

One of the key advantages of annubar flowmeters is their accuracy, which can range from ±1% to ±2% of the actual flow rate, depending on the specific model and installation conditions. This accuracy is influenced by factors such as the Reynolds number, fluid properties, and the installation environment. In geothermal power plants, where precise steam flow measurement is crucial for efficient operation, the accuracy of annubar flowmeters makes them a reliable choice. However, achieving optimal accuracy requires careful attention to installation and calibration procedures, as any misalignment or improper positioning can lead to measurement errors.

In terms of pressure drop, annubar flowmeters typically exhibit a very low pressure-drop compared to other differential pressure flowmeters like orifice plates. This lower pressure-drop is due to the streamlined design of the annubar sensor, which minimizes disruption to the flow and reduces energy losses. For geothermal applications, where maintaining system pressure is essential, this characteristic is particularly beneficial, as it helps preserve the overall efficiency of the power plant. The lower pressure-drop also means that less energy is required to maintain the desired flow rate, contributing to overall cost savings in the operation of the plant.

Maintenance requirements for annubar flowmeters are generally low, making them an attractive option for geothermal power plants. These meters are often equipped with retractable insertion devices that allow for inspection or repair without interrupting the flow. The annubar sensor, typically constructed from corrosion-resistant materials such as stainless steel or high-strength alloys, ensures durability even in harsh environments. However, regular inspections are necessary to check for any signs of wear, corrosion, or scaling, especially in geothermal applications where the steam may contain impurities that can deposit on the sensor over time. Fouling can affect the accuracy of the flow measurement and should be addressed promptly through cleaning or chemical treatment.

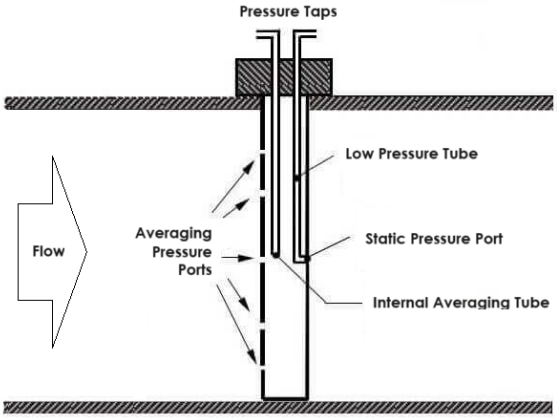

Figure 4: Measurement Principle of Annubar (Averaging Pitot Tubes).

The installation complexity of annubar flowmeters is relatively moderate compared to other differential pressure flowmeter types. These flowmeters are generally easier to install than orifice plates, as they do not require extensive straight pipe runs upstream and downstream of the sensor. However, proper alignment and positioning of the annubar sensor within the pipe are critical to ensuring accurate measurements. In geothermal power plants, where space may be limited, the compact design of the Annubar flowmeter can be advantageous, allowing for installation in areas where larger flowmeters might not fit. Additionally, the ability to install Annubar flowmeters in existing pipelines with minimal modifications makes them a flexible option for both new installations and retrofits.

Another consideration in using annubar flowmeters is the risk of resonance vibration. A vibration force perpendicular to the flow stream can occur due to the shedding of alternate vortices. It is important to check the frequency of this shedding against the natural resonance frequency of the sensor. A failed Annubar sensor could potentially enter and damage downstream equipment, so opposite-side support should be considered, especially for large line sizes.

Fluid compatibility is another important factor for annubar flowmeters, particularly in geothermal applications. The materials used in constructing the annubar sensor must be compatible with the steam and other fluids in the system. In geothermal power plants, where steam may be corrosive or contain particulate matter, selecting the appropriate materials is crucial for ensuring long-term reliability and performance. Stainless steel, high-strength alloys, and other corrosion-resistant materials are commonly used to withstand the harsh conditions found in geothermal environments.

Scaling potential is a significant concern in geothermal applications, where steam often contains dissolved minerals that can precipitate and form deposits on the surfaces of the flowmeter. While annubar flowmeters are less prone to scaling than some other flowmeter types due to their smooth design and minimal surface area, scaling can still occur, particularly in the pressure-sensing ports. Regular maintenance and cleaning are essential to prevent scaling from affecting the accuracy of the flow measurements. In some cases, chemical treatments or the use of anti-scaling agents may be necessary to keep the flowmeter functioning optimally.

Another factor to consider when using annubar flowmeters in geothermal power plants is the potential for cavitation and erosion. High-velocity steam flows can lead to cavitation, where vapor bubbles form and collapse, potentially damaging the sensor and other components. To mitigate this risk, it is important to ensure that the flowmeter is installed in a location where the steam velocity is within acceptable limits and that the sensor is designed to withstand the operating conditions. Additionally, using erosion-resistant materials can help extend the lifespan of the flowmeter in environments where particulate matter is present.

In summary, annubar flowmeters have emerged as a valuable option for steam flow measurement in geothermal power plants, particularly in applications where non-intrusive measurement, very low pressure-drop, wide flow

range, and accuracy are critical. Their ability to handle fluid compatibility and fluctuating flow rates makes them well-suited for geothermal environments. However, their higher cost, sensitivity to installation, risks of resonance vibration, and potential issues with fouling require careful consideration when selecting a flowmeter technology for geothermal applications.

3.4 Summary of DP Flowmeters

Differential Pressure (DP) flowmeters, including orifice plates, venturi tubes, and annubar flowmeters, are commonly used in geothermal steam measurement due to their reliability and established industry standards. Each type of DP flowmeter has distinct characteristics, advantages, and limitations that make them suitable for specific applications within geothermal power plants.

DP flowmeters offer a range of options for steam measurement in geothermal power plants, each with its own set of strengths and weaknesses. Orifice plates are cost-effective and simple but suffer from higher pressure-drops and potential accuracy issues. Venturi tubes provide a good balance between accuracy and pressure-drop, making them suitable for maintaining system efficiency, though they come with higher installation complexity. Annubar flowmeters combine low pressure-drop with ease of installation, though they require careful handling to avoid issues like vibration and fouling. The choice between these options depends on the specific requirements of the geothermal application, including the need for accuracy, pressure management, ease of installation, and long-term maintenance.

4. VORTEX FLOWMETERS

Vortex flowmeters are a popular choice for steam measurement in various industrial applications, including geothermal power plants, due to their robustness, reliability, and relatively low maintenance requirements. These flowmeters operate on the principle of vortex shedding, where an obstruction or bluff body placed in the flow path causes vortices to form alternately on each side of the bluff body. The frequency of these vortices is directly proportional to the flow velocity, allowing the flowmeter to calculate the volumetric flow rate. Vortex flowmeters are particularly well-suited for measuring the flow of steam, gases, and liquids, offering a versatile solution for geothermal power plant applications. Figure 5 describes the measurement principle of vortex flowmeters.

One of the primary advantages of vortex flowmeters is their accuracy, which typically ranges from ±0.75% to ±2% of the reading, depending on the specific model and the flow conditions. This level of accuracy is generally sufficient for most steam measurement applications in geothermal power plants, where precise flow measurement is critical for efficient plant operation. The accuracy of vortex flowmeters can be affected by factors such as fluid density, viscosity, and velocity (max 250 fps for steam and gases). Considering this limitation, vortex meters require minimum Reynolds number typically ranging from 10,000 to 40,000 for common shape of bluff body. However, modern designs often include compensation algorithms to account for these variables for enhancing measurement reliability.

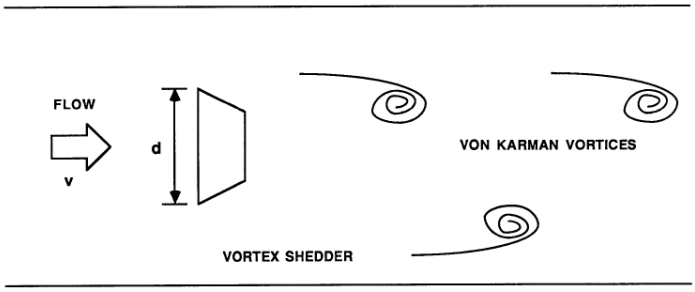

Figure 5: Measurement Principle of Vortex Flowmeter.

Vortex flowmeters also have the advantage of a relatively low pressure-drop compared to other flow measurement technologies like orifice plates. The pressure drop across a vortex flowmeter is mainly due to the presence of the bluff body in the flow path, which is designed to minimize flow disruption while still generating vortices. This low pressure-drop is beneficial in geothermal power plants, where maintaining system pressure is essential for operational efficiency. By minimizing energy losses, vortex flowmeters contribute to the overall energy efficiency of the plant.

Maintenance requirements for vortex flowmeters are relatively low, making them an attractive option for geothermal power plants. The design of vortex flowmeters is inherently simple, with no moving parts that can wear out or fail over time. This simplicity reduces the need for regular maintenance and makes vortex flowmeters more reliable in the long term. However, periodic inspections are still necessary to ensure that the bluff body and

the sensors are free from any buildup of deposits or scaling, which can occur in geothermal applications due to the presence of minerals in the steam.

Installation of vortex flowmeters is relatively straightforward, but it is important to follow specific guidelines to ensure accurate measurements. Vortex flowmeters require a certain length of straight pipe upstream and downstream of the meter to ensure a stable flow profile. Typically, 15 to 50 pipe diameters depend on the piping elements upstream of meter and 5 to 10 pipe diameters downstream are recommended. In geothermal power plants, where space can be limited, careful consideration must be given to the placement of the flowmeter to meet these requirements without compromising the overall system design.

Fluid compatibility is another important factor to consider when selecting vortex flowmeters for geothermal applications. The materials used in the construction of the flowmeter must be compatible with the steam and any impurities present in the fluid. In geothermal environments, where the steam can be corrosive or contain particulate matter, selecting the appropriate materials is crucial to ensure the longevity and reliability of the flowmeter. Common materials include stainless steel and high-grade alloys that offer resistance to corrosion and erosion.

Scaling risk is a significant concern in geothermal power plants due to the high mineral content of the steam. While vortex flowmeters are generally less prone to scaling than some other flowmeter types, scaling can still occur on the bluff body or in the sensor area, leading to inaccuracies in flow measurement. Regular cleaning and maintenance are necessary to prevent scaling from affecting the performance of the flowmeter. In some cases, the use of anti-scaling agents or chemical treatments may be required to keep the flowmeter operating at optimal performance levels.

Vortex flowmeters are also known for their versatility in handling a wide range of flow rates, making them suitable for geothermal power plants with varying steam output. The ability to accurately measure both low and high flow rates without requiring recalibration or significant adjustments is a key benefit of vortex flowmeters. This versatility makes them a reliable choice for geothermal applications, where steam flow can fluctuate based on operational demands.

In summary, vortex flowmeters are a robust and reliable choice for steam measurement in geothermal power plants, offering a good balance of accuracy, low pressure drop, and minimal maintenance requirements. Their versatility in handling different flow rates, combined with their compatibility with corrosive and particulate-laden fluids, makes them well-suited for the challenging conditions found in geothermal environments. However, careful attention to installation, fluid compatibility, and scaling potential is necessary to ensure the long-term performance and reliability of vortex flowmeters in these applications. The installed cost of vortex meters through 4 inch is typically less than for orifice meters. Vortex meters 6 inches and larger may have higher costs than orifice meters.

5. CORIOLIS FLOWMETERS

Coriolis flowmeters are widely recognized for their high precision and versatility in various industrial applications, including steam measurement in geothermal power plants. These meters operate on the principle of the Coriolis effect, where the mass flow rate is determined by measuring the phase shift caused by the fluid's inertia as it flows through vibrating tubes. This direct measurement of mass flow, rather than volume flow, allows for extremely accurate and reliable readings, which is particularly valuable in geothermal steam applications where precise flow measurement is crucial for efficient power generation. Figure 6 describes the measurement principle of Coriolis flowmeters.

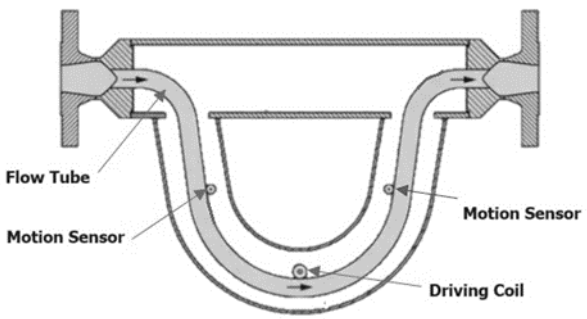

Figure 6: Measurement Principle of Coriolis Flowmeter.

One of the most significant advantages of Coriolis flowmeters is their exceptional measurement accuracy, often within ±0.1% to ±0.2% of the actual mass flow rate. This level of precision makes them one of the most accurate flow measurement technologies available, far surpassing other types such as orifice plates or vortex flowmeters. This accuracy is maintained even under varying process conditions, including changes in temperature, pressure, and flow rate, making Coriolis meters particularly well-suited for the dynamic environments often encountered in several industries.

In terms of pressure drop, Coriolis flowmeters typically exhibit a high pressure-drop compared to other flow measurement technologies. The pressure drop is primarily a function of the tube geometry and the density and viscosity of the fluid. While the pressure drop in Coriolis meters is generally higher than that in annubar or venturi flowmeters, it is often lower than that in orifice plates, making it a balanced choice in terms of energy efficiency. In geothermal applications, where maintaining system pressure is essential, the moderate pressure-drop of Coriolis meters is usually acceptable, especially when balanced against their accuracy and other benefits.

Coriolis flowmeters are known for their relatively low maintenance requirements, which is a significant advantage in geothermal power plants where equipment accessibility can be challenging. The design of these meters, with no moving parts and minimal internal components, reduces the likelihood of wear and tear. However, regular inspections are recommended to ensure the integrity of the vibrating tubes, especially in environments with corrosive or abrasive fluids, such as geothermal steam. Over time, buildup or scaling inside the tubes can occur, potentially affecting the meter's performance, so periodic cleaning or chemical treatment may be necessary to maintain optimal operation.

Installation complexity is another factor to consider when implementing Coriolis flowmeters in geothermal power plants. While these meters are relatively easy to install compared to more complex systems like venturi tubes, they do require careful alignment and mounting to ensure accurate readings. The installation process must account for factors such as vibration isolation, as external vibrations can interfere with the meter's operation. Coriolis meters installation is also sensitive to electromagnetic interference, so sensor unit should be located at least 0.6 m from large transformer of motors. Higher fluid temperature should be considered, since flow tube assembly limits operating temperature within ranges -240°C to 204°C. Additionally, the need for straight pipe runs upstream and downstream of the meter is minimal, which can simplify installation in constrained spaces commonly found in geothermal facilities.

Fluid compatibility is a critical consideration for Coriolis flowmeters, particularly in geothermal applications where steam can contain various impurities, such as dissolved minerals and gases. The materials used in the construction of Coriolis meters must be selected to withstand these harsh conditions. Common materials include stainless steel and other high-strength alloys, which offer resistance to corrosion and erosion. In cases where the steam contains particularly aggressive chemicals, specialized coatings or materials may be required to ensure long-term durability.

In geothermal steam applications, scaling is a significant concern for Coriolis flowmeters due to the high mineral content in the steam, which can lead to the deposition of solids on the internal surfaces, particularly in the small size of flow tubes of the meter. This risk is heightened in the bends and junctions where fluid velocity changes, potentially reducing measurement accuracy and causing blockages. To mitigate this, regular maintenance, including inspections and cleaning, as well as the use of anti-scaling agents or chemical treatments, is essential to ensure reliable operation and maintain the accuracy of steam flow measurements in geothermal power plants.

Coriolis flowmeters are widely regarded as a robust and reliable choice for steam measurement in geothermal power plants, but they come with certain trade-offs. Their initial cost is generally higher than that of other flow measurement technologies, such as orifice plates or venturi meters. However, this higher upfront investment is often justified by their superior accuracy, lower maintenance requirements, and long-term reliability. Selecting the optimal flowmeter requires a comprehensive evaluation of all factors, not just measurement accuracy, to ensure the best balance of performance and cost-effectiveness.

Finally, it is important to consider the potential for process disruptions when using Coriolis flowmeters in geothermal power plants. While these meters are generally very reliable, any issues with the vibrating tubes, such as damage or fouling and sensitivity to electromagnetic interference, can lead to measurement inaccuracies or even meter failure. Therefore, it is essential to have a robust maintenance and monitoring program in place to detect and address any potential issues before they impact plant operations. This proactive approach can help ensure that the Coriolis meters continue to provide accurate and reliable steam flow measurements, contributing to the overall efficiency and effectiveness of the geothermal power plant.

6. ULTRASONIC FLOWMETERS

Ultrasonic flowmeters are increasingly being adopted in geothermal power plants for steam measurement due to their non-intrusive design, high accuracy, and low pressure-drop characteristics. These flowmeters operate based on the principle of measuring the transit time or Doppler shift of ultrasonic signals as they pass through the steam. By analyzing the time, it takes for ultrasonic waves to travel between sensors, the flow rate of the steam can be determined with high precision. Figure 7 describes the measurement principles of ultrasonic flowmeters using transit time and Doppler effect.

In terms of measurement accuracy, ultrasonic flowmeters are known for their high accuracy, typically within ±0.5% to ±2% of the actual flow rate. This accuracy is largely unaffected by changes in steam density, pressure, or temperature, making them particularly suitable for the variable conditions often found in geothermal power plants. However, the accuracy can be influenced by the homogeneity of the steam flow, as ultrasonic signals require a clear path through the fluid. Any presence of condensate, air bubble, particulate matter, or large temperature gradients can affect the readings, necessitating careful monitoring and calibration to ensure optimal performance.

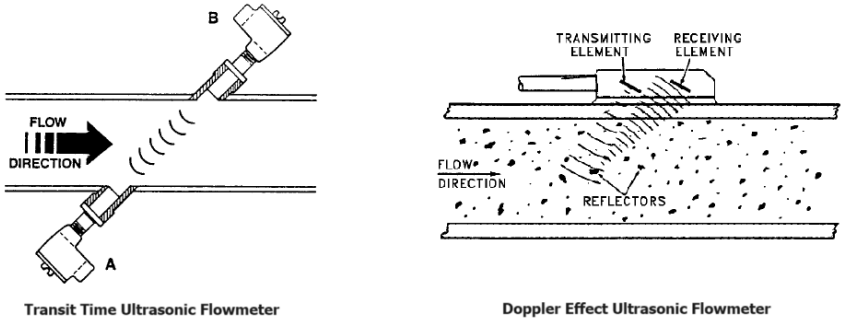

Figure 7: Measurement Principles of Ultrasonic Flowmeter.

One of the standout features of ultrasonic flowmeters is their negligible pressure drop. Unlike traditional flowmeters that rely on obstructions or constrictions in the flow path, ultrasonic flowmeters are non-intrusive and do not disrupt the flow of steam. This characteristic is crucial in geothermal power plants, where maintaining system pressure is vital for efficient operation. The lack of pressure drop also translates to energy savings, as there is no need to compensate for the losses typically associated with other flow measurement technologies.

When it comes to maintenance requirements, ultrasonic flowmeters are relatively low maintenance compared to mechanical flowmeters. Since there are no moving parts or direct contact with the steam, wear and tear are minimized, leading to longer service intervals and reduced maintenance costs. However, regular inspections are still necessary to ensure that the sensors are clean and functioning correctly. In geothermal environments, where steam can contain impurities and scaling is a common issue, periodic cleaning of the sensors is essential to maintain accuracy and prevent any buildup that could interfere with the ultrasonic signals.

The installation complexity of ultrasonic flowmeters can vary depending on the specific design and application. Clamp-on ultrasonic flowmeters, which are attached externally to the pipe, offer the advantage of easy installation without the need for pipe modifications or process shutdowns. However, clamp-on sensor requires special attention to ensure solid acoustic contact with the pipe wall through the use of conducting grease or gel material. In contrast, inline ultrasonic flowmeters, which require installation directly into the pipeline, may involve more complex procedures, including precise alignment and calibration. Ultrasonic flowmeters require a minimum straight pipe (meter run) from valves, tees, elbows, pumps, compressors, etc., to meet performance specifications. Typically, 10 to 20 diameters upstream and 5 diameters downstream are required. Upstream length requirement can be reduced by installing flow conditioners. Despite this, the installation of ultrasonic flowmeters is generally less invasive than that of other flowmeter types, making them an attractive option for both new installations and retrofits in geothermal power plants.

Fluid compatibility is another critical factor in the use of ultrasonic flowmeters in geothermal applications. These flowmeters are highly versatile and can be used with a wide range of fluids, including steam. However, the presence of non-uniform steam flow, such as droplets or solid particles, can affect the transmission of ultrasonic signals. It is important to ensure that the steam is as homogenous as possible to achieve accurate measurements. In geothermal power plants, where steam quality can vary, proper steam conditioning and monitoring are essential to optimize the performance of ultrasonic flowmeters.

Scaling potential is a concern in geothermal applications due to the high mineral content of the steam. While ultrasonic flowmeters are less prone to scaling than some other types of flowmeters, the buildup of scale on the sensors can still occur over time, particularly in harsh geothermal environments. Regular maintenance and cleaning, as well as the use of anti-scaling agents, can help mitigate this issue. Additionally, selecting flowmeters with robust sensor designs that can withstand scaling and corrosion is crucial for long-term reliability.

The ability to measure bidirectional flow is another advantage of ultrasonic flowmeters, making them particularly useful in complex geothermal power plant systems where steam flow may need to be measured in both directions. This feature enhances their versatility and allows for more comprehensive monitoring and control of the steam flow throughout the plant.

In summary, ultrasonic flowmeters offer a compelling solution for steam measurement in geothermal power plants, combining high accuracy, low pressure-drop, and minimal maintenance requirements. Their non-intrusive design and adaptability to various installation scenarios make them suitable for both new and existing installations. However, to maximize their effectiveness, careful consideration must be given to factors such as steam homogeneity, sensor maintenance, and scaling risk. When properly selected and maintained, ultrasonic flowmeters can provide reliable and accurate steam flow measurements, contributing to the overall efficiency and performance of geothermal power plants.

7. MAGNETIC FLOWMETERS

Magnetic flowmeters, also known as electromagnetic flowmeters, measure volumetric liquid flow rate. Its fundamental operating principle is based on Faraday's law of electromagnetic induction. The voltage induced across any conductor, as it moves through a magnetic field at right angles to the lines of flux, is proportional to the velocity of that conductor. The magnetic flowmeters commonly used in various industrial applications for measuring the flow of conductive fluids. However, their application in steam measurement, particularly in geothermal power plants, is less common due to the specific challenges posed by steam as a fluid. Despite these challenges, magnetic flowmeters can still be considered for certain steam measurement applications, provided that the right specifications and special requirements are considered. Figure 8 describes the measurement principles of magnetic flowmeters.

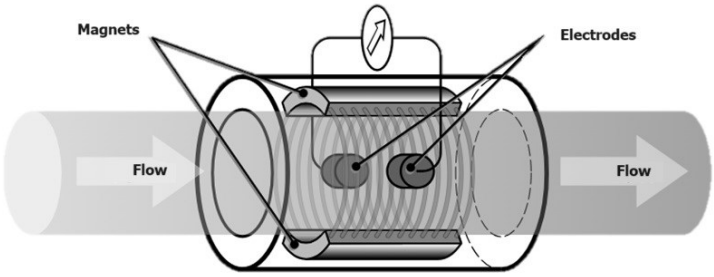

Figure 8: Measurement Principles of Magnetic Flowmeter.

One of the primary advantages of magnetic flowmeters is their high accuracy, which typically ranges from ±0.2% to ±1.0% of the actual flow rate. This level of accuracy is particularly valuable in geothermal power plants, where precise measurement of steam flow is crucial for optimizing plant efficiency and ensuring accurate billing in commercial applications. However, it is important to note that magnetic flowmeters require the fluid to be electrically conductive, which is not the case with steam. As a result, special considerations, such as using a conductive fluid in a two-phase flow system or employing alternative technologies, must be made when considering magnetic flowmeters for steam.

In terms of pressure drop, magnetic flowmeters have a distinct advantage over other types of flowmeters, such as orifice plates or venturi tubes. Since they do not have any moving parts or obstructions in the flow path, the pressure drop across a magnetic flowmeter is negligible. This characteristic is beneficial in geothermal power plants, where maintaining system pressure is critical for efficient operation. The low pressure-drop associated with magnetic flowmeters helps to minimize energy losses and maintain the overall efficiency of the plant.

Maintenance requirements for magnetic flowmeters are generally low, making them an attractive option for geothermal power plants. The absence of moving parts reduces the likelihood of mechanical wear and tear, leading to longer service intervals and lower maintenance costs. However, in geothermal applications, where the steam may contain impurities such as dissolved minerals or particulates, regular inspections and cleaning may still be necessary to prevent fouling of the flowmeter's electrodes. Ensuring that the electrodes remain clean and free from deposits is essential for maintaining accurate measurements over time.

The installation complexity of magnetic flowmeters is relatively straightforward compared to other flowmeter types. Magnetic flowmeters can be installed in both horizontal and vertical piping configurations, provided that the pipe is completely filled with the fluid being measured. In geothermal power plants, where space and piping configurations can vary, this flexibility in installation is advantageous. However, it is important to ensure that the flowmeter is properly grounded and that the installation adheres to manufacturer guidelines to avoid issues such as electrical noise interference, which can affect measurement accuracy.

Fluid compatibility is a critical consideration when selecting a flowmeter for geothermal steam measurement. While magnetic flowmeters are well-suited for measuring the flow of conductive liquids, their application in steam measurement is very limited due to the non-conductive nature of steam. In geothermal power plants, where the steam may contain a high level of dissolved solids or other impurities, these impurities can potentially render the steam conductive, allowing for the use of magnetic flowmeters in certain cases. However, this approach requires careful analysis of the steam's properties and may not be suitable for all applications.

Scaling risk is a concern in geothermal applications, where the steam often contains minerals that can precipitate and form deposits on the flowmeter's electrodes. These deposits can interfere with the flowmeter's ability to accurately measure flow and can lead to maintenance issues over time. To mitigate scaling, regular cleaning and the use of anti-scaling agents may be necessary. Additionally, selecting materials for the flowmeter that are resistant to scaling and corrosion, such as certain alloys or coatings, can help to extend the flowmeter's lifespan in harsh geothermal environments.

Another consideration for using magnetic flowmeters in geothermal power plants is the potential impact of temperature and pressure on the flowmeter's performance. Geothermal steam is typically at high temperatures and pressures, which can affect the materials used in the flowmeter and the overall measurement accuracy. Ensuring that the flowmeter is rated for the specific temperature and pressure conditions of the geothermal application is crucial for reliable operation. Additionally, the flowmeter should be calibrated to account for any temperature or pressure variations that may occur during operation.

In summary, while magnetic flowmeters are not commonly used for steam measurement in geothermal power plants due to the non-conductive nature of steam, they can still be considered for certain applications where the steam contains sufficient impurities to render it conductive. Their high accuracy, low pressure-drop, and minimal maintenance requirements make them an attractive option, provided that the specific challenges of geothermal steam measurement are addressed. Careful consideration of factors such as fluid compatibility, scaling risk, and installation complexity is essential to ensure the successful application of magnetic flowmeters in geothermal environments.

8. DISCUSSION

Steam flow measurement plays a critical role in the operation of geothermal power plants, ensuring efficiency, reliability, and overall effectiveness. Steam flowmeters are essential tools that provide real-time data on steam flow rates, which is vital for optimizing power generation, maintaining plant reliability, and enhancing operational efficiency. Accurate steam flow measurements enable operators to fine-tune turbine operations, promptly address anomalies or fluctuations, and identify opportunities for efficiency improvements, thereby reducing operational costs and optimizing the use of steam resources.

However, measuring steam flow in geothermal environments presents unique challenges. The presence of liquid droplets, impurities, and corrosive fluids within the steam requires flowmeters that are specifically designed to handle these harsh conditions. The selected flowmeters must be constructed from corrosion-resistant materials capable of withstanding high-velocity flows while maintaining accuracy. Additionally, they must be able to accommodate varying flow rates and endure the high temperatures and pressures typical of geothermal steam, ensuring consistent and reliable performance under diverse operating conditions.

The comparison chart (Table 1) outlines the key factors to consider -accuracy, pressure drop, maintenance requirements, installation complexity, fluid compatibility, scaling risk, and cost- when selecting steam flowmeters for geothermal power plants.

Table 1: Key Factors for Selecting Steam Flowmeters in Geothermal Power Plants.

Flowmeter	Accuracy	Pressure Drop	Maintenance	Installation	Fluid Compatibility	Scaling Risk	Cost
Orifice	±0.5% to ±5%	Moderate	Low	Low	Applicable	Low	Low
Venturi	±0.5% to ±3%	Low	Low	Low to Moderate	Applicable	Low	Moderate
Annubar	±1% to ±2%	Very Low	Low to Moderate	Low to Moderate	Applicable	Low to Moderate	Low

Vortex	±0.75% to ±2%	Low	Low	Low	Applicable	Low to Moderate	Moderate
Coriolis	±0.1% to ±0.2%	High	Low	Low	Applicable with Note (1)	High	High
Ultrasonic	±0.5% to ±2%	Very Low	Low	Low	Applicable with Note (2)	Low	Moderate
Magnetic	±0.2% to ±1.0%	Very Low	Low	Low	Not Applicable	Low	High

Note:
(1). Manufacturer to be consulted for certain pipe size, special steam conditions and other potential interferences.
(2). Significant solids or impurities flowing through the meter may affect to signal degradation.

Given the complexities and challenges inherent in geothermal environments, selecting the appropriate steam flowmeter requires careful consideration of these factors. The above chart provides a general comparison to aid in the initial selection process. However, specific operating conditions, process requirements, or unique circumstances may necessitate deviations from these general guidelines. In such cases, engineers should consult applicable industrial standards and seek guidance from manufacturers to ensure that the selected flowmeter meets the specific needs of the geothermal power plant.

9. FORWARD PLAN

To further refine the selection and implementation of steam flowmeters in geothermal power plants, a comprehensive forward plan is essential. This plan should encompass several key areas as follows:

- **Quantitative Analysis and Performance Evaluation:** The first step in the forward plan is to conduct a thorough quantitative analysis of the existing flowmeter performance across all geothermal power plant assets. This analysis should focus on measuring the accuracy, reliability, and efficiency of the current steam flowmeters under varying operational conditions. Important parameters such as measurement accuracy, pressure drop, maintenance frequency, and operational costs should be tracked and compared across different types of flowmeters. This data will provide a solid foundation for assessing the effectiveness of current technologies and identifying areas where improvements can be made.
- **Vendor Input and Detailed Specifications:** Engaging with flowmeter vendors is crucial for obtaining detailed specifications, understanding the latest technological advancements, and gathering budgetary information for potential upgrades or new installations. Vendors should be consulted to provide tailored recommendations based on the specific conditions of each geothermal site, including steam quality, flow rate variability, and environmental challenges. This input will help in refining the flowmeter selection criteria and ensuring that the chosen technologies align with the operational needs of the plants. Additionally, obtaining budgetary estimates will facilitate financial planning and decision-making for future investments in flow measurement technology.
- **Evaluation of Company Best Practices:** A review of the company's best practices in steam flow measurement should be conducted to identify successful strategies and lessons learned from past experiences. This review should include case studies from existing geothermal sites, focusing on the effectiveness of different flowmeter technologies in enhancing plant performance. Insights gained from these practices can be used to develop standardized procedures for flowmeter selection, installation, and maintenance across all geothermal assets. Sharing these best practices internally will ensure consistency in operations and help avoid common pitfalls associated with steam flow measurement.
- **Integration with Future Geothermal Development Plans**: The forward plan should be aligned with the company's future geothermal development plans. As new geothermal fields are explored and additional power generation capacity is brought online, the selection and deployment of steam flowmeters must be integrated into the overall project planning. This includes early-stage engineering design, budgeting, and procurement processes to ensure that the most suitable flow measurement technologies are selected for new installations. Moreover, as the company expands its geothermal footprint, there should be an emphasis on adopting innovative flowmeter technologies that offer enhanced accuracy, lower maintenance, and better adaptability to the unique challenges of geothermal steam.

Following this forward plan will ensure that steam flow measurement systems are optimized for current operations while being well-prepared for future geothermal developments. This proactive approach will enhance the long-term efficiency, reliability, and sustainability of geothermal power generation.

10. SUMMARY

Effective steam flow measurement is crucial for the efficient and reliable operation of geothermal power plants. Steam flowmeters provide the real-time data necessary to optimize turbine operations, detect process anomalies, and enhance overall plant efficiency. Accurate steam flow measurement allows operators to fine-tune power generation processes, ensuring that energy output is maximized while minimizing waste and operational costs. Given the unique challenges presented by geothermal steam, such as the presence of liquid droplets, impurities, and corrosive substances, selecting the right flowmeter is a critical decision that directly impacts plant performance.

In geothermal environments, the harsh conditions require flowmeters that are robust and capable of maintaining accuracy under specific temperatures, pressures, and varying flow rates. The materials used must resist corrosion and erosion, ensuring long-term reliability and consistent performance. Flowmeters like Coriolis, Venturi, Vortex, and Ultrasonic meters each offer specific advantages, such as high accuracy, low maintenance requirements, and suitability for varying operational conditions. However, each technology also presents trade-offs, such as the higher initial costs associated with certain flowmeters or the moderate scaling risks in specific applications. Although magnetic flowmeters offer high accuracy and very low pressure drop, they are not applicable for geothermal steam measurement due to their incompatibility with geothermal steam.

Venturi tubes, annubar, and orifice plates are the most commonly used flowmeters in geothermal applications, each offering distinct benefits suited to geothermal steam measurement. Venturi tubes are valued for their low pressure drop and reliability at high velocities, making them cost-effective. Annubar flowmeters excel in accuracy and minimal pressure drop, especially in fluctuating flow rates. Orifice plates, though prone to higher pressure loss, are cost-effective and standardized, with proven reliability. Supported by industry standards, these flowmeters balance accuracy, maintenance, and installation complexity, making them well-suited for geothermal environments. Their proven track record and cost-effectiveness solidify their preference for steam flow measurement in geothermal plants.

Ultimately, the selection of steam flowmeters in geothermal power plants should be guided by a comprehensive analysis of the plant's specific requirements, operating conditions, and long-term goals. Engineers must weigh the benefits and trade-offs of each technology, consult with manufacturers, and adhere to industry standards to ensure that the chosen flowmeter meets the operational demands of the plant. By carefully considering these factors, geothermal power plants can achieve optimal performance, reliability, and efficiency in steam flow measurement, contributing to the broader goal of sustainable energy production.

Keywords: Lubrication, Maintenance, Condition Monitoring

ABSTRACT

Abnormal wear is the opposite of good health for machinery. A high wear rate implies poor machinery health. 6%–7% of the gross national product is required to repair the damage caused by mechanical wear, Rabinowicz, E.(2008). Abnormal wear is one of the damages caused by poor lubrication. The end result of poor lubrication and contamination control is often an unnecessarily high downtime and a high cost of business, such as unacceptable levels of downtime and lost revenue, high energy consumption, and high usage of consumable parts. To overcome these challenges, modern maintenance principles are based on the application of equipment condition monitoring techniques. One of these techniques is condition-based lubrication using offsite oil analysis, which is designed to keep track of the health of lubricants as well the equipment. The methodology used before implementing a condition-based lubrication oil analysis program is critical machine selection, selection and testing of lubricant parameters, data analysis, and maintenance decision support. To illustrate the benefits of implementing condition-based lubrication, a case study of lubrication system on steam turbine, lubrication system on hot well pump and lubrication system on cooling tower gearbox is presented. In this case study, wear, contamination, and chemistry were analysed. The result of the analysis shows that rotating pressure vessel oxidation test (RPVOT) on the lubrication system of steam turbines is decreasing, it is in line with the aging of lubricant. With this method, the right maintenance decision protected the steam turbine from catastrophic failure. Furthermore, condition-based lubricant oil analysis has succeeded in extending the oil change of the lubrication system on the hot well pump and cooling tower gearbox. There are many hidden costs of failure due to poor lubrication and hidden costs of an oil change that have influenced companies to find a more efficient approach to keeping oil healthy and reliable, including downtime costs and maintenance costs. Therefore, a condition-based lubricant program will help to determine when an oil change is necessary and can assist in analysing lubrication-induced damage that could result in equipment breakdown.

1. INTRODUCTION

PT Geo Dipa Energy geothermal working area is located in Patuha, West Java Province. Geothermal powerplant consist of major system such as main steam system, circulating water system, auxiliary water system, gas extraction system, and condensate drain system. The equipment on the system have a lubrication system. Lubrication oil is used to reduce wear, improving machine reliability and reduce economic cost associated with possible future unplanned maintenance. Therefore, an oil lubrication system should be monitored regularly and the oil should be replaced in time to extend the period over which the machine operating in a healthy state. In a modern maintenance technology, condition monitoring especially lubrication analysis plays a crucial role in optimizing the machine activities, as a part of an effective maintenance policy. Lubricant oil analysis has an important rule to drive down maintenance cost and downtime cost because there are many hidden cost of failure due to poor lubrication. The primary purpose of lubricant oil analysis is to register any abnormalities of oil parameters of the machine before the functional breakdown occurs. Oil analysis have a many parameter, main parameter consist of viscosity, water content, solid particle content, and total acid number. Another parameter can be applied according to operational of equipment. Rotating vessel oxidation test is an additional of lubricant test beside the main parameter. RVPOT is a test that determines the oxidation stability of an oil and it is a more proactive approach because can respond to pending problem before permanent harm is done to the oil or machine. The test is ideal for large oil volume with low make up fluid requirements and also severe duty application. In this paper, we present a condition based maintenance lubricant oil analysis to drives down maintenance and down time cost by conducting regular check adjusted to the lubricant capacity of each equipment, adding lubricant alarm limit and lubricant critical limit on the equipment. also improve to some equipment for supporting this program. Condition based lubrication is expected to reduce maintenance cost and operational cost due to equipment breakdown.

1.1 Predictive Maintenance

Maintenance is concerned with keeping an asset in a good working condition so that the asset may be used to its full productive capacity, Ramesh,G., and O'hanlon, T (2013). Predictive maintenance is one of the management maintenance method. Predictive maintenance. The common premise of predictive maintenance is that regular monitoring of the actual mechanical condition, operating efficiency, and other indicators of the operating condition of machine-trains and process system will provide the data required to ensure the maximum interval between repairs and minimize the number and cost of unscheduled outages created by machine – train failures, Keith,R. (2018). A comprehensive predictive maintenance management program uses an effective tools, vibration monitoring, thermography, oil analysis, sound level ultrasonic, partial discharge, and corona detection. All of the equipment to obtain the actual operating condition of plant system based on actual data.

1.2 Lubricating Oil Analysis

Now it is one of the most important component of condition based maintenance is lubricating oil analysis. Oil analysis can provide information about machine condition. The object of oil analysis is to determine an assets mechanical wear condition, lubricant condition, and the contamination on lubricant. Simply, oil analysis is a routine activity for analysis oil health. Machine wear analysis is the analysis of particle in the oil. Contaminant in oil can be in solid or liquid form. Solid contaminants such as sand and dirt. Lubricant condition should be monitored, one key oil properties for lubricant condition is viscosity. In rotating machines, oxidation and acidity of the oil are monitored to determine if the oil is still fit for use and to prevent corrosion. As a predictive maintenance tool, lubricating oil analysis can be used to schedule oil change intervals based on the actual condition of oil. in midsize to large plants, a reduction in the number of oil changes can amount to a considerable annual reduction in maintenance costs.

2. METHODOLOGY

This study incorporated a case study from the major equipment in Patuha Geothermal Powerplant consist of steam turbine lubrication system, hot well pump lubrication system, and cooling tower gearbox lubrication system. This study concerned on improving machine reliability and reduce breakdown level due to poor lubrication so maintenance cost and breakdown cost can be reduced. Figure 1, illustrated several steps to be taken in the methodology.

Research method start with identifying the problem that occur in lubrication system of steam turbine, hot well pump and cooling tower gearbox. After that conduct a literary study to find the best method of condition based maintenance oil analysis. The result of the literary study were applied to the critical machine selection, in this section machine should be categorized as a critical machine level use maintenance priority index (MPI) with system equipment reliability prioritization (SERP). Selection and testing lubricant parameter based on equipment condition. Steam turbine have a different testing parameter with other equipment because steam turbine use a large oil capacity. After the data is obtained, the next step is analyze the data, create an alarm limit and critical limit also improve lubrication maintenance method. so maintenance team can makes a decision on maintenance strategy such as topping up turbine lubricant for increasing the additive level of oil, drives down the rate of oil aging and extend the interval for oil change with several kind of lubrication maintenance strategy.

2.1 Critical Machine Selection

Since the Patuha Geothermal Powerplant had numerous equipment. The first phase of the study involved selection of the critical machine type amongst them. To assist in selecting the critical machines, several factors among others were considered and evaluated. First, does the machine failure significantly affect the productivity of company. Second, does the machine service imply high cost and the last, does the machine have a high complexity level (Karanovic,2018). After the consideration of all the aforementioned factors, steam turbine should be conduct lubrication test more complex than routine test, RVPOT should be include on lubricant analysis. Different with hot well pump and cooling tower gearbox, they used only routine test for lubricant analysis.

2.2 Selection and testing lubricant parameter

The chemistry related testing lubricant parameters are viscosity and total acid number. Steam turbine have more complicated testing parameters. Routine test and rotating pressure vessels to determine the oxidation stability of their oils. Lubrication testing parameters additionally include water content and particle content as contamination parameter. Steam turbine have more complex testing parameter, using routine test and determination of oxidation stability of steam turbine oils by rotating pressure vessel. Beside the testing lubricant parameter, sampling frequency must be considered, machinery manufactures will often suggest a sampling interval, but that should only be a rough guideline. The equipment asset owner is the best judge of sampling interval include safety risk, criticality of equipment, operating condition, how costly is a failure in repair cost or lost production and what is

the failure history. Steam turbine and hot well pump use quarterly sampling frequency for cooling tower gearbox use semiannually sampling frequency.

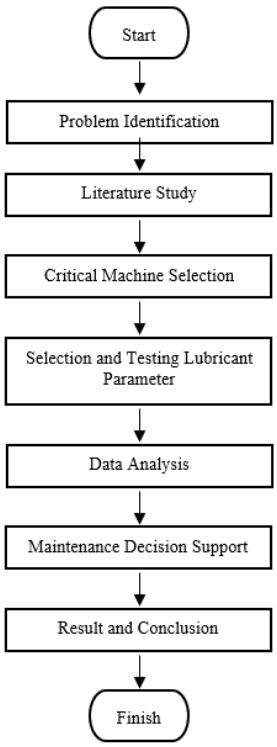

Figure 1: Research Method Flow Diagram.

2.2.1 Viscosity

Viscosity is the most important physical property of a lubricant. Viscosity is an oil's resistance to flow and shear. The correct balance between high viscosity for load carrying and low viscosity for ease of circulation must be considered for any lubricant and its application oil provide benefits in addition to lubrication and its is vital that it be able to flow under all condition. Excessively low viscosity will reduce the oil film strength, weakening its ability to prevent metal to metal contact. Excessively high viscosity reducing its ability to lubricated. The viscosity of oil impacted by temperature variation, additives, water contamination, thermal and oxidation degradation. Considering the most important physical property of a lubricant is viscosity, any change in viscosity higher or lower than cautionary limit, should be investigated, these change of chemical characteristic of oil like oxidation, evaporation, and thermal cracking of oil molecules. The increase viscosity leads to high internal friction affected to raise the lubricant temperature and energy losses over time, while if the viscosity decrease lowest that lower cautionary limit, offer less lubricity and low fil thickness that contribute to the high wear on the lubricated parts. Standard used for testing oil viscosity is ASTM D 445.

2.2.2 Total Acid Number

TAN or total acid number values are commonly used to measure degradation of machine lubricants in order to avoid machine wear, corrosion, varnish, clogged filters and other problems. Degradation of a lubricant caused by the breakdown of chemical component in the oil which result in the formation of acidic by products, formed by chemical reaction between oil base and additive component. Its lead to corrosion of oil wetted machine parts and the formation of varnish and sludge which can quickly clog oil filters. Standard used for testing oil total acid number is ASTM D 974.

2.2.3 Water Content

Water is the second most destructive contaminant. Water promotes change in chemical and physical properties in mineral oils and some synthetic such as acid formation, viscosity change, varnish, and sludge beside that water encourages aeration problems such as foaming and air entrainment and for viscosity effects water leads to stable emulsions, higher viscosity and non newtonian properties. Water contaminant have a three type. First dissolved water, the molecules dispersed one by one throughout the oil like. Second, emulsified water, microscopic globules of water dispersed in stable suspension in the oil. And the last free water, water that readily settles to tank/sump bottom. Standard used for testing oil water content is Karl Fischer.

2.2.4 Particle count

The vigilant practice of monitoring particles in oil effectively tracks the cause of wear and the effect of wear. In this test, high particle counts indicate that machinery may be wearing abnormally or that failures may occur because oof temporarily or permanently blocked orifices. Standard used for testing particle count is ISO 4406.

2.3 Data Analysis

In this method data analysis play an important rule in root cause failure analysis if the equipment breakdown caused by poor lubrication and help maintenance team to make a decision of maintenance or repair. The first of all, collecting, categorizing and evaluating all design and operating manuals including schematic are required to understand the complexity of equipment. Operating parameter also need to be considered, reflect the minimum requirement for operating the equipment this include operating temperature, lubricant requirements, filtration requirement and other parameters that directly or indirectly impact reliability and life cycle cost. Oil sampling location should be identified for each piece of equipment to allow trouble free, repetitive, and representative so that the good data will be obtained. To compare the data, fresh oil baseline must serve as a reference point, lubricant and additive packages might change over time, thus updating lubrication targets and alarm should take these change. The last step is database development, which involves organizing equipment data and information also collecting data along with the equipment specific targets and alarm.

2.4 Maintenance Decision Support

To take a maintenance decision support, in this method the most sophisticated use of oil analysis data and reports will aid strategic with scatter gram . Identify the types of equipment that breakdown most, extend oil drain with minimal risk by finding the threshold where severity level spike and make purchasing decisions based on which makes and models perform the longest before replacement is required, target for saving maintenance cost and reduce downtime cost expected to be accomplished.

3. RESULT AND DISCUSSION

In this section, the result data is presented with case studies related to the lubricant analysis. Advantage lubricant analysis for reducing maintenance cost and for reducing the downtime cost following to the methodology in section 2. The case studies include aging on steam turbines lubricant, Improve replacement oil schedule on Hot Well Pump from time based maintenance to the condition based maintenance, and upgrade base oil material on cooling tower due to high temperature operational.

3.1 Aging on Steam Turbines Lubricant

Lubricant on steam turbine, oil flowing through the bearing absorbs heat from the journal as the shaft carries it over the upper half of the lining. Steam turbine operate on a family of lubricating oil known as R&O oils (Rust & Oxidation inhibited oil). the rotating pressure vessel oxidation test (RPVOT) is a test that determines the oxidation stability of an oil, RVPOT measure the actual resistance to oil oxidation. The RVPOT value drops to 144 after 6 years of operations.

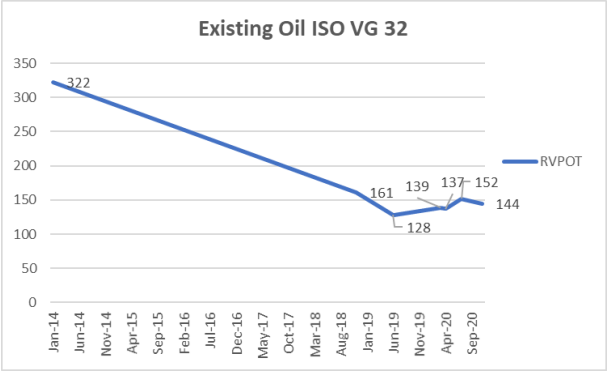

Figure 2: Trend Existing Oil ISO VG 32.

Based on figure 2. A sign of oil oxidation appears when the RVPOT value decreases. It can cause damage to the lubrication system in the future. To avoid this case, management decide to replace steam turbine oil with a higher RVPOT value. More RVPOT value can slow down the rate of oil oxidation and oil aging. Comparison of the specifications between the manual operation, the existing oil and the new oil may be seen in figure 3.

As a result, extend oil life and avoid a sudden damage. If no replacement is carried out, the risk of maintenance costs and downtime costs as follows, Total Downtime for six days plant shutdown is equal with downtime cost IDR 11,772,596. Cost for material oil and purifier task is IDR 600,000,000. If management doesn't take action in

this case, total losses cost will reach IDR 12,327,596,246. Based on analytical data and troubleshooting, management take an action to replace oil with the higher RVPOT and perform oil analysis quarterly. Oil replacement was carried out during the overhaul 2021. Based on Figure 4, during the monitoring period of steam turbines lubricant from 2021, Parameter in a normal condition. Viscosity did not significantly changes. In this research recommended alarm limit for viscosity change with percentage deviation from baseline, +5% for upper cautionary, -5% for lower cautionary, +10% for upper critical, -10% for lower critical. The second test is total acid number, TAN value moved within the recommended tolerance for steam turbine lubricant, Less than 0.5 mgKHO/g.

Aspect	Manual Operation	Existing Oil (Brand A ISO VG 32)	New Oil (Brand B ISO VG 32)
Kinematic Viscosity @40degC	28.8 cSt - 35.2 cSt	31.2 cSt	30 cSt
Viscosity Index	≥ 95	105	117
Flash Point	≥190° C	226° C	228° C
Pour Point	≥-10°C	-20°C	-30°C
Neutralization Value	≤ 0.3 (mg KOH/g)	-	0.1 (mg KOH/g)
Rust Prevention Test	Shall Pass	Pass	Pass
RVPOT		322 minutes	1000 minutes

Figure 3: Comparison of Oil Specification.

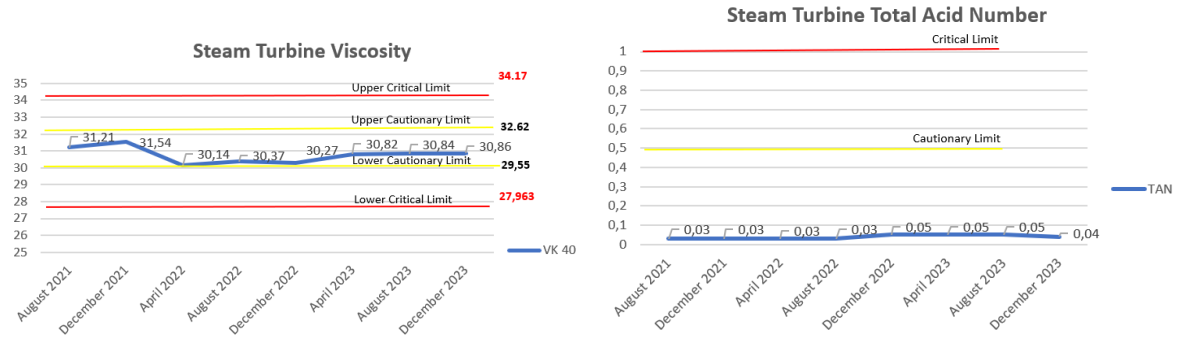

Figure 4: Trend of viscosity and TAN values change on Steam Turbine.

In line with other parameter, water content keeps on track below the alarm limit, in a lubricating system, the two most harmful phases are free and emulsified water. In a journal bearing on steam turbine, the incompressibility of water relative to oil can result in a loss of the hydrodynamic oil film that in turn leads to excessive wear. As little as one percent water in oil can reduce the life expectancy of journal bearing by as much as 90% (Hannon, 2022). The standard of water content on steam turbine is less than 500 ppm.

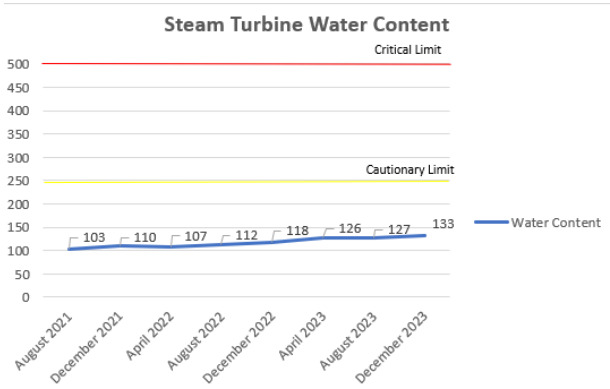

Figure 5: Trend of Water Content on Steam Turbine.

Since 2021, According to the figure 6. RVPOT value remains at 1360 and higher. RVPOT still corresponds to the value of the new oil analyzed. Performing RVPOT testing is recommended to be part of a complete test slate to helping evaluate condition of the fluid and the analysis should be supported with limit tip alarm limit and caution limit for early detection failure on lubricating system. Limit tip for cautionary limit is baseline RVPOT x 0.5 and limit tip for critical limit is baseline RVPOT x 0.4.

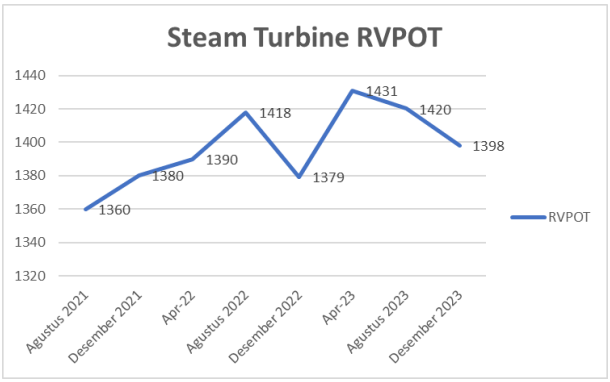

Figure 6: Trend of Steam Turbine RVPOT.

Considering of aging oil are associated with solid particle oil contamination. The solid particle test should be performed. During the research, the solid particle content did not significantly change and mostly constant within the permitted limits, solid particle content value from august 2021 to December 2023 according to the ISO 4406 solid particle test is 16/14/11 and it has not changed after 3 years of operation.

3.2 Improving oil replacement schedule on hot well pump from time based maintenance to the condition based maintenance.

According to the manual instruction maintenance hot well pump, oil filling of the motor hot well pump is changing every years, no matter what the condition of lubricant. Hot well pump oil analysis can't be performed because the sampling port on hot well pump is not available. For improving predictive maintenance task, sampling port should be installed, sampling port plays an important role in oil analysis program design repeatability data. Lubricant properties that can be used for oil drain according to condition based use viscosity properties, water content, Total acid number and solid particle content. The research mission is improving the oil replacement schedule and the two-year mission involved sampling and evaluating the lubricant every four months. if the oil drain carried out every year, resulting in 4 hours of downtime. If the production loss that occur is 60 MW/h, total production loss is 100 MW when performed oil replacement for each equipment. Patuha geothermal powerplant use two hot well pump with 100 % operation method. total maintenance cost and downtime cost that can be saved is IDR 723,840,000. the material for oil replacement that can be saved is IDR 10,000,000. In addition, this program can reduce the risk of waste oil due to replacing or drain oil according to the condition based lubricant. According to the figure 7. During monitoring the research since 2021, four main parameters in a good condition. Viscosity value didn't significantly change. Same as limit tip viscosity value on steam turbine, Hot well pump use alarm limit for viscosity change with percentage deviation from baseline, +5% for upper cautionary, -5% for lower cautionary, +10% for upper critical, -10% for lower critical. The second test is total acid number, the value TAN remains in a normal condition and less than the cautionary limit.

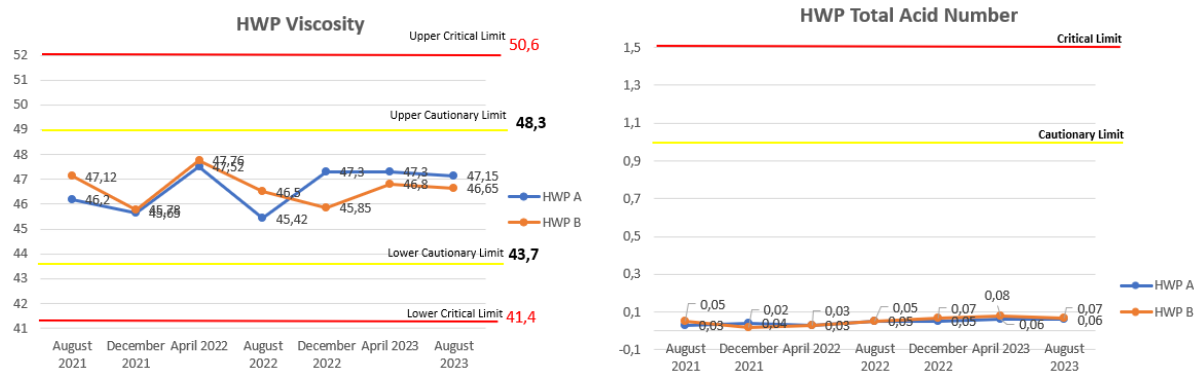

Figure 7: Trend of viscosity and TAN values change on Hot Well Pump.

The water content and solid particle content of the lubricant are the next to parameters to be examined. Under normal conditions during the experiment, the water contents was constant at 200 ppm, which is less than the 500 ppm cautionary limit for both hot well pumps A and B.

Solid particle content "hot well pump A" better one step particle contaminant than "hot well pump B", According to the ISO 4406, solid particle content for "hot well pump A" is 17/15/12, meanwhile "hot well pump B" has a 18/16/13. Even though the value are different, both equipment still in a good condition, Seen from the viscosity

value and TAN value didn't change significant. Because solid particle content is one of the contaminants that can increase a viscosity and total acid number in line with an aging oil.

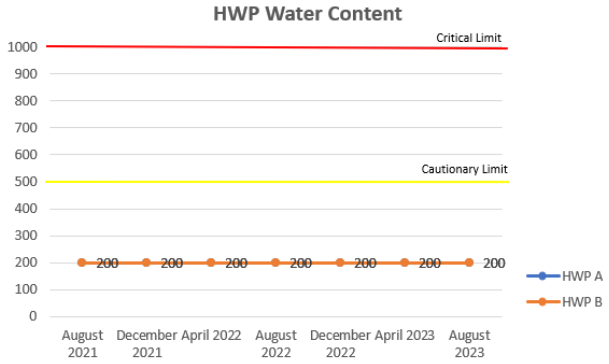

Figure 8: Trend of Hot Well Pump Water Content.

3.3 Improving base oil material on cooling tower gearbox because of high temperature operational.

Cooling tower is a specialized heat exchanger in which air and water are brought into direct contact with each other in order to reduce the water temperature. One of the Main equipment in cooling tower is Gearbox. Gearboxes are available in a variety of design and reduction ratios to accommodate the different fan speeds and horsepower of cooling towers. Gearbox that used in Patuha Geothermal Powerplant reduce rotation per minutes from 3000 RPM to 112 RPM. In accordance to the visual inspection result. Temperature of gearbox lubricant reach a maximum value above 82ºC and when inspect the internal gear, varnish formation starting to appear. Several corrective actions have been taken, but the oil temperature is still high. At this elevated temperature, viscosity to decrease, the lubricant film to become thinner, an acceleration in abrasion and scuffing conditions, the oil to age sooner, the additives to deplete quicker, an acceleration of corrosion, and the formation of sludge and varnish. The fluid film needs to be thick enough at operating temperature to separate the surface even under load, however, they should not be so thick that the parts have difficulty moving due to the viscous lubricant. The Arrhenius law states that with every increase of 10ºC in a lubricant's base temperature, oil life is halved (Whitby, 2022). Based on figure 9 & figure 10 below. the results of oil analysis, there was an increase value in water content and total acid number.

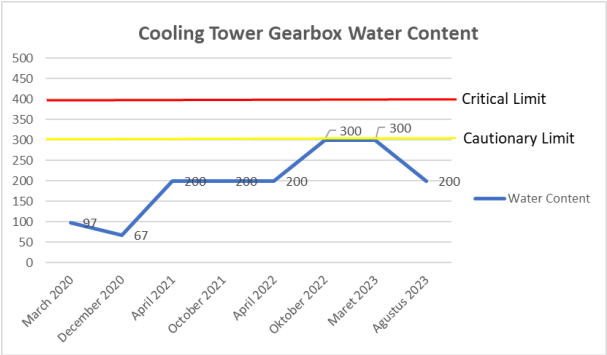

Figure 9: Trending Water Content on Gearbox.

Water content value continues to increase from 97 PPM to 300 PPM reached cautionary limit. In accordance with the result, management decide to take good corrective action starting with troubleshooting cause water system can be increases in the lubricating system. The presence of water in a lubricating oil can cause the progress of oxidation to increase tenfold, resulting in premature aging of the oil, particularly in the presence of catalytic metals such as copper, lead and tin. in addition, Certain additives such as sulfurous anti wear and extreme pressure type additives and phenolic antioxidants are readily hydrolyzed by water, resulting in both additive mortality and the formation of acidic by-products. Currently cooling tower gearbox use additive Extreme Pressure. Solid particle content for gearbox cooling tower according to the ISO 4406 is 20/18/15. Solid particle contaminant like dirt, metal particles, soft insoluble, and soot can affect to the change oil chemistry oxidation and additive depletion. In addition, chemically attacks machine surface one of the is adherent varnish. During the research period, TAN value moved within the recommended tolerance, however the trending of TAN is increasing. Most of acids in lubricating system are product of oil oxidation process or aging. Oxidation is the permanent degradation of a lubricant by chemical reactions involving oxygen. As oxidation progresses long chain molecules are produced, which lead to sludge, tars and varnish. Acids are produced which leads to corrosion.

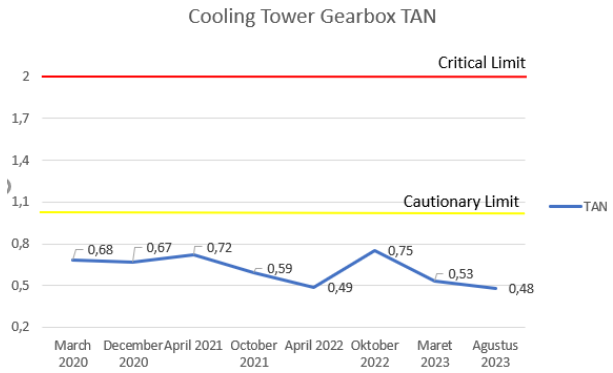

Figure 10: Trending Gearbox Total Acid Number.

From troubleshooting result, proactive maintenance was carried out. After that, execute study literature associated with lubricating system on cooling tower gearbox. In manual specification and standard, viscosity grade should be use ISO VG 220 complete with rust and oxidation additive but without extreme pressure additive. In case the temperature above 82° C, base material of oil must be use synthetic for base material of oil. Due to synthetic lubricant offer advantages of extended service life, a broader operational temperature range, reduce friction, and the ability to maintain a higher film strength which can extend service of life of the gear drive. Considering to the result of oil analysis and study literature about maintenance manual of gearbox cooling tower. Management decide to improving base material of oil from mineral oil to synthetic oil made from polyalphaolefins base stock. This is intended to reduce working temperature because the synthetic base has advantages in viscosity index and thermal oxidative stability. The viscosity index of an oil is the term used to express an oil's resistance to viscosity change as the temperature change. An oil that thins out significantly as its temperature increases is said to have a low viscosity index. An oil whose viscosity does not change significantly as its is heated up is said to have high VI. If the oils viscosity is to high with a low potential shear rate, the internal resistance to flow will increase the temperature dramatically, causing an overheated condition, which can also cause a breakdown of the oil film and may cause oxidation of the oil. beside that oil with lower viscosity and high potential shear rate must still maintain a sufficient oil film, it's quite apparent that as temperature rise, the oil film may fail and metal to metal contact may occur.

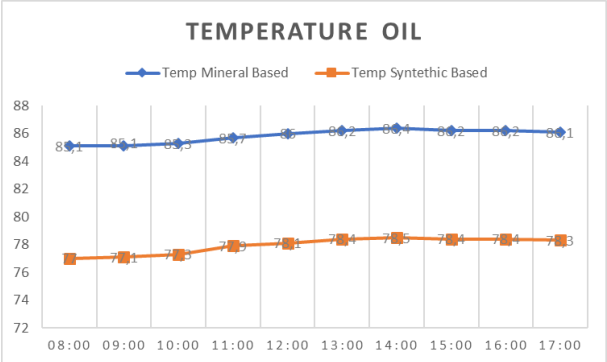

Figure 11: Temperature Oil Comparison.

After oil replacement has been done, there is a decrease in oil temperature around 6°C – 8°C. with these result the new oil expected to decrease the rate of oxidation and acid number, so that can extend service of life of the gear drive oil. Related to water content and solid particle contamination, management decide to install desiccant breathers. The desiccant breather can control of dirt and moisture ingress. A gearbox breakdown may happen if management keeps using mineral base oil and the operating temperature rises above 82°C. Potential maintenance cost and downtime cost as follows: IDR 200,000<000 for recondition the gear drives and 8 hours of downtime for cooling tower gearbox replacement. Eight hours of downtime results in a output loss of megawatts. Meanwhile total lost income up to IDR 11,440,000. this improvement is expected to extend replacement oil schedule from semiannually to every 2 years. It can be achieved if management perform oil analysis to determinant the condition of oil. perform oil replacement every two years can provide economically benefit as Figure 12.

According to the figure 12. The cost saving that can be obtained if management perform every two years oil replacement compared with semiannually oil replacement are IDR 19,208,106 for single unit cooling tower. The program can save around IDR 48,020,285 every years and IDR 96,040,530 every two years, if it's implemented for five units of the cooling tower. In addition to the financial aspect, there are several advantages that have an

impact on safety and the environment. The Impact on safety is increasing total safe working hours, this is related to work accident that may occur when conducting oil replacement. The impact on the environment is decreasing total oil waste. and also, the most important thing when base material has been upgraded to the synthetic based is all about operation and oil parameters. Gearbox can operate optimally according to the standard working temperature below 80^{o}C and prevent the gearbox from sudden damage which will impact to the maintenance costs and downtime costs.

Aspect	Mineral Oil	Synthetic
Period	2 Years	2 Years
Oil Replacement	4 times	1 times
Total Production Lost	IDR 25,472,261	IDR 6,368,155
Oil Replacement Cost	IDR 14,176,000	IDR 17,072,000
Waste Oil Processing Cost	IDR 4,000,000	IDR 1,000,000
Total Cost For 1 unit cooling tower	IDR 43,648,261	IDR 24,440,155
Total Cost For 5 unit Cooling tower	IDR 218,241,305	IDR 122,200,775

Figure 12: Table Comparison of oil replacement costs.

4. CONCLUSION

The poor lubrication and contamination control plays a key role in high downtime and high cost of business. such as unacceptable levels of downtime and lost revenue, high energy consumption, and high usage of consumable parts. To overcome these challenge this paper studies about condition based lubrication program. This program enables a user to have confidence in the quality of the lubricants in each machine and to help analyze the condition of the machine in its current state. Condition based lubricant can be used to determine when lubricant needs to be changed, so that its inferior properties of performance doesn't not impact the useful life of the machine. For achieving excellence in condition based lubricant program, analyzing the result of the routine test, using cautionary limits and critical limits, using trend graphs, will enable machines or equipment and system to be monitored effectively to determine both lubricant service lifetime. In this research three cases study were observed to prove that maintenance costs and downtime cost can decrease when implementing a condition based lubrication program. In the case of oil aging on steam turbine due to oil degradation, condition based monitoring oil analysis works in the troubleshooting process, problem solving and decision making. In addition, oil analysis can assist in continues improvement such as in the case of improving base oil material on cooling tower gearbox and extend service life of oil in hot well pump. The three cases studies above can reduce maintenance cost and downtime cost up to IDR 13,099,456,511. Establishing an effective condition base lubrication can start with small aspect, establish the methods, correct lubricant sampling methods and comprehensive testing are important for accurate data, data analysis with tip limit standard, reporting and corrective action, and then gradually expand the program integration with other condition monitoring program, expand the program as the cost-benefits become clear. The management should be commits and support, so that condition based lubrication program can running properly and can give benefit for the company.

Geothermal Champaign a Success Story of GRE Pipe for Downhole Casing in Geothermal Well

Nico Riyanto

P.T. FUTURE PIPE INDUSTRIES, Talavera Office Park 8th floor, South Jakarta, Indonesia

n.riyanto@futurepipe.com

Keywords: GRE Pipe, Direct Use, District Heating, Composite Pipe

ABSTRACT

Glass Reinforced Epoxy (GRE) pipe is a composite material made of glass fibre filament and polymer resin that used as a binder. The usage of this material is mainly to substitute metallic material against corrosive environment such as water, CO2 and H2S. The main advantages of GRE pipe for geothermal application are its ability to maintain the flow without scaling and less maintenance required during the lifetime. However, there are also some limitations as of today on what GRE pipe can provide, especially on the temperature limit that can only reach up to 100°C and pressure up to 3000 psi. Most of the application of composite pipe is for the cooling tower pipeline system in geothermal power plant where it requires low temperature and pressure, but used as alternative of metallic pipe which might corroded over the lifetime.

This paper will provide the detail of GRE pipe for district heating in Champigny, France that has low enthalpy and water dominated reservoir. Compared to common steel pipe, GRE pipe can provide better OPEX that require less maintenance and work-over for the well. Furthermore, we might foresee the application of GRE pipe for different application in geothermal sector in Indonesia for its direct use such as agriculture, tourism, hospital, and other potential application that only require low enthalpy reservoir type.

1. INTRODUCTION

1.1 Glass reinforced pipe types

Glass reinforced pipe is type of composite pipe that use the glass fiber and plastic resin to create dense structure material with high resistance against corrosive fluid that might appear using metallic material. There are several types of glass composite pipe depending on the resin types and each of type has different application and advantages. Below is a short introduction of glass reinforced pipe.

Table 1: Types of Composite Resin and Its Application.

Resin Type	Advantages	Application
Glass Reinforced **Epoxy** (GRE)	High resistance against water, brine, H2S and gas	Pressure rate up to 3000 psi, Temperature rate up to 100°C
Glass Reinforced **Polyester** (GRP)	High resistance against water and brine	Pressure rate up to 60 bar, Temperature rate up to 60°C
Glass Reinforced **Vinylester** (GRV)	Better chemical resistance than Epoxy material	Pressure rate up to 60 bar, Temperature rate up to 100°C

The main material for fiber glass composite pipe is the silica filament fiber which provide the mechanical strength needed, while the resin is used as the binder of the filament and to distribute the load evenly throughout the filament structure. Depending on the degree of winding angle of filament wound, it will provide different characteristic of structural strength. Commonly GRE pipe is produced with winding of 55° to reach its optimum strength of 2:1 burst and tensile strength.

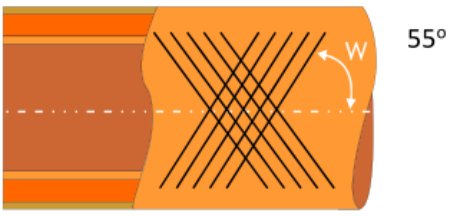

Figure 1: Winding Angle of Pipe Wall Construction.

1.2 Composite pipe manufacturing process and jointing system

Commonly there are several types of manufacturing depending on the application and desired structural strength:

1.2.1 Helical winding:

The silica fiber filament is dipped into the bucket full of resin as a binder. The filament is then winded with winding angle 55° around the mandrel as mould until it reached the desired thickness. The pipe then heated at temperature up to 160°C to cure the resin until harden. This type of manufacturing process normally produce glass reinforced epoxy (GRE), glass reinforced polyester (GRP) or glass reinforced vynilester (GRV). Due to the mandrel available, the pipe dimension can be produced up to 48inch.

1.2.2 Continuous winding:

Using chopped fiber glass that pour into the mandrel. Resin and topcoat material then added on top of the fiber glass. Sometimes silica sand also added to increase the stiffness. Normally using polyester or Vynilester resin type that is self-cured once mixed. The pipe diameter that can be produced by this process from DN 300 up to DN 4000 which it has high productivity rate for larger diameter than helical winding process.

Once manufactured, the pipe will be jointed depending on the design and condition. There are several types of jointing system for composite pipe as per figure 2 depending on each application such as the design pressure requirement and field utilization. The mechanical joint, such as thread and couple joint, integral joint, and flange joint, have better mechanical strength compared to the other types of joint. However, the strength is compensated with the need of thicker pipes than adhesive or lamination joint.

Figure 2: Helical winding machine.

1.3 Composite pipe application and advantages

The main application of composite pipe is used as an alternative solution of corrosive environment that can't be overcame by metallic material such as carbon steel and stainless-steel material. There are several advantages of composite pipes compare to other metallic materials such as:

- Longer lifetime up to 30 – 50 years design lifetime since it's not corroded overtime.
- Less maintenance required since no scale build-up and no corrosion appear during the life application that leads to less operation expense.
- Less weight than metallic material which leads to better logistics and delivery process to remote area.

Due to those advantages, the application is various even more for the application that has high water content which is the main factor of corrosion for metallic material. One of the potential usages is the geothermal well for production casing and we had one example of success story in Champigny Sur Marne, France for the application of GRE pipe casing with high water content and high salinity which highly corrosive for carbon steel material.

Figure 3: Continuous winding machine.

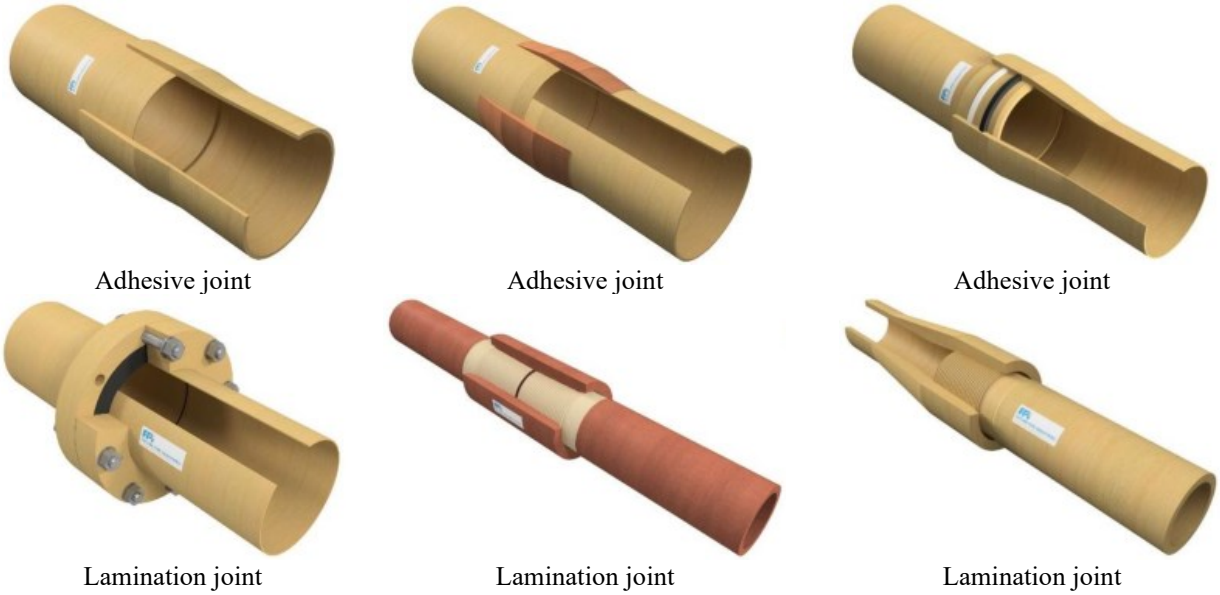

Figure 4: Types of jointing system for composite pipe.

2. GEOTHERMAL CHAMPIGNY-SUR-MARNE PROJECT OVERVIEW

2.1 Project Background

Group Coriance is a French company that focusing to achieve green energy provide for communal and industrial application. The company has been established since 1998 as subsidiary of Gaz de France to operate geothermal networks for Meaux (41km east from Paris) and Fresnes (12km south from Paris). One of the main services is direct heating using geothermal energy for the habitant area and for industrial application. Since then the company also provide other source of energies such as biogas, biomass, and energy recovery from the industrial area below are several projects that has been done:

- Geothermal for district heating 10 projects
- Biomass for power plant and heating 18 projects

- Biogas 1 project and
- Energy recovery from biomass and waste treatment 4 projects

2.2 Well parameter and casing design

The project was done in 2023 operated by Group Coriance in France who is operated to provide heating network in the area. The initial project was done in 1983 for the first geothermal well in Champigny Sur Marne and it has been operated as heat source for 5,477 habitants which account for 75% of the heating by renewable energy. The characteristic of the reservoir as per table 2 below.

Table 2: Well parameter. Bureau de Recherches Geologiques et Minieres (1984).

Description	Remarks
Bottom Hole Temperature	80°C – 90°C
Well Head Temperature	68°C – 72°C
Injection Well Temperature	40°C
Total depth	1,805m
Production rate	350 m3/h water dominated
Fluid type	high water salinity 150 g/L of equivalent NaCl (common sea water at 35 g/L NaCl)
Reservoir formation	limestone with 14% porosity

Future Pipe Industries supplied the material of casing GRE pipe to General Tubular Services Gmbh as the sub-contractor which running the downhole casing pipe. There are 2 wells drilled for this project which are production and reinjection well, the well schematics of the 2 wells are similar as summarized in the table 3.

Table 3: Casing design.

Casing Section	Casing Specification
Conductor Casing	18-5/8” 87.5# K55 Buttress Connection, Depth 130m
Intermediate Casing	13-3/8” GRE pipe 750psi 4RD connection, Depth 400m
Production Casing	10” GRE pipe 1000psi 4RD connection, Depth 1000m
Production Casing liner	7-5/8” GRE pipe 1000psi 4RD connection, Depth up to 1800m

2.3 Rig running process

The connection type offered is 4RD connection type which is a FPI’s patented connection that has 4 thread per inch (TPI) on the thread profile for faster rig running and better mechanical strength. Considering the pipe wall thickness of GRE pipe is thicker than metallic pipe, the hole section and OD diameter of pipe should be determined further to get a better clearance. Future Pipe Industries also in coordination with running services to design several accessories equipment such as cross over, centralizer and other downhole equipment to be compatible with GRE pipe. Another solution to reduce the clearance is to use carbon filament rooving that has better mechanical strength and temperature resistance than silica filament rooving. Using this material as a coupler can reduce the pipe wall thickness significantly.

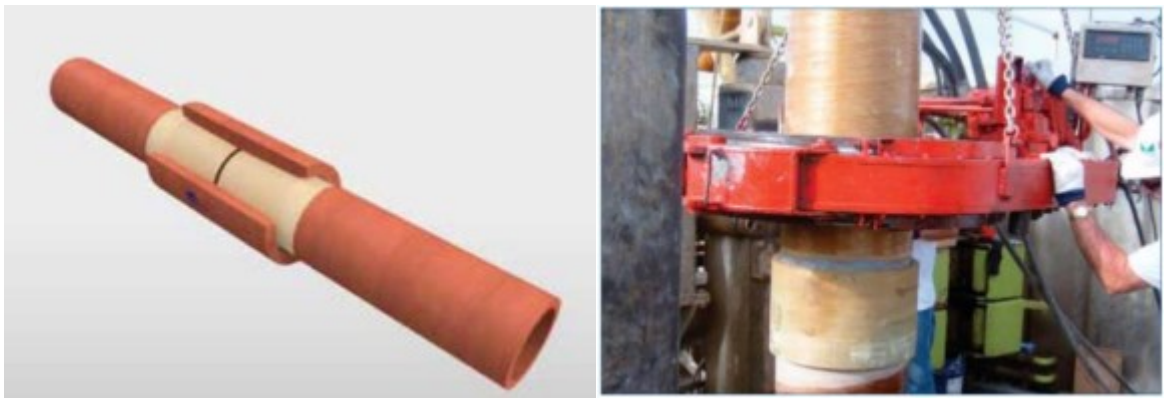

Figure 5: GRE pipe with thread and couple connection (left) and rig Running on the field (right).

Figure 6: Application of thread sealant on pin and box.

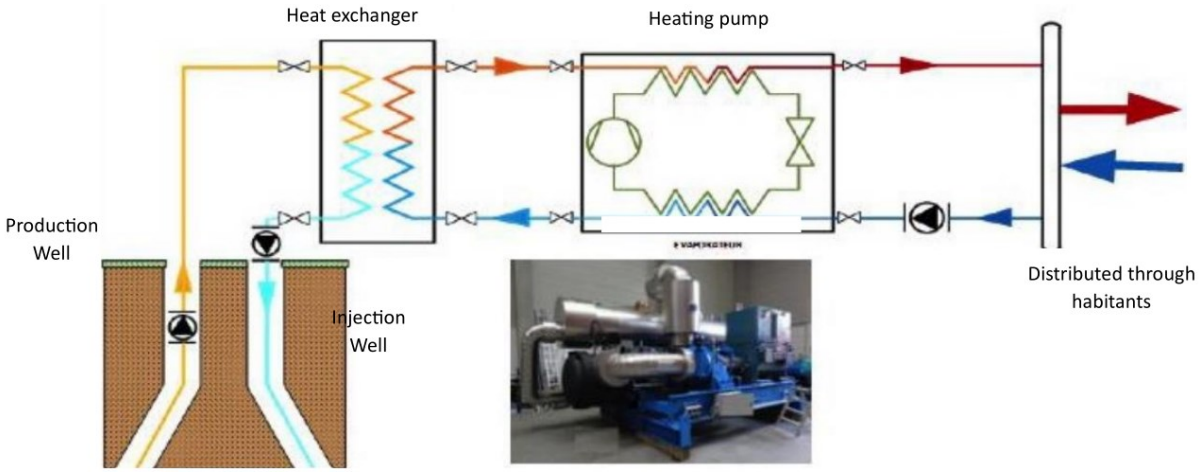

Figure 7: Project layout.

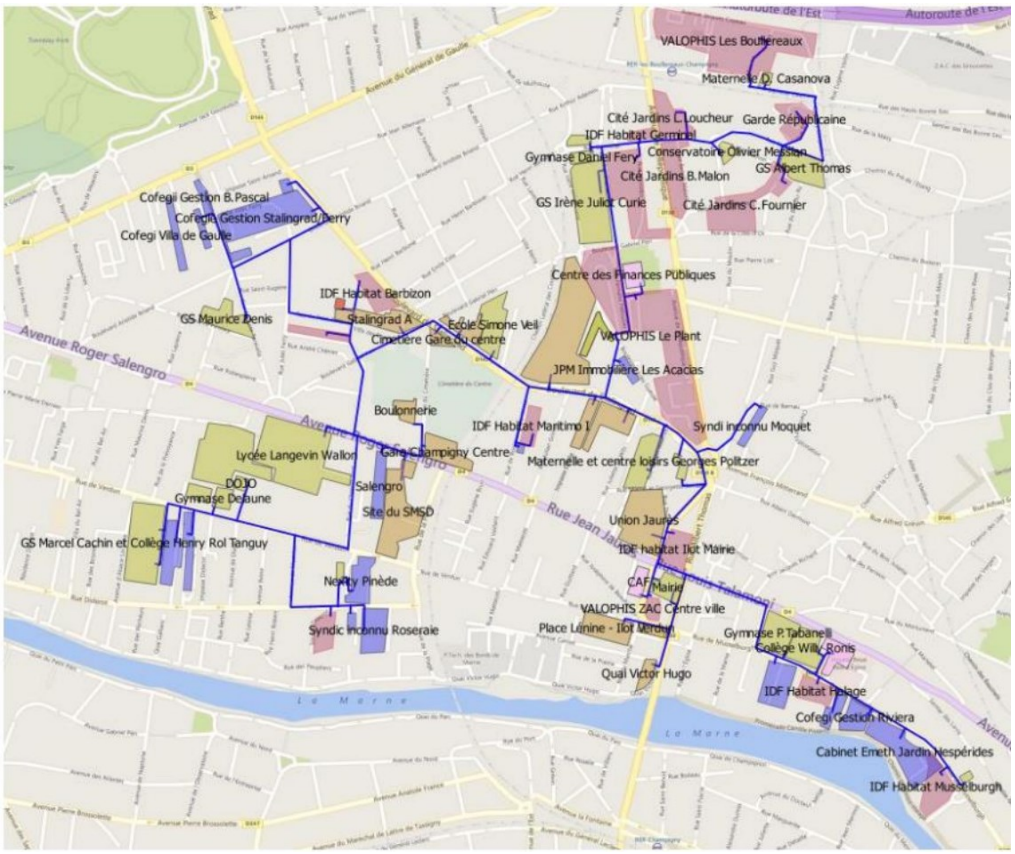

Figure 8: Pipeline distribution around the habitant (up to 9km pipeline).

The running process of GRE pipe is a little bit different compared to common metallic pipe. Normally metallic pipe require grease to be applied to reduce friction, while GRE pipe require sealant on thread for permanent casing application to increase the jointing strength. The thread sealant should be applied on both pin and box and combed evenly throughout the thread surface.

2.4 Project layout and result

The production fluid is then circulated into the heat exchanger which then the heat will be circulated with heating pump to habitants in the area. The production fluid will be reinjected into the earth to be circulated and maintain the pore pressure. Figure 7 and figure 8 describes the project layout and the heating distribution throughout the habitants.

The project is quite successful that it reduces the carbon emission by 9,500 tonnes of CO2 each year compared to common natural gas heating source. The use of GRE pipe material is also reducing the maintenance and workover required during operation which also leads to increase the productivity rate of the well. Since the successful project in 2023, FPI received another continuous order from Groupe Coriance for another field for similar application in France in 2024.

3. POTENTIAL USE OF COMPOSITE PIPE IN INDONESIA GEOTHERMAL

3.1 Direct use potential application

Indonesia geothermal application is mainly for power generation since its location is within the ring of fire. The common temperature required for power generation application in Indonesia can reach above 250°C which is too high for composite pipe to reach. However, there are several potential applications for low enthalpy geothermal that can be used for direct use other than communal heating such as agriculture, fishery, hospital, and recreation. Below are some example and application based on the temperature of production well:

- **Aquaculture and fish farming**. Maintaining specific water temperature is a challenge in aquaculture and fish farming industry where it can impact the yield rate and quality of fish produced. Low enthalpy geothermal well with temperature range between 30°C – 50°C can be a solution for this application since the temperature can be maintained 24/7 with very low carbon footprint. Indonesia as maritime country has high potential for this application since it has wide biodiversity that can harness further the potential and improve the quality.
- **Industrial processes**. Several industries will require heating such as food drying, pasteurization and sterilization which require heating process. Geothermal energy can be used and integrated in the process to reduce the use of electricity that heavily used in the application. Several industries such as food processing, pulp and paper, textile manufacturer can be benefited for such application. Even though the initial capex is high, the operation and maintenance required with geothermal will provide better total operating cost. The temperature required for this application is various from 50°C for drying and washing, up to 120°C for sterilization.
- **Greenhouse cultivation**. This application is similar to aquaculture, greenhouse cultivation can benefit further with the well maintained and controlled temperature from geothermal well. The optimal temperature maintained by geothermal heat source can increase the crop yield, growth and provide uniform produce. Several countries such as Netherland has embraced this application to increase their agricultural cultivation such as potato, tulips, etc which is quite important for 4 seasons countries such as Netherland to be able to maintain the optimum temperature throughout the year. Indonesia can also be benefited further with this application to increase the crop yield on the lack-fertilized field. Furthermore, with the current condition of global warming, where the temperature has increased significantly and extended dry season throughout the year, this can impact the production.

The economics of scale for those applications needs to be determined further since the utilization is not to generate power, then it needs to convert the equivalent to the power replacement. However, the recent study shows that between 2010 to 2020, the application of direct use geothermal has increased from 400 petajoule/year to 1,000 petajoule/year which increase over doubled in the duration of 10 years. Most of it used for district heating (80%), bath and recreation (15%), and agriculture and industry (5%). The main driver of this increments due to several factors such as:

- Sustainable and clean energy
- Reliable 24/7 throughout the year
- Affordable in the rural area
- Independent heat source

There are several challenges to realize the direct use of geothermal as per below:

- High CAPEX that upfront that needs to be prepared. The highest factors are drilling process and equipment, infrastructure and heating distribution.
- High OPEX which include maintenance and potential workover during the life cycle of the well is also another challenge that need to be addressed.
- Geothermal wells are very dependent on the location of the heat source. Green field will require exploration process to understand the geological structure which an additional cost that might not be recovered if the location is not suitable.
- Some countries or location has cheaper substitute source of energy such as fossil fuels, solar energy, or wind energy that might generate higher energy source.

Figure 9: GRE pipe as cement stinger application in oil and gas field.

3.2 Other potential application of composite pipe in geothermal sector

There are other applications of composite for geothermal sector which can be a better choice compared to common metallic pipe. Below summarize the application and advantages with composite pipe compared to metallic pipe:

- **Cooling tower in power plant**. Operating temperature can be up to 70ºC and dimension requirement up to 1.8m will be challenging to install when using metallic pipe. Not to mention the production of large diameter pipe is expensive, the logistic and installation process in remote area will increase the cost even more. Additionally, the fluid water for the cooling tower can heavily corroded when using common steel pipe that increase the cost for repair and replacement during the life cycle which add the operation cost.
- **Reinjection pipeline**. The reinjection pipeline from power plant to the water injection well can provide additional benefit by using composite pipe. There are 2 main benefits for this application.
    - The installation process of GRE pipe is easier even in the remote and mountainous area due to its density is only 25% of steel pipe density. This can lead to better loading and unloading on the site, faster process, and better safety risk.
    - Corrosive resistance of composite pipe against water can provide better operational cost (less maintenance and inspection) which lead to lesser frequency of shut down the well due to inspection, maintenance, and replacement process.
- **Cement stinger**. Geothermal well normally require high permeability to assure the heat flow and production of steam are promising. This condition is quite challenging with cementing process where imperfect cementation can cause collapse built-up which can damage the casing pipe and lead to pipe failure, even more in Indonesia which has high temperature up to 350ºC. Therefore, one of the solutions is to use quickset cement type that can easily harden once set-up. The challenge of quickset cement type is it can harden inside the pipe ID and can causes stuck on the pipe (normally drill pipe), this leads to problem to retrieve the pipe and fishing, even more it can lead to abandoning the pipe. Composite pipe

can be a solution for this application since the pipe can be used as sacrificial pipe that can reduce the rig running time when there is a pipe stuck inside the well. Whenever the quick-set cement hardens inside the pipe, composite pipe can be drilled-out (penetration rate up to 80ft/hour) and the well can continue for the next stage of operation.

4. CONCLUSION

The application of composite material in geothermal sector has several advantages due to its high corrosion resistance against water and brine water which can reduce the operational expense compared to conventional steel pipes due to its frequent maintenance and inspection. However, there are several limitations of glass fiber composite pipe in geothermal sector which is the high temperature. Up to today the application of glass fiber composite pipe can only reach up to 100ºC of operation temperature, which is very low for geothermal well for power generation which can reach up to 350ºC (highest record can reach 400ºC).

There are several other applications where composite pipe is suitable option such as:

- Direct use geothermal well which has operation temperature up to 100oC.
- Cement stinger for quickset cement type to reduce the risk of well abandon.
- Reinjection pipeline from sumpit or power plant to injection well.
- Cooling tower in geothermal plant which can provide better value due to its corrosive resistance and lightweight.

Based on the result of geothermal application in Champigny which shows high potential application, there is also some potential application of direct use of geothermal in Indonesia. There are several studies that shows its potential, but the main challenge is how to articulate the economics of scale from conventional energy source to geothermal source.

Keywords: metasediment, geothermal drilling, stuck pipe, fracture, cost, drilling

ABSTRACT

Drilling formation along with fracture network and metasedimentary rocks in accessing reservoir process is known as the one of the greatest challenging tasks in Sumatra geothermal drilling operations. The associated formation risks in drilling operations causes total loss of circulation, well control problems, hole instability, drilling dynamic issues and several stuck pipe incidents that lead to loss in hole BHA. With the understanding that the interaction between each element within the drilling operation system, including rock mechanics, drilling parameters and drilling fluid properties, can be known well by each work function. Unfortunately, in the process of achieving the goal and hitting the target there are still shortcomings in understanding the behavioral differences of penetrated formation.

Operations safely is a key factor in making the entire process safe, economical, and environmentally friendly. Indeed, the primary objective is to overcome these risks and necessary to ensure the borehole can be drilled safely and meet the Well objectives/target. The concern arises regarding the phenomenon that occurs is the difficulty in estimating drilling mud due to fluid's transmissibility is very unpredictable. Considerable non-productive time has been recorded due to hole cleaning issue and packing-off then causing stuck pipe event. In addition, partial to total loss circulation occurs when drilling reservoirs section adding the complexity of the problem. Realizing that continuing to drill development wells using conventional drilling practices in the same manner and expecting different results is not a solution. Hence, drilling development well in the same field will repeat the same problems to be occurred.

The objective of this study is eliminating stuck pipe events and enhancing drilling efficiency, particularly in wells where metasedimentary formations are present. By collecting data from offset wells to design and build qualitative parameters to ensure drilling operations run flawlessly. Design begins with selection process review of available information in the area based on the results of sonic logs, lithology, and subsurface modeling to get the best offset well candidate. The categories on which information is collected must have empirical correlation to fill in zones of missing and/or poor-quality result well. The emerged empirical correlation will be developed to obtain strategic needs. Every single element in the drilling function from trajectory, bottom hole assembly, drilling parameters, remedial work and escalation plans resulted in successful and safe drilling of metasedimentary formation moreover reduce drilling time and being ahead of plan in recent wells.

1. INTRODUCTION

In several areas of Sumatra where geothermal drilling operations take place, metasedimentary rocks are commonly encountered when drilling through the reservoir section. In general, metasedimentary rocks are metamorphic rocks that originate from the transformation of sedimentary rocks under conditions of high temperature and pressure deep in the earth's crust. They are characterized by features such as foliation, where mineral grains align in parallel layers. These rocks exhibit varying degrees of hardness, abrasiveness, and structural integrity depending on their specific type.

The identified characteristics of metasedimentary formations will notably impact drilling operations. Formation hardness and abrasive nature of metasedimentary rocks can lead to accelerated wear on drilling tools and equipment, increasing the risk of mechanical failure and operational downtime. Additionally, the presence of foliation planes in metasedimentary rocks creates planes of weakness where rocks can cleave or fracture easily, potentially causing instability in the wellbore and increasing the likelihood of stuck pipe incidents.

Stuck pipe incidents in metasedimentary formations often occur due to abrupt changes in rock hardness, encountering foliation planes, or inadequate drilling practices. To prevent and mitigate these challenges, thorough geological assessment and planning are essential before drilling commences. Employing appropriate drilling techniques and equipment, such as robust drilling fluids and wellbore stability analysis, helps manage the variable

conditions encountered in metasedimentary formations. Continuous monitoring of drilling parameters and real-time data analysis can aid in early detection of potential issues, allowing for prompt adjustments to drilling operations to prevent stuck pipe incidents. Furthermore, investing in advanced technologies and training programs that focus on geomechanically understanding and drilling optimization contributes to safer and more efficient drilling practices in metasedimentary environments.

2. PROBLEM AND CHALLENGE

Geothermal drilling presents unique challenges and risks. If not effectively managed, these risks can lead to high impact event, i.e stuck pipe, which prolongs the drilling process. This extended duration directly increases costs due to higher consumption of resources such as consumables, drilling mud, and bottom hole assembly. Additionally, encountering obstacles such as wells failing to reach target reservoir depths adds to these costs.

In figure 1 illustrates that high impact events and additional time during drilling account for around 50% of the total time spent in the process. Majority of these issues stem from unpredictable conditions within the drilling holes, resulting in significant time losses categorized as high impact event. The dynamic changes in drilling hole conditions especially in reservoir section with the exist of metasediment formation necessitate rapid decision-making. The metasediment formation in this field is the main factor causing stuck pipes incident. The efforts to free the pipe and conduct new drilling process(side track) take a very long time with an uncertain success rate. Therefore, accurate field data is crucial to support agile and informed decision-making throughout the drilling operation.

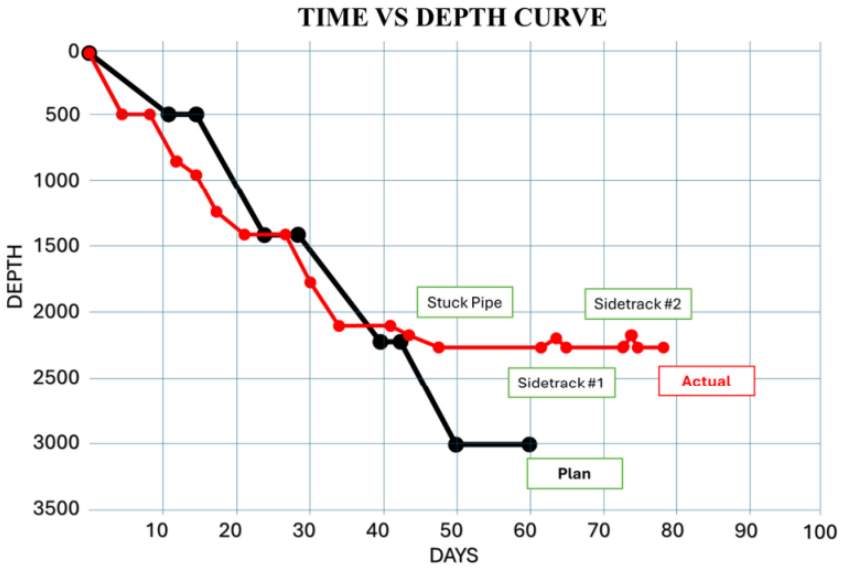

Figure 1: Time vs Depth Curve.

Knowing which processes consume the most time is crucial because inefficiencies can lead to significant additional costs. Stuck pipe and remedial action exacerbate these costs and contribute to company losses that must be addressed. Based on the background above, the main focus of this research is the need to improve the operational model due to the negative impacts caused by these challenges. The development of this model aims to minimize or eliminate the impact, thereby reducing its detrimental effects and enhancing the overall effectiveness of the drilling process.

2.1 Stuck pipe and Hole Problems

Drilling operations encounter numerous challenges due to highly dynamic conditions, resulting in increased effort, time, and implementation costs. For instance, the red curve in figure 1 illustrating actual time which shows no progress in depth increase over consecutive days, highlighting significant inefficiencies. Failing to reach the target depth underscores a clear discrepancy between the objective and actual performance.

Target implementation time or working days during drilling activities for the development of the Well based on the Program were completed within 60 days, however the actual implementation was 89.25 days. Meanwhile, the target depth achieved is shallower than the 3000m as per initial program, namely 2274m. The decision to complete drilling at a depth of 2274 m was due to the many drilling problems occurred. The main problem that caused the delay in drilling time for the subject well was the presence of a metasedimentary zone which prone to collapse and lead pack off at a depth of 2220 to 2274m which resulted in frequent stuck pipe event and require sidetrack drilling.

2.2 Prolonged Flat Time

Basically, the well construction involves two primary phases: on bottom drilling and flat time, where the depth of the hole remains unchanged. Activities during flat time include tripping, casing and liner installation, cementing, etc. These activities contribute significantly to the total time spent as clearly shown in figure 2 where the portion of time breakdown is dominated by flat time. Therefore, any problem during these activities can extend the overall well conditioning time or vice versa, problems during drilling will create additional sequence for flat time activities. Proper strategy at the planning stage, thorough preparation, and clear procedural instructions are essential to optimize flat time activities and reduce such potential delays.

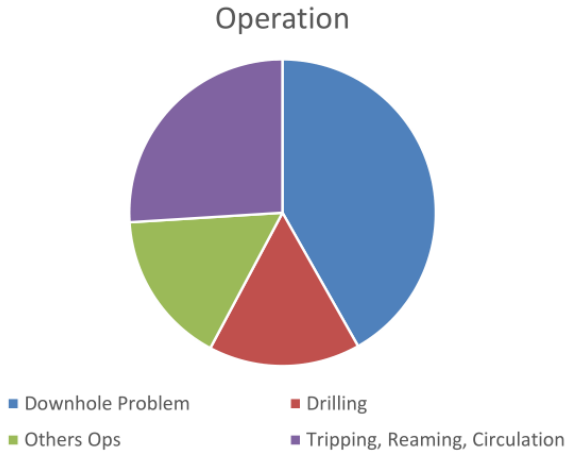

Figure 2: Operation Breakdown.

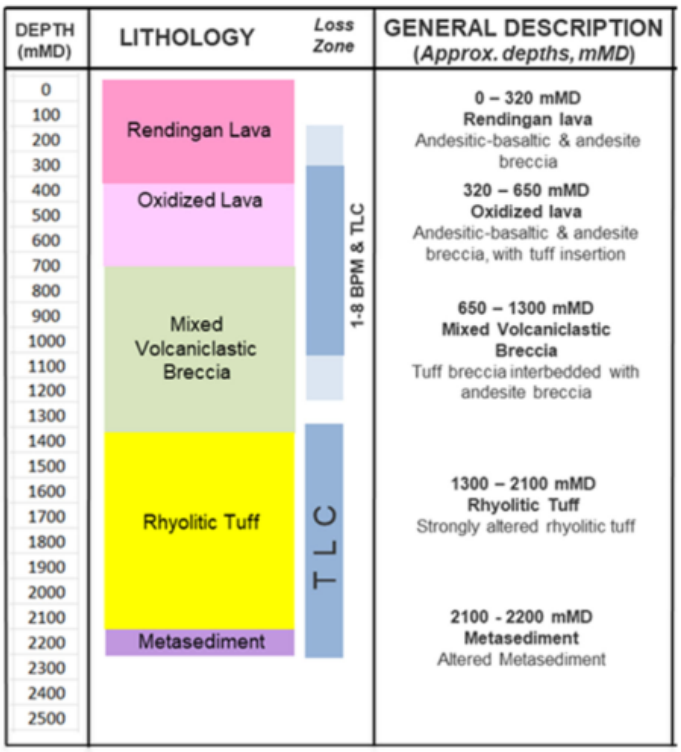

Figure 3: Formation Prognostic.

These operational hurdles severely impede the company's ability to achieve its goals efficiently. Figure 2 illustrates this with a significant percentage of work dedicated to unproductive activity, sidetracking and making a new path. This discrepancy underscores the need to explore the pack off phenomenon and devise strategies to address it. Thus, it is expected that inefficient activities which led remedial actions required to address issues is avoidable.

3. METHODOLOGY

Drilling for geothermal energy in Indonesia poses significant challenges, primarily due to widespread reservoirs with loss circulation during drilling. These fields are located in varied geological environments across the country, each posing distinct challenges for drilling activities. Stretching from North Sumatra to East Java, these geothermal fields can experience severe loss circulation, sometimes leading to complete losses.

3.1 Risk Identification

To successfully drilling and reach target through sedimentary rocks environments, specific strategy needs to be addressed in planning stage to overcome and reduce the severity of impact based on risk identification.

Registered risk include:

- Prognostic data: Identifying the concern depth of metasedimentary rocks presence during drilling and its respective hole section are derived from subsurface data as shown in Figure 3.
- Drilling Parameter: Utilizing offset well data to identify the implication of applied parameter within concern depth interval.
- BHA Configuration: Reassessing used BHA drilling that adding potential and/or limitation issue while penetrating the problem zone.

3.2 Planning and Simulation

The derived simulation from prognostic profiles and optimized using offset well data provides a detailed circulation ECD profile during drilling operations, as illustrated in Figure 4. The most accurate/precise simulation results play a critical role in assessing the feasibility of drilling strategies and equipment funding for successful geothermal drilling operations. By obtaining information related to ECD expectations obtained during the drilling process, drilling parameters can be monitored and adjusted during the next execution phase. The obtained ECD value will be used as a benchmark to be achieved during penetration of metasedimentary formations.

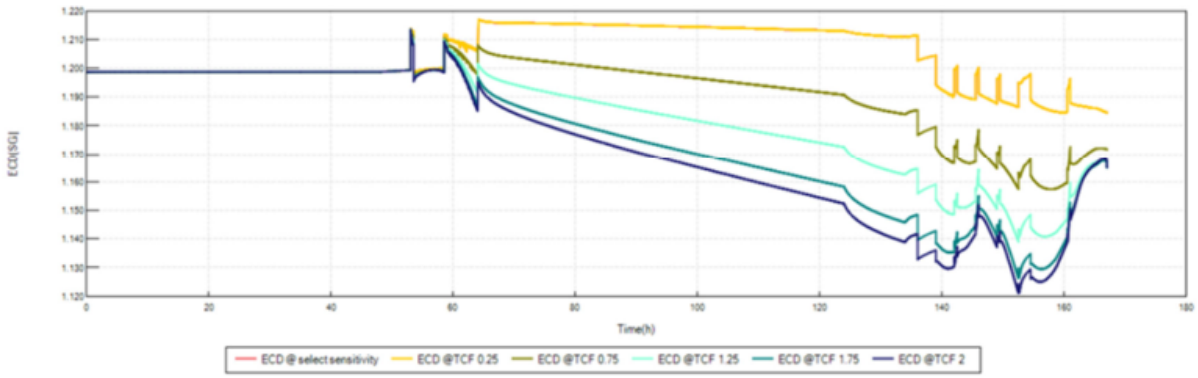

Figure 4: Prediction and Simulation ECD Profile.

By leveraging advanced modeling techniques, such as those integrating historical data from offset wells, drilling engineer and stakeholders can make better decisions that mitigate risks and optimize operational efficiency. Based on Thermal Calibration Factor(TCF) sensitivity, predicted ECD value will help executor during drilling.

Furthermore, these precise simulations not only enhance operational planning but also contribute to cost-effectiveness and project viability. This proactive approach not only instills confidence in stakeholder and executor of robust simulation methodologies remains essential for driving innovation and achieving sustainable success in geothermal drilling.

3.3 Drilling Strategies in through metasediment

Effective drilling strategies are essential when operating in metasedimentary reservoir sections. One approach is to use a combination of high-viscosity drilling mud and aerated fluids to increase the carrying cutting capability. The expected ECD value from simulation results becomes the basis of information/parameters to adjust drilling parameters by monitoring real-time ECD from the MWD tool. By having this practice, the fluid in the annulus able to maintain borehole integrity and prevent cuttings from falling/pack into BHA, thus drilling process going safely and smoothly to the intended target depth.

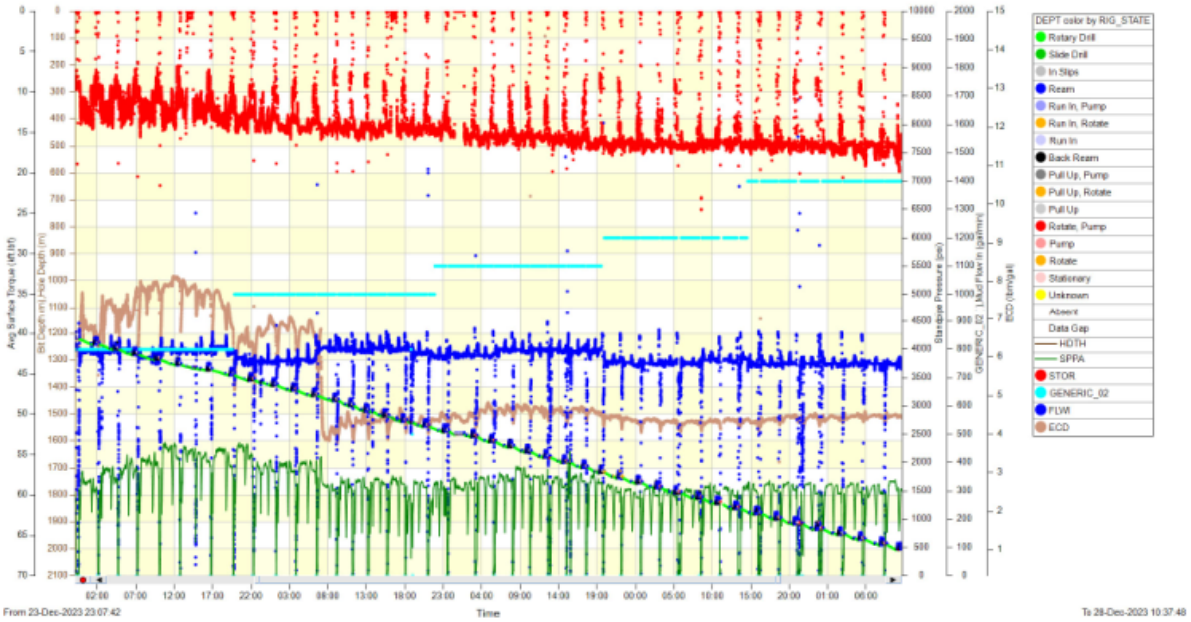

Figure 5: Drilling Parameter Monitoring.

Another strategy involves intermittent drilling, where the operation is paused periodically to allow the cutting away from BHA, thereby extending the operational flawlessly. Specific drilling practices must be implemented, which practices include:

- Circulation Management: Maintaining an optimal mud circulation rate to allow cutting move up to surface and going to fracture/loos zone.
- Monitoring: Continuous monitoring of surface and downhole measurements to anticipate and address potential problem before they occur.
- Adaptive Strategies: Implementing flexible drilling strategies that can be adjusted based on real-time data from the drilling operation as shown in Figure 5.

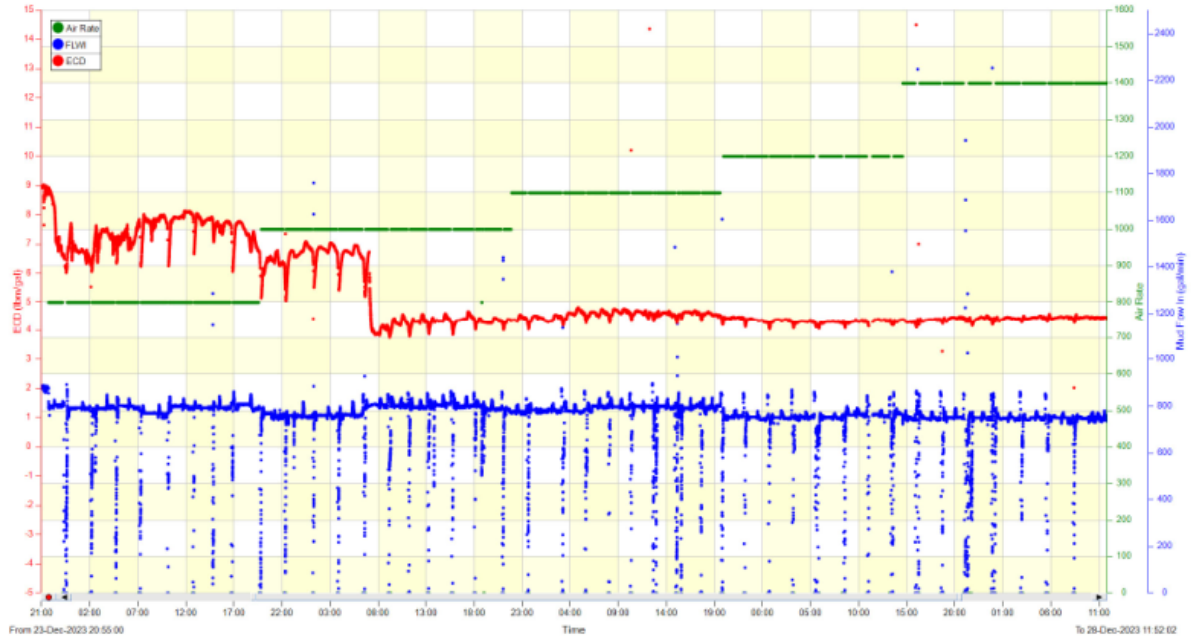

Figure 6: Managing Down Hole Pressure.

4. RESULT AND DISCUSSION

4.1 Actual Circulating ECD Profile

Field data shows that maintaining an optimal ECD profile is crucial for the success of geothermal drilling operations especially in penetrating sedimentary rocks as shown at Figure 6

By carefully managing the circulation rate, combination on pump rate of Mud and Air it is possible to keep the down hole pressure or ECD in the wellbore within a range that is safe for drilling operation. This practice helps in confirming the surface measurements and downhole condition which is annular around the BHA.

4.2 Supporting Operation

To ensure smooth and efficient drilling operations, it is essential to have clear contract requirements that support the use of downhole measurements to support drilling operation. These requirements should include provisions for:

- Downhole Annulus Pressure: Agreements on using and monitoring parameter based on downhole measurements as a surface reading confirmation.
- Operational Flexibility: Allowances for adaptive drilling strategies based on real-time data.
- Plan to action: Clear instruction and procedure from the stakeholder to the executor.

4.3 Operational Efficiency

- Eliminate Non-Productive Time (NPT): Stuck pipe event and side tracking can lead to significant non-productive time (NPT), where drilling operations are halted for remedial working. This not only increases operational costs but also delays project timelines. As an implementation result can be seen in Figure 7 where the actual progress much faster compare to the plan with 19days save time.

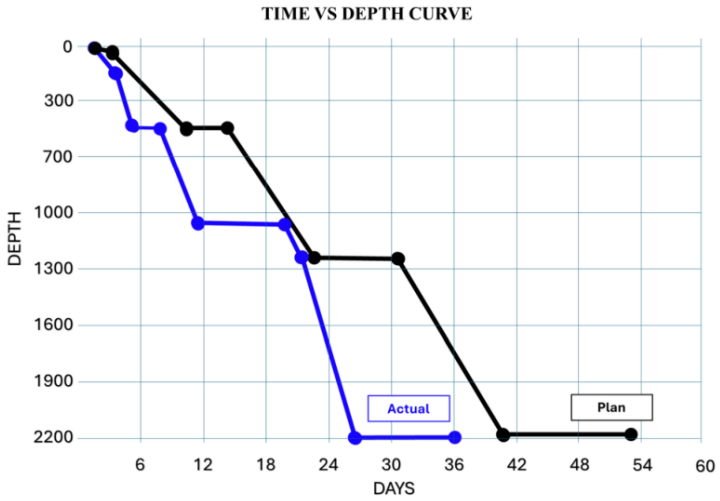

Figure 7: Operational Efficiency.

- Parameter Adjustment: Managing the metasedimentary drilling requires effective combination strategies, such as optimizing aerated mud circulation rates and using downhole pressure sensor. These measures are essential to maintain the integrity of the annulus so as not to complicate the drilling process and increase operational complexity.

5. CONCLUSION

Geothermal drilling in losses circulation with metasedimentary rock presents unique challenges that require innovative approaches and robust risk mitigation strategies. While complex drilling environment necessitate the exploration of alternative methods, using downhole measurements offer reliability with specific drilling practices provides a viable solution, enabling efficient and safe operations while controlling costs. By having engineered approach, integrated simulation, monitoring and implementing comprehensive risk mitigation strategies, it is possible to overcome the challenges of geothermal drilling through sedimentary rocks.

ABSTRACT

The very aggressive development of geothermal assets requires innovative solutions to overcome the complexity of the drilling process. As global interest in environmentally friendly energy increases, geothermal challenges need to be addressed. The unique challenges often faced in geothermal drilling are harsh environments, fractured formations, and highly dynamic operations. Short drill bit life, low penetration rates, and equipment failure are common problems, coupled with reduced drilling fluid properties and difficulty in managing mud systems.

Understanding and mitigating these technical challenges is critical to minimizing risk and increasing economic viability. Experience and knowledge from the oil and gas industry is invaluable in dealing with drilling challenges. While some strategies may prove effective, others lead to inflated costs. Adapting drilling methodologies and systems to the unique geothermal environment is critical to optimizing drilling projects and controlling costs. especially demanding drilling conditions require great effort, energy and strategic thinking.

This paper highlights the value of unified well construction for managing and consulting in improving drilling performance and reducing costs. During a three-year Geothermal Project in West Java, Indonesia, 70-75% reduction in well costs per meter resulted in millions of dollars in savings through knowledge management and accelerated learning.

1. INTRODUCTION

There has been a steep increased in drilling activity happening over the past years in search of geothermal energy. As the search for new and continues friendly environmental energy, of course operators will increasingly move towards drilling with more challenging well trajectories toachieve their objectives and led operators to a more complex drilling environment. Drilling in unique environments and complex well designs will need a huge concern from technical, environmental and economic risks. Historically speaking, too much time was spent to deal with stuck pipes event before results in lost in holes (LIH). To pursue efficient and effective geothermal drilling operations, new approaches need to be introduced to this industrial climate.

Dealing with challenging environments requires integration on every single element to fulfill its objectives. The idea is to improve process by having all service requirement, increase response time to potential problems before they occur and finally cost reduction. The collaboration come up with the main goal to improve service quality. By providing a real-time data and support for 24/7 connection as a part of unified solution process made huge improvement on service quality. This must be achieved by defining operational workflows that utilize integration data and information to bring improvement in place on each phase: plans, execution, evaluation stages. Discussion of the operational framework and background and the role of technology to support operational performance will be described in this paper.

2. PROBLEM AND CHALLENGE

The risk of geothermal drilling will turn into a problem and become non-productive time (NPT) if it is not prevented and mitigated properly. Increasing the drilling process will directly increase drilling cost.

As can be seen in Figure 1 Drilling Time Distribution, unplanned events and Non-Productive Time (NPT) reaches 45.3% of the total time. The uncertainty in geothermal drilling makes the decision-making process very dynamic. Making fast and precise decisions in this dynamic process certainly requires support in the form of good information from the field. Analyzing on time allocation during drilling process, providing a breakdown to highlight durations for activities such as drilling, tripping, casing, cementing, logging, and others. Understanding these time distributions is crucial because inefficiencies can lead to significant cost escalations. Issues such as low Rate of Penetration (ROP), stuck pipe incidents, loss circulation, and flat time exacerbate these challenges, contributing to financial losses for the company.

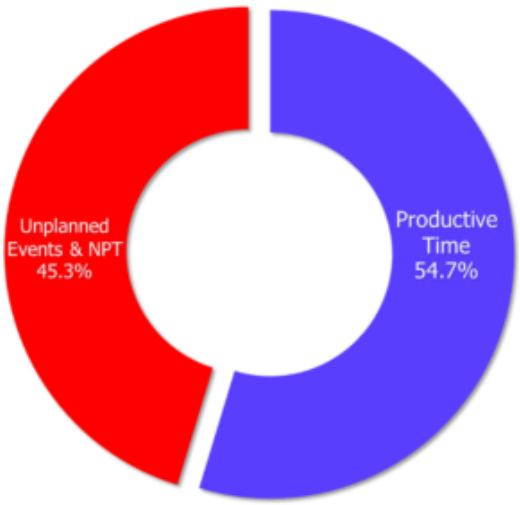

Figure 1: Drilling Time Distribution on Previous Campaign.

Given this context, the primary focus of this research is to enhance the operational model. This model aims to swiftly mitigate Non-Productive Time (NPT), thereby reducing its adverse effects and enhancing overall drilling efficiency. The research will delve into several key areas to address fundamental issues.

2.1 Hard and Abrasive Formation

The hardness and abrasiveness of geothermal formations significantly influence various aspects of drilling operations. Issues such as slow Rate of Penetration (ROP) and equipment damage are common due to the characteristics of rocks in geothermal environments. These factors not only slow down drilling progress but also escalate costs. Equipment damage can necessitate replacements and being more complicated when stuck pipe happen. Increasing the need for costly remedial measures in terms of time, money, and energy.

Figure 2: Drilling Bit Condition, Left: Pre-Run and Right: Post-Run.

Figure 2 illustrates the real contrast in drilling bit condition before and after use, highlighting the frequent occurrence of tool failures that reduce ROP and require operational consideration or replace Bottom Hole Assembly (BHA) components. Despising many mitigation efforts, attempting optimal results is still difficult to achieve. Overcoming these ongoing challenges is especially in geothermal drilling environment. Therefore, a comprehensive evaluation is essential, combining mathematical modeling through simulation results and empirical research based on historical data.

2.2 Stuck pipe and Hole Problems

The challenges encountered in each drilling operation poses significant barriers to the company's effective goal attainment. Figure 3, the Previous Campaign Drilling Curve, vividly illustrates the diverse patterns in drilling performance, encompassing variations in slopes and final depth outcomes. Discrepancies in slowdowns and unmet depth targets across different wells underscore the array of issues encountered during drilling, resulting in inconsistent overall performance.

As previously elucidated, the significant prevalence of problems arising from uncertain drilling conditions results in extensive time consumption and Non-Productive Time (NPT) during the drilling process, classified as unplanned. For instance, the yellow curve representing Well-E displays the most pronounced and deepest curve among all wells, indicating a notable deviation from the performance of other wells. None of the wells achieved the slope and depth reached by Well-E, highlighting a misalignment between the objective function and actual accomplishments.

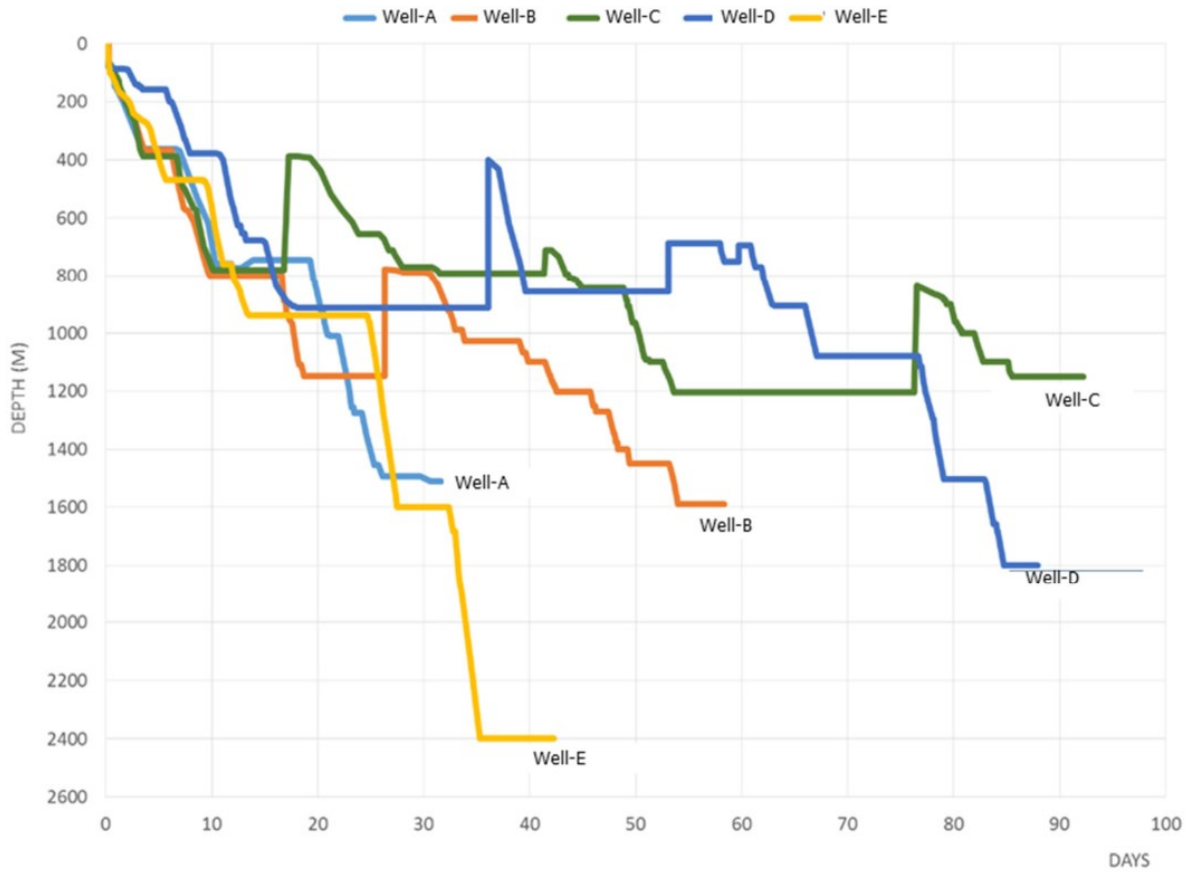

Figure 3: Previous Campaign Drilling Curve.

This discrepancy underscores the need to explore the factors contributing to this phenomenon and devise strategies to address it, a topic which will be elaborated upon in the subsequent chapter utilizing the previously outlined methodology.

2.3 Drilling in Total Lost Circulation

A critical risk associated with geothermal drilling is lost circulation. This often results in significant losses of mud, making it exceptionally challenging to remedy the situation using lost circulation materials or even cement plug job. The formation characteristics consist of fracture propagation which is subsequent to lost circulation. This challenge is further compounded maintaining wellbore stability in formations with micro-network fractures poses considerable challenges during drilling. The penetration of drilling fluid into these fractures fails to equilibrate the pore pressure with the mud pressure, leading the fluid level to drop and fail mud pressure support from overbalance. Therefore, cuttings-induced pack-off over the Bottom Hole Assembly (BHA) can be happen during making up new connection due to insufficient annular pressure. This scenario has been observed repeatedly when drilling fluid fails to suspend cuttings, ultimately culminating in a stuck pipe event.

2.4 Prolonged Flat Time

Essentially, well construction encompasses two main phases which are drilling (on bottom) and flat time, where no advancement occurs in hole depth. As previously mentioned, flat time activities encompass various operations such as pipe tripping, casing and liner installations, cementing, BOP and wellhead handling, pressure testing, and completions-significantly contributing to the overall time allocation. This downtime, often resulting from challenges outside the drilling operation, heightens risks such as failure during casing/liner installation and completion.

Another critical aspect of well construction, characterized by substantial the “unseen" loss time, occurs during flat times. As evidenced in the preceding discussion, particularly in Figure 3 Drilling Curve, several wells exhibit prolonged flat times, depicted by a horizontal line indicating no depth increase over time. Consequently, any issues arising during these activities can prolong the average time required to condition the well. Rig performance, meticulous planning, comprehensive preparation, and clarity in low-level instructions are paramount in optimizing flat time activities. Therefore, this paper will elucidate strategies for reducing flat time to enhance performance and minimize costs.

3. SOLUTION

Star Energy Geothermal has implemented a comprehensive strategy following extensive consultations with technical experts from its service providers to optimize resources across systems, technology, and workforce. The primary objective is to tackle drilling challenges, address issues with loss circulation and implement best practices to ensure geothermal drilling process are safe, efficient, and cost-effective. Consequently, these solutions enable expedited drilling operations without constraints, effectively resolving existing issues.

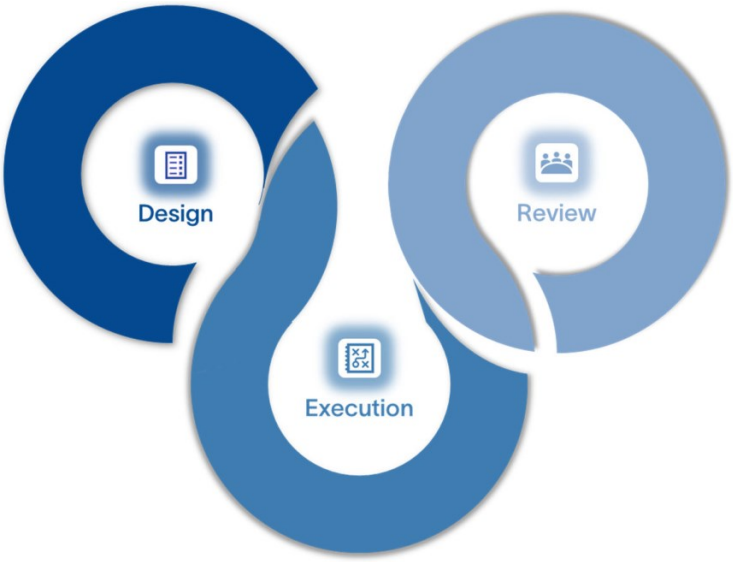

Figure 4: Improvement Cycle.

The improvement initiatives encompass three fundamental phases: design, execution, and review, detailed in Figure 4. Each phase yields substantial information and data crucial for developing strategies and bridging operational gaps. In the design stage, the process begins with establishing a Risk Register to proactively identify potential issues. Subsequently, potential problem scenarios are modeled for the subject well using data from offset and similar wells in term of geological prognosis, accompanied by comprehensive solutions and lessons learned. Further analysis will refine initial best practices to uncover opportunities for enhancement and improvement.

Once the strategy and program are finalized in the design stage, real-time monitoring of all operations ensures adherence to the plan and enables immediate support for swift resolution of any deviations caused by unforeseen challenges. Specifically, the proposed solutions for mitigating loss circulation, hole instability issues led to stuck pipe and optimizing drilling processes empower operators to minimize risks, enhance performance, and achieve safer operation.

4. MANAGING THE CHALLENGES

Significant advancement in drilling operations, showcasing the successful implementation of proven technological solutions and integration services resulting from enhanced cognitive capabilities within the improvement cycle.

The achievement is underpinned by five core pillars: Key Performance Indicators (KPIs), Historical Performance analysis, Performance Improvement plans, Implementation Strategy, and Performance Lookback as shown in Figure5. This discussion will elucidate how optimizing each of these critical components has contributed to this remarkable progress.

Figure 5: Managing the Challenges.

Table 1: Drilling Well Objectives.

Objectives	Information
Value Based Well Objective (VBWO)	Maintain well control at all times.
	Meet or exceed P50 initial expected steam rate at commercial wellhead pressure
	Meet or exceed project economic of positive NPV
	Complete well hook-up one month after flow test and put the well on-line right after well hook-up commissioning.
	Complete the well within AFE days and budget.
	Characterize the well as per plan i.e. completion test, flow test, geological data
	Flow test within five days on availability of SIMOPS permission otherwise after rig move
Health, Safety, & Environment (HSE)	No LTI'S (lost time injuries).
	No environmental incidents, spills and minimum environment impact.
	No major or catastrophic service quality incident.
	Incident and injury free operation (IIFO) .

4.1 Key Performance Index

To enhance overall asset investment efficiency, the focus is on assessing and drilling complex wells aimed at boosting well productivity. This involves strategically selecting existing locations or those with minimal footprint, optimizing resource usage and concerning environmental impact. Collaboration among function plays a crucial role in enhancing collective capabilities, aimed at achieving more economical drilling costs for future geothermal operations. By pooling resources and expertise, operators can leverage shared knowledge and technologies to streamline processes and reduce operational expenses.

Efforts to enhance drilling efficiency and minimize environmental impacts are central to this collaborative approach. As depicted in Table 1, Key Performance Index are translated into specific objectives for each well drilling activity. Through collaborative initiatives, operators can explore innovative drilling techniques and technologies that enhance operational efficiency while prioritizing sustainability. This collective endeavor not only facilitates cost-effective development of geothermal resources but also promotes responsible management of natural resources. By aligning strategies and leveraging collaborative advantages, operators can pave the way for sustainable growth in geothermal energy production, simultaneously driving economic benefits and environmental sustainability.

4.2 Historical Performance and Performance Lookback

In the domain of drilling operations, data derived from offset wells plays a pivotal role as a foundational reference throughout the stages of design and implementation. This dataset offers critical insights into a spectrum of parameters that exert influence over drilling conditions. These insights are instrumental in preemptively identifying potential challenges, such as risks of circulation loss or drilling breaks, which can significantly impact operational efficiency and safety. Moreover, the data aids in strategizing effective responses to unforeseen issues that may arise during operations, such as managing cuttings during pipe landing and casing operations, and addressing downtime for repairs, such as the installation of Blowout Preventer (BOP) connections and reaming activities.

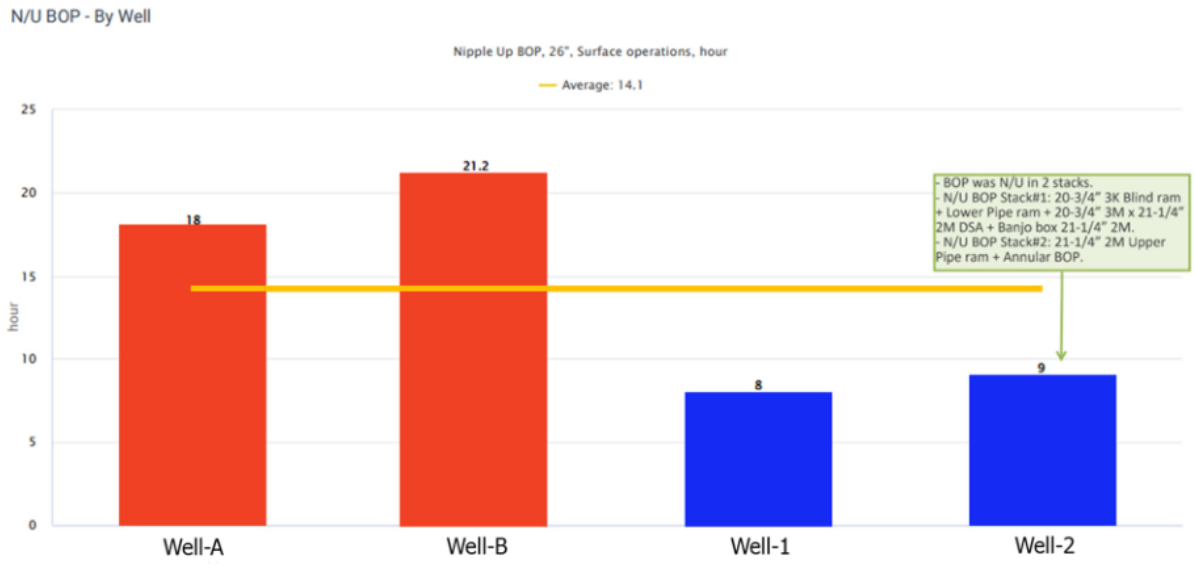

Figure 6: Improvement of N/U BOP.

Leveraging offset well data allows drilling engineers can proactively anticipate complications and develop solutions that mitigate risks while optimizing operational outcomes, as illustrated in Figure 6 which highlights improvements in process efficiency. Through effective utilization of historical data, engineers enhance decision-making processes, streamline operations, and uphold rigorous safety protocols. This proactive approach ensures that drilling activities proceed smoothly, minimizing disruptions and maximizing productivity. Ultimately, integrating comprehensive data analysis from offset wells plays a crucial role in achieving operational excellence and resilience in the dynamic field of drilling operations.

4.3 Performance Improvement Plan and Implementation

Following the thorough completing comprehensive identification and measurement processes outlined earlier, the collaborative teams engineering and drilling operations initiate strategic interventions using precise principles and methodologies. These actions are aimed at effectively addressing inefficiencies and unlocking opportunities for enhancing performance. In response to identified operational shortcomings and instances of downtime, comprehensive strategies have been meticulously formulated to bolster drilling performance across all operational

domains. These initiatives encompass a comprehensive approach that integrates process improvement, technology integration, and procedure optimization. This holistic strategy aims to maximize operational efficiency and minimize disruption, addressing both immediate and intermediate time frames.

4.3.1 Immediate Within 6 Month

In the realm of drilling operations, the data from offset wells serves as invaluable reference throughout both the design and execution stages. These datasets provide crucial insights into various parameters that influence drilling conditions. By analyzing how these parameters behaved in past operations, engineers gain a clearer understanding of expected outcomes and potential challenges. This historical data is particularly critical during the monitoring phase, where real-time data is consistently benchmarked against established standards from offset wells. This comparison enables Real-time Decision Center (RTDC) engineers to promptly identify and evaluate any deviations or anomalies occurring at depth, as depicted in Figure 7 which illustrates deviations in well trajectory. Through continuous comparison and real-time monitoring, early detection of deviations allows for swift decision-making regarding necessary solutions. These insights facilitate proactive adjustments, ensuring operational continuity and minimizing risks associated with unforeseen drilling conditions.

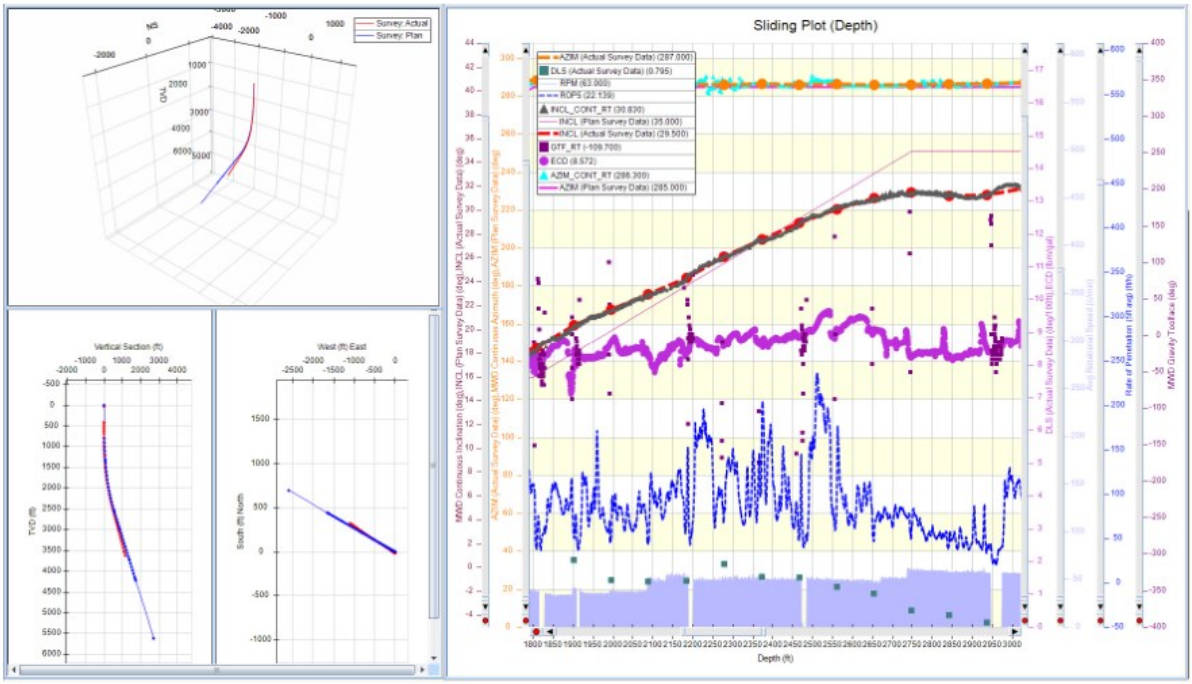

Figure 7: Real-Time Trajectory Monitoring.

This visual representation not only facilitates rapid identification of anomalies but also enhances the precision of decision-making processes. Engineers can promptly correlate observed data trends with known benchmarks, swiftly diagnosing any discrepancies and taking appropriate corrective measures. This proactive approach not only enhances operational efficiency but also reduces potential downtime and optimizes resource utilization. The monitoring plot derived from real-time data as shown in Figure 7 provides a clear visualization of trajectory adjustments and their feasibility. Assessing the likelihood of achieving desired trajectories and identifying potential challenges could expedite decision-making throughout drilling operations. Leveraging insights from offset well data empowers engineers to effectively navigate complexities and uphold stringent standards of safety, efficiency, and performance in geothermal operations. This integrated approach ensures that operational objectives are met with precision while minimizing risks and maximizing operational success.

4.3.2 Intermediate 1 – 2 Years

The improvement strategies developed are meticulously introduced to stakeholders and higher-level management, ensuring they are aligned with organizational objectives and project goals. This involves comprehensive communication and detailed presentations that methodically outline the potential impact and benefits strategies. This collaborative effort aims to cultivate a shared understanding and commitment among all stakeholders, setting the stage for seamless execution by the project implementation team. Translating these strategies into actionable steps, the teams are well-positioned to implement effective solutions that not only address current inefficiencies but also establish a pathway towards sustained operational excellence in drilling operations.

Intermediate improvement plan makes decision makers and the teams deal with hard system changes, fundamental changes, not only changing on the form of procedures or strategies. The improvement plan on the basic elements requires costs and a long process so that it is targeted with a time span of 1-2 years of improvement. Therefore, when considering well design, several critical factors are taken into account to optimize performance and mitigate risks. Anticipating subsurface hazards is crucial, as it involves thorough geological and geophysical assessments to identify potential challenges such as underbalance formation pressures, loss circulation, or hard and abrasive formations that impact to service quality as shown in Figure 8. Dropping tendency is shown in Figure 8 as the result of stabilizer worn out that led to near miss accident by missing the target.

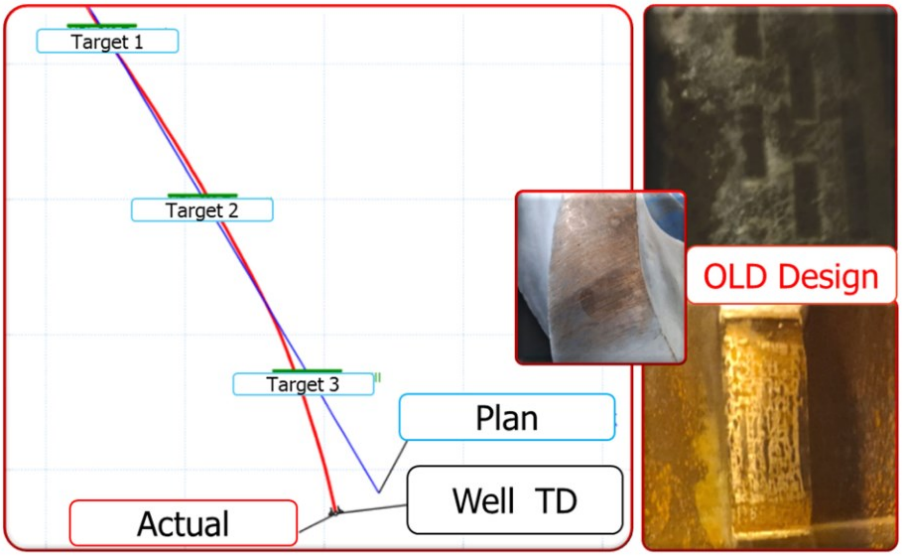

Figure 8: Equipment Deformation and Consequence.

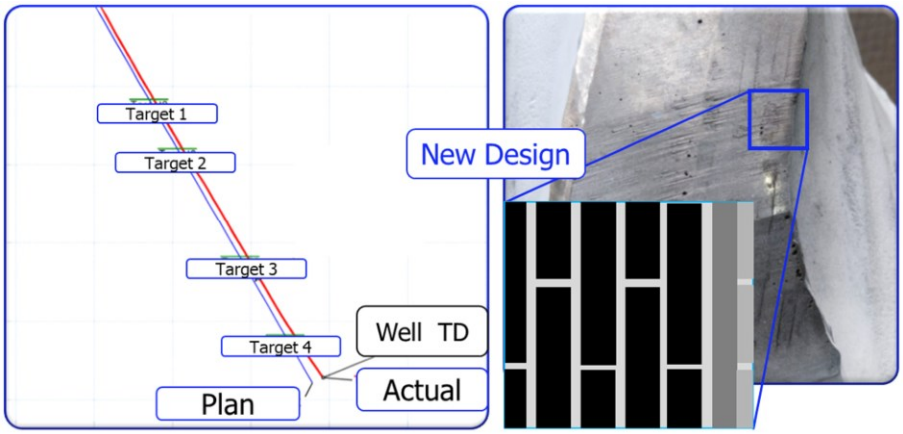

Figure 9: Quality Assurance through Innovative Design.

Improvement has been addressed with careful consideration is given to depth, formation hardness, and well trajectory requirements to ensure service quality guarantee. Increasing drilling efficiency involves adapting equipment protection designs for abrasive formations and implementing advanced drilling techniques, which contribute to increasing penetration rates and guaranteeing the quality of services provided as shown in Figure 9. Additionally, selecting appropriate drilling equipment protection plays a vital role in preventing drilling problems, ensuring robust equipment no drop tendency is shown and all targets are hit without any exception in term of efficient drilling operations.

In conclusion, integrating these advanced strategies and technologies into drilling operations not only improves immediate efficiency but also lays the groundwork for long-term success. By focusing on meticulous planning, stakeholder alignment, and leveraging cutting-edge technologies, drilling teams can navigate challenges effectively, achieve operational excellence, and uphold high standards of safety and performance in geothermal and other drilling operations.

5. RESULT

Building up a strong organizational capability is crucial for achieving continuous improvement in drilling operations. This entails leveraging advanced technologies such as real-time monitoring systems and enhancing cognitive skills. Efforts are also focused on enhancing overall asset investment efficiency through the assessment and drilling of complex wells aimed at increasing productivity.

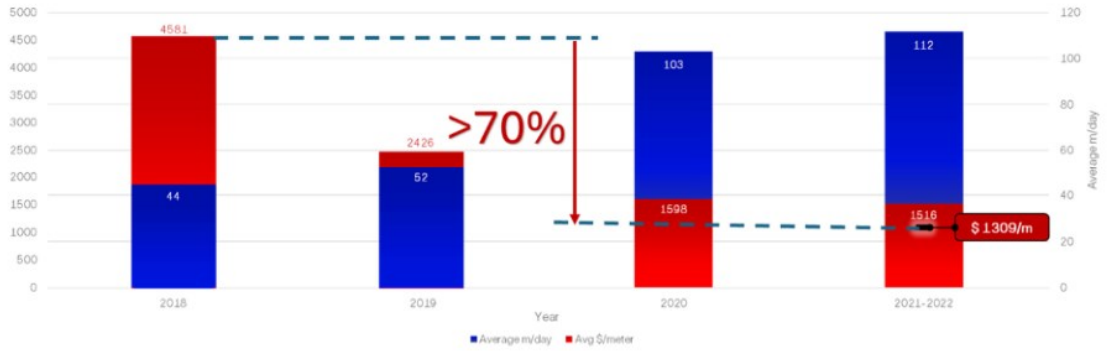

Figure 10: Reduction in Well Cost per Meter.

These initiatives embody a holistic approach to optimizing operational efficiency, reducing expenses, and ensuring long-term sustainability in geothermal drilling practices. This is exemplified by the fastest and most cost-effective drilling of geothermal wells in Indonesia over the past five years, as depicted in Figure 10. The learning curve and improvements achieved in this campaign are clearly shown, with drilling costs per meter decreasing by 70-75% and drilling speed increasing. Collaborative efforts among operators further enhance capabilities, aiming to achieve more cost-effective drilling operations in future geothermal developments.

ACKNOWLEDGEMENT

This successful implementation of systems, technology, and integration by Star Energy Geothermal demonstrates that Integrated Well Construction is a viable solution for the entire geothermal industry. The author extends sincere gratitude to Star Energy Geothermal for their invaluable support of this research. We are grateful for their permission to publish this paper and commend their dedication to advancing sustainable geothermal drilling. Special thanks are also due to the field and office personnel, including SEG and SLB crews, wellsite supervisors, and workshop personnel, whose contributions were instrumental in achieving this success.

ABSTRACT

The technology, widely used in tension leg platform (TLP) applications for oil and gas wells, holds immense potential if adopted in deep geothermal wells. Its implementation could lead to significant reductions in well construction costs, bolster long-term well integrity, and enhance the life-long thermal performance of the wells, thereby painting a promising financial picture. The paper introduces a technology that has already demonstrated its global reach and long-term reliability in its current application (Wybro and Chaison, 1995). However, its use in geothermal wells could revolutionise standard well design methodologies and cost assumptions, sparking further research and development in the industry.

Traditionally, geothermal well construction requires that the casing strings be cemented back to the surface to manage the axial compressive loads on the casing body and casing couplings caused by thermal expansion, which would otherwise lead to premature loss of well integrity (Arbad et al., 2022; Finger and Blankenship, 2010; Teodoriu and Falcone, 2009). With the repurposing of the existing technology, the requirement for the entire annulus to be cemented will be removed, as the unique design allows casing expansion to be accommodated without increasing the axial compressive load. Removing the requirement to cement the annulus to the surface presents considerable technical and financial opportunities over the entire well life cycle. In geothermal well construction, managing the axial compressive loads at the surface considerably reduces the casing costs, as the traditional primary approach to managing collapse, in addition to a fully cemented annulus, is to increase the tubular wall thickness. This approach is especially costly in reservoir-dependent (hydrothermal) wells as the aggressive corrosive environments created by the production of geothermal brines often require high-cost corrosion-resistant tubulars (Belayneh and Tantuoyir, 2021). The maintenance of the casing-to-casing annulus allows the potential for lifelong, continuous automated surveillance of the integrity of the primary production conduit, which is not currently possible with traditional geothermal well construction methodologies.

The instigation of continuous well integrity surveillance, made possible by the proposed approach, offers the opportunity to reduce monitoring and maintenance intervals, and it is likely that the need to schedule periodic well shut down to allow wall thickness checks will be reduced as the annulus can be under continual surveillance and action taken at first appearance of a leak path (NORSOK, 2013). The proposed approach allows a reduced cementing requirement, lowers cementing costs, and minimises exposure to cementing risks, as only a minimal conventional annulus cement job will be sufficient to manage well integrity. Removing the need to cement the entire length of the casing allows consideration of using externally insulated casings and sleeves on the uncemented section of the production casing. This lower loss of heat to shallower, thermally parasitic formations will allow production wellhead temperatures to be higher, with a consequent lifelong improvement in the well's thermal performance.(Adams, 1991; Belayneh and Tantuoyir, 2021) From an Environmental Social Governmance (ESG) standpoint, a conventional 'cut and pull' abandonment approach at the end of the wells' life. For lifetime carbon footprint assessment (Energy Sector Management Assistance Program (ESMAP), 2012), this method allows the recovered steel from the abandoned well to offset the well's energy footprint, thereby reducing the lifetime carbon impact of the well construction process. Reducing the carbon footprint of a geothermal well further improves the technology's contribution to improving the geothermal project's net sustainability and environmental benefits.

1. INTRODUCTION

In higher enthalpy geothermal wells, the most, widely adopted methodology for managing the compressive casing loads caused by the thermal expansion of the casing string is conventionally placed annular cementing (Sanyal and Urmeneta, 2005; Mulders, 2006), filling the entire annulus back to the surface. This approach is often combined with selecting casings with higher wall thicknesses.

Cementing the annulus back to the surface is not without difficulties (Teodoriu et al., 2022). Managing cement slurry losses and ensuring high-quality, void- and leak-path-free cement placement can be challenging in some geological environments, especially those that are highly fractured or have high bulk permeabilities Typical of reservoir-dependent (hydrothermal) geothermal wells.

Figure 1: Original application as a Tendon Top Connector Assembly.

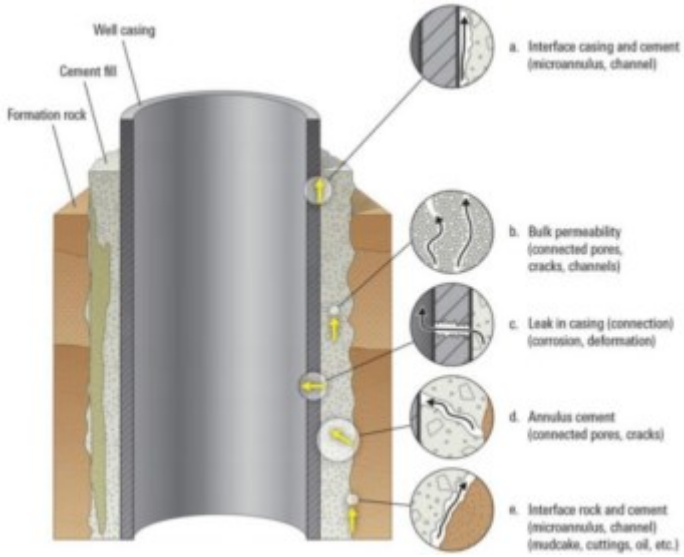

Figure 2: Poorly executed cementing operations can lead to Potential Leak paths, including channelling, micro annuli, and poor mud cake removal. (https://www.slb.com/-/media/files/well-intervention/industry-article/201705-os-bdt-promill-north-sea).

In such geological conditions, cementing will likely not be completed successfully (Figure 2) without the need for some form of tertiary loss control measures, which leads to more complex cementing operations, more expensive slurry designs, and higher material consumption.

The need for highly specialised metallurgies for tubular goods, such as Corrosion-Resistant Alloys (CRA) required as large-diameter high-weight casing rather than the lighter small-diameter production tubing used for oil and gas wells, adds to the project's financial, organisational, and logistical burden.

The long lead times and high cost of the specialised alloys required to assure well integrity by minimising corrosion effects over the long-anticipated operational life of geothermal wells must be considered in the early stages of project planning. These high well-construction costs can often inhibit project feasibility. Cementing the annulus to the surface also sacrifices the ability to add annulus surveillance capability to the well and prevents the well operator from immediately identifying a production leak. Within wells with a fully cemented annulus, casing

leaks of geothermal brines can go unnoticed for long periods of time, risking contaminating shallow aquifers. This problem has affected many early pioneering geothermal projects.

In order to minimise the risk of developing corrosion and leak paths, the traditional approach uses monitoring tools such as multi-finger calliper (MFC) and ultrasonic (USIT) logging to determine the residual casing wall thickness over the length of the casing string. Deploying these highly specialised logging tools is also associated with additional costs, not just for the tools themselves but with the shutdown of production flow whilst the well is prepared for logging.

A high-quality cement-to-formation bond, without any void spaces or potential fluid pathways, is critical for axial load management and avoiding collapse risk due to trapped fluid expansion. In deep geothermal wells, this also causes a higher heat loss to the formation in the shallow sections of the well due to their lower temperature and, hence, can be regarded as a loss of production. (figure 3)

In a geothermal well cemented to the surface, the operator has limited options for running insulated coatings on the production casing. This limitation has a considerable lifetime impact on the economic return of the entire project.

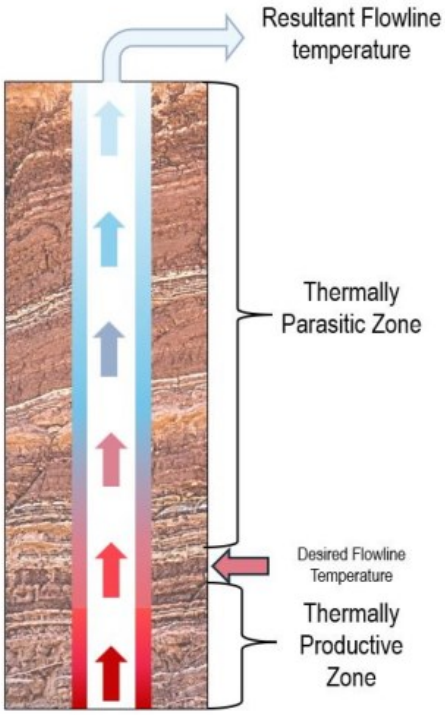

Figure 3: Thermally Productive and Thermally Parasitic zones in a geothermal well (Black Reiver Thermal Modeling Service).

Another consideration of the fully cemented annulus is that if there is a need for well recompletion, side-tracking (or abandonment), a simple "cut-and-pull" approach to recover the casing string is no longer an option. In some cases, this can render the well unrecoverable, resulting in the need to redrill the entire well or section.

The high heat transfer coefficient of the cement in the 'overburden', thermally parasitic well section leads to considerable heat losses to the surrounding rocks. (Asadia et al., 2018) The heating of shallower formations over the operational life of the well creates the potential for changing the stress regime acting around the wellbore. Thermally-induced geo-mechanical changes to the formation around the wellbore may cause numerous issues with wellbore integrity and stability, from simple loss of the cement to formation bond up to the casing collapsing. These effects will become more significant as the industry pushes towards higher enthalpy wells.

In addition to the geomechanical effects of shallow formation warming, changing the temperature of the shallow well sections and potentially transferring the heat to the aquifers is considered 'an act of pollution' in some regulatory jurisdictions. (Blum et al., 2021) It may be associated with significant financial sanctions for projects adversely impacting aquifer temperatures.

2. AN ALTERNATIVE METHOD

Geo-LOK Technology might be considered an innovative approach to tubing/casing hanger systems for deep geothermal wells. However, the technology is not new for the drilling industry in general, as it has been successfully used for many years for tendon tensioning in floating tension leg offshore platforms (TLPs). Geo-LOK technology represents a potentially significant advancement in tubing and casing hanger systems, particularly in deep, high-enthalpy geothermal wells. This section explores the mechanics and benefits of the Geo-LOK system, comparing it with conventional methods and highlighting its impact on well integrity and performance.

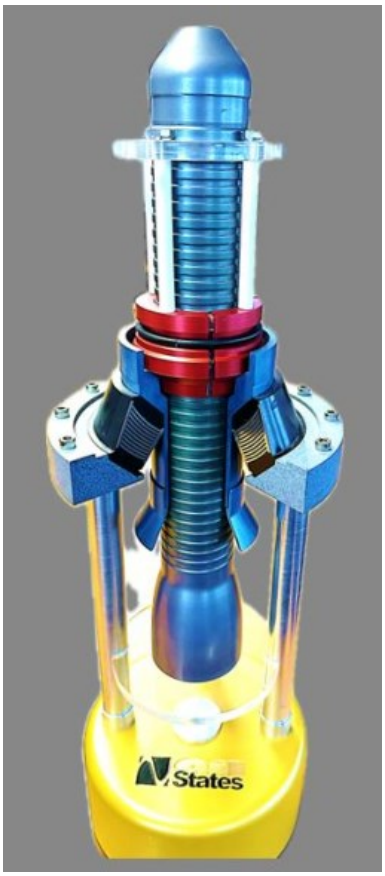

Figure 4: Simplified model of Geo-LOK operating principles (Image credit Black Reiver Consulting).

3. DESIGN AND FUNCTIONALITY OF GEO-LOK

Geo-LOK is an adaptive tubing/casing hanger system specifically engineered to accommodate the string's axial expansion without imposing an additional compressive load on the casing and its connections. Its design allows for the axial extension of the tubular string during the heating phase of geothermal operations. In contrast to conventional methods (Bellarby, 2009), which often struggle to cope with the increased compressive load on the string, Geo-LOK provides for a controlled axial movement.

4. MECHANISM OF ACTION

Geo-LOK (figure 4) supports the tubular string expansion in increments, effectively adapting to the axial growth of the tubular string. This incremental support ensures the string remains stable and well-supported throughout the heating and cooling cycles. When a geothermal well using a Geo-LOK hanger is cooled and the tubular string contracts, Geo-LOK facilitates a controlled mechanical release of the increased tension, preventing over-tensioning of the tubular string and its connections. This ability to control the axial stress in the production string allows for maintaining structural integrity without annular cementing to the surface and without requiring increased wall thickness tubulars.

5. ADDRESSING AXIAL STRESS CHALLENGES

For deep geothermal wells, excessive compression due to string expansion during the production phase and excessive tension during the cooling phase present significant challenges for casing design.

These cyclic thermal-induced stresses are a common source of failure of casing strings in existing geothermal wells. Traditional mitigation techniques, such as cementing the annulus to the surface and choosing tubulars with thicker walls, often fail to fully address these issues in a technically feasible or financially acceptable manner. This failure often leads to compromised well integrity and/or reduced operational efficiency being imposed on the well at the design stage.

6. ADVANTAGES OF GEO-LOK TECHNOLOGY

While effective in some applications, traditional cementing of the annulus to the surface often fails to address the unique challenges posed by the extreme temperature variations typical in higher enthalpy, deep geothermal wells. With its adaptive and supportive design, Geo-LOK technology offers a superior, better-value alternative that also permits a considerable improvement in the thermal performance over the life of the well.

Among the potential advantages of Geo-LOK application in deep geothermal wells, the authors can list the following:

6.1 Axial Stress Management

Geo-LOK minimises the risk of excessive compressive and tensile stresses being placed on the production conduit by varying operational conditions in the well. Allowing controlled axial growth and contraction avoids these stress variations, removing the potential for damage to the casing and its connections and reducing the potential for failure of the casing to cement bond.

6.2 Enhanced Well Integrity With Lower Costs

Geo-LOK technology enhances the overall integrity and longevity of geothermal wells primarily by mitigating the effects of thermal-induced stresses on the casing string and the annular cement barrier, reducing the potential for failure.

The use of Geo-LOK technology allows the simple instrumentation of the annulus of the production conduit with continuous pressure measurement sensors, equipped with upper, lower and rate of change state alarms. This permits instantaneous identification and notification of potentially damaging leak paths that may allow geothermal brines to contaminate surface sweet-water aquifers.

The ability to demonstrate continuous well surveillance may be sufficient to satisfy regulators that the periodic monitoring of the well using specialised logging cased hole techniques, such as MFC and Ultra-Sonic Imaging (USI) Tools for residual casing wall thickness assessment is not required or may be performed with a much longer interval between monitoring interventions. This considerably reduces ongoing well maintenance and regulatory compliance costs.

Table 1: Thermal model inputs for a simplified mono-bore well (Ben Adams, Black Reiver Consulting, Thermal Modeling Service).

Model Inputs	
Hole Diameter	12.25"
Casing OD	9 5/8"
Casing ID	8 5/8"
Insulation Thickness	0.015 m
Surface Temperature	10 degC
Bottomhole Temperature	120 degC
Formation Density	2700 kg/m3
Fluid Density	997 kg/m3
Fluid Specific Heat	790 J/(kg.K)
Formation Specific Heat	4180 K.kg/K
Thermal Conductivity of Casing	45 W/(m.K)
Thermal Conductivity of Cement	1.2 W/(m.K)
Thermal Conductivity of Annular Fluid	0.594 W/(m.K)
Thermal Conductivity of Casing Insulation	0.05 - 0.1 W/(m.K)
TVD	2500 m
Fluid Inflow Temperature	120 degC

6.3 Reduction Of Heat Loss To Formation

One key benefit of Geo-LOK technology is its ability to minimise heat loss to the formations in thermally parasitic sections of the well. By providing a barrier with a lower heat exchange coefficient than cement, Geo-LOK helps maintain the well's thermal efficiency, which is critical for optimising geothermal energy production. To illustrate this further Black Reiver Consulting ran a number of thermal scenarios on the same theoretical well (Table 1) using our in-house thermal model.

From these models, it was possible to evaluate the increased thermal power available from the same well completed with a conventional cemented to the surface annulus (Scenario 1), a Geo-LOK well with a fluid-filled annulus (Scenario 2) and two Geo- OK wells where due to the preserved ability to insulate the external surface of the casing, it had been insulated with materials of differing thermal conductivity. The thermal conductivity of the 2 insulations was modelled with a high TC example at 0.1 and a low TC example at 0.05. The basic design of the well was a simplified 2500m deep monobore well cased with 9 5/8" casing and a maximum BHT of 120°C.

The model was run over a range of flow rates taken after 5 years of operation to show instantaneous gain in power of the three scenarios using Geo-LOK. (Tables 2 and 3) This flowrate sensitivity analysis was done under the well conditions as simulated after 5 years of continuous operation. This was done in order to moderate the gains shown in the initial years and present a more conservative picture of the thermal benefits of removing the annular cement.

Table 2: Conventional cemented annulus well compared to flowing wellhead temperatures and gain in thermal power from a Geo-LOK well with fluid in the annulus. (Ben Adams, Black Reiver Consulting, Thermal Modeling Service)

Conventional Cemented Annulus		Geo-LOK with Fluid in Annulus		
Flow Rate (L/s)	WHT (degC)	WHT (degC)	Δ degC	Gain in thermal power (kW)

Geo-LOK with External Casing Insulation (Insulation TC = 0.1 W/m/K				Geo-LOK with External Casing Insulation (Insulation TC = 0.05 W/m/K		
Flow Rate (L/s)	WHT (degC)	Δ degC	Gain in thermal power (kW)	WHT (degC)	Δ degC	Gain in thermal power (kW)
2.0	92.6	12.0	99.9	99.0	18.3	153.2
4.0	105.0	7.6	127.6	108.8	11.4	190.6
6.0	109.7	5.5	138.7	112.3	8.2	205.4
8.0	112.1	4.3	144.8	114.2	6.4	213.3
10.0	113.6	3.6	148.4	115.3	5.2	218.2
15.0	115.7	2.5	153.6	116.8	3.6	225.1
20.0	116.8	1.9	156.3	117.6	2.7	229.1
30.0	117.8	1.3	159.3	118.4	1.9	232.0
40.0	118.4	1.0	160.5	118.8	1.4	234.1
50.0	118.7	0.8	160.9	119.0	1.1	234.1
60.0	118.9	0.6	160.5	119.2	0.9	235.8
70.0	119.1	0.5	160.9	119.3	0.8	234.1
80.0	119.2	0.5	163.9	119.4	0.7	237.4
90.0	119.3	0.4	161.8	119.5	0.6	237.0
100.0	119.3	0.4	163.0	119.5	0.6	238.3

The model was also run at a constant 20 l/s flowrate over an anticipated 30-year operational well life to show a potential lifetime increase in total thermal return. (Table 4)

Whilst it is beyond the scope of this paper to assign direct monetary values to the achievable, increased power outputs, it would be easy to calculate the value of an individual project if given the applicable energy feed-in tariffs and power conversion efficiencies. It is sufficient to say that the value of this increase is significant.

6.4. Cost Reduction in Drilling and Casing

Geo-LOK reduces the overall drilling and casing costs by lessening the dependency on thicker-walled, high-cost corrosion-resistant tubulars. The drilling rig specification for any specific well is often defined by the hoisting requirements of the heaviest casing string. The ability to reduce casing string weight by running lighter, lower wall thickness tubulars can considerably reduce the drilling rig hook-load requirement and the additional drilling costs associated with larger capacity rigs.

6.5 Cementing Costs

Geo-LOK reduces the amount of cement required for well construction, simplifies the cement placement, and eliminates the need for high-cost lightweight and low-viscosity slurries. By decreasing the need to cement the annulus to the surface, the technology lowers the bottom hole pressures experienced during cemening, increasing the probability of successful, loss-free cement placement. The removal of annular cement from the lower temperature sections of the well also removes the casing collapse risk associated with the heating of the trapped fluid in voids or channels behind the casing due to poor cement placement. This, in turn, substantially reduces the need for expensive cement placement evaluation logging.

Table 4: Flowing wellhead temperatures and gain in thermal power from a Geo-LOK well with externally insulated casing shown on a time basis over a 30-year operational lifespan. BHT = 120°C (Ben Adams, Black Reiver Consulting, Thermal Modeling Service)

	Conventional Cemented Annulus	Geo-LOK with External Casing Insulation (Insulation TC = 0.05 W/m/K

28.0	115.5	117.8	2.3	188.9
29.0	115.5	117.8	2.3	188.1
30.0	115.5	117.8	2.2	187.3

6.6 Enhanced Abandonment Processes

Geo-LOK technology simplifies the abandonment process of geothermal wells. A fully cemented casing string left in the well requires section milling to permit the currently accepted abandonment standards, a time-consuming and costly process. In contrast, Geo-LOK enables a more efficient, easy and cost-effective "cut-and-pull" approach to be adopted. This is especially true in hard rock geothermal applications where long-term maintenance of a full wellbore is assured. This ability to fully recover the bulk of the casing back from the well, as previously mentioned, also allows the offsetting of the carbon footprint of the recovered alloys, improving the lifetime ESG profile of the well.

7. CONCLUSION

The Geo-LOK casing hanger technology represents a potentially significant advancement in geothermal well construction, offering a promising solution to the challenges and limitations of conventional cementing methods. Its unique ability to manage axial stresses without the need for full-length annulus cementing brings both technical and economic benefits. These include substantial cost reductions in casing and cementing, improved well integrity assurance, and enhanced thermal performance of geothermal wells.

Geo-LOK technology offers substantial benefits across financial, operational, and environmental aspects when considered as an alternative to conventional cementing for deep geothermal wells. Financially, it reduces cementing, casing, logging, and abandonment costs, making well construction and operation more cost-effective. Operationally, it enables continuous annulus surveillance and real-time management of well integrity, reducing monitoring intervals. This further improves the economic performance of the well.

Environmentally, Geo-LOK supports more sustainable well abandonment practices, minimizes heat loss of the produced fluids, and lowers the carbon footprint of geothermal projects. Moving forward from this paper, the adoption of Geo-LOK technology needs to be fully validated across the full 'ecosystem' of geothermal environments; the authors encourage further research and field trials. This will not only enhance understanding of the technology but also pave the way for continuous improvement and optimization in the industry.

Keywords: Liquid Ring Vacuum Pump (LRVP), Flow Switch (FS), Pressure Transmitter (PT), Reliability

ABSTRACT

Non-Condensable Gas (NCG) is a natural component of geothermal fluids in the form of a gas matter that is unable to undergo a condensation process in a cooling water system. NCG could interfere with the heat transfer process inside a condenser by raising its internal vessel temperature, resulting in reduced turbine efficiency. In principle, the liquid ring vacuum pump (LRVP) is a compressor that compresses NCGs before distributing it to the cooling tower, as a part of the cooling water process. The seal water system inside an LRVP is transferred by an Auxiliary Cooling Water Pump (ACWP), creating a sealing ring that works both as a gas compressor and as a prevention against foreign fluids that interfere with the pump's process. A fault in the seal water system can cause serious problems, such as overheating, corrosion, or reduced performance. As this seal water system holds a major role in the LRVP system, it is necessary to maintain both safe and reliable implementation of the instrumentation and control system. Kamojang Geothermal Power Plant Unit IV uses a flow switch as a detector to ensure proper operation of the seal water flow system and as a permission for activating or tripping the LRVP. The Power Plant experienced three plant trips between 2016 and 2023, due to some false signals transmitted by the flow switch. The addition of a pressure transmitter in parallel with the flow switch was proposed to enhance reliability. Data from turbine trip failures due to flow switch issues were analyzed to determine the Mean Time Between Failures (MTBF) and system reliability. The parallel configuration aimed to improve the cooling water system's dependability. Results indicate a significant reliability improvement, with the new system achieving a reliability of 0.92 compared to 0.37 for the existing system over 3.5 years, demonstrating a 0.55 increase.

1. INTRODUCTION

Geothermal Power Plant (GPP) holds its remarkable use of dry steam from the earth's reservoir to generate electricity by propelling the steam turbine. As one of Indonesia's oldest geothermal producers, PT Pertamina Geothermal Energy Tbk (PGE) has generated 235 MW of total power generated, with Kamojang Geothermal Power Plant Unit IV as one of the pioneers of Pertamina's owned GPP (Dwikorianto, Hendriansyah, Sastranegara, & Nugroho, 2018). The GPP extracts the dry steam that powers the coupled turbine-generator with power generated at 60 MW, where the steam is condensed into a condenser and processed into a cooling water process. The condensed steam then being reinjected into a reinjection well, which plays a vital role in both sustaining its geothermal reservoir quality and producing a low emission byproduct. Albeit for its well-known low-emission power plant, Kamojang Geothermal Power Plant Unit IV still produces a relatively low gas emission known as the NCG.

NCG is a type of gas unable to undergo a condensation process in a cooling water system. CO2 and H2S gas have the greatest percentage of content in the NCG produced. To remove the NCG from the system, the Gas Extraction System holds a vital role in the circulation process. The removal process has been automated into several sequences of operation between LRVP and Ejector (Novtafiani, Adhikihal, & Zaki Hamidi, 2018). By creating a vacuum chamber in the suction port, the NCGs are transported and then discharged through a discharged port with pressure from the impeller. To create a vacuum chamber inside the LRVP, an ACWP discharged the sealing water into the LRVP to create a seal water system. However, there have been some operational issues reports regarding the flow control system from ACWP into LRVP, resulting in the cooling water system's reliability.

When determining the seal water performance in LRVP systems, one of the sensors used is the flow switch (FS). which then decides the logic system of a GPP. However, it became crucial since it caused several power plant failures since 2016. The main factor is the sensor being installed as the sole component to monitor the sealing water flow from ACWP to LRVP, which increases the probability of a failure to occur. As this raises a new concern of a single sensor use in the system, a new system should be taken out to enhance the LRVP's performance, defined through a mathematical prediction that describes the system's reliability.

This paper discusses the re-evaluation of the flow control system's reliability from ACWP to LRVP from commissioning until the recent operation in 2023. Additionally, a pressure transmitter is installed on the same line as the flow switch to monitor the sealing water flow to the LRVP as the new modification, ensuring sufficient cooling water supply. The current study aims to investigate the effect of a logical modification towards increment on the reliability of a cooling water system in GPP. Based on its evidence of the new modification, the result can directly improve the further development and operation of other GPP in Indonesia. Furthermore, the result can also predict the foreseeable future of the repair time of the LRVP systems in the Kamojang Area.

2. METHODS

The objective of this paper is to enhance the power plant's reliability by resolving issues caused by false signals from the flow switch. Identification of the system and data collection were conducted to support the reliability analysis of the system using an exponential distribution.

The assumptions used in this paper are as follows:

- All parameters are statistically independent
- Exponential distribution is taken for all repair activities
- After repair/replacement unit works as new
- Flow switch and Pressure transmitter work in parallel and fail with a constant rate

The failure data for turbine trips caused by flow switch failure were gathered from PGE's internal records from commissioning until the recent operation in 2023. Based on the collected data, the system's MTBF (Mean Time Between Failures) value is determined, which is then utilized to determine the reliability function of the existing system.

A pressure transmitter is then added as an additional criterion to enhance the system's reliability. The MTBF value used for the pressure transmitter is based on references from previous research. The pressure transmitter is configured in parallel with the flow switch. The reliability values of the existing system and the new system implementation are then compared to assess the improvement in reliability achieved.

2.1 System Description

In principle, LRVP is a compressor that compresses NCGs before distributing it to the cooling tower, as a part of the cooling water process. The seal water system inside the LRVP is transferred by an ACWP, creating a sealing ring that works both as a gas compressor and as a prevention against foreign fluids interfering with pump's process.

Flow Switch is a mechanical switch that is switched on or off in response to the flow or non-flow of a fluid such as air or water (Mcrill, 2017). The flow switch in this system functions as a safety feature for the LRVP pump, ensuring that the sealing water line receives the appropriate water supply.

Figure 1 shows the Process Flow Diagram (PFD) of the geothermal power plant and details the process of FS as an indicator that water from the cooling water supply has flowed into the LRVP sealing water process. This component is considered to have failed if it is unable to monitor the flow through the sealing water process in the LRVP.

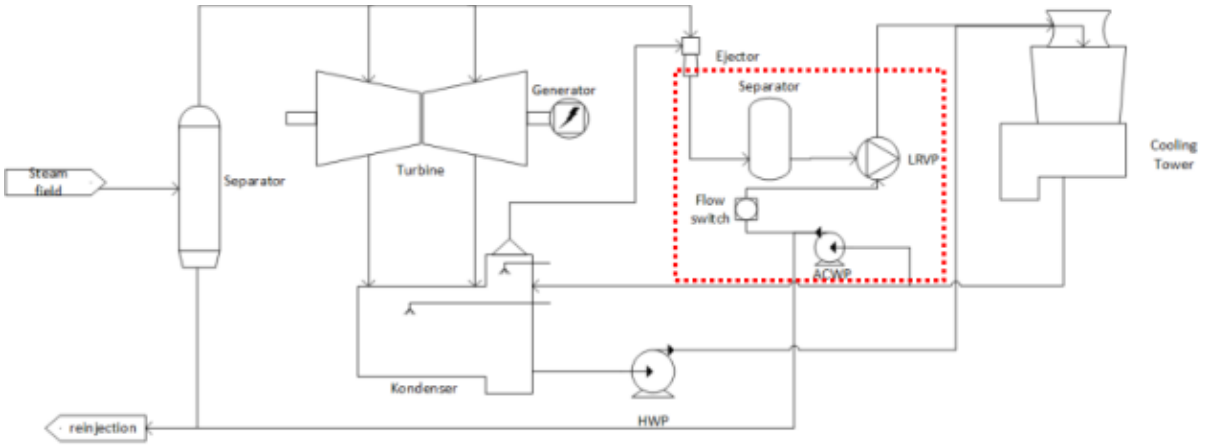

Figure 1: PFD of GPP and existing system details.

The following is the interlock and control diagram that causes the LRVP to trip.

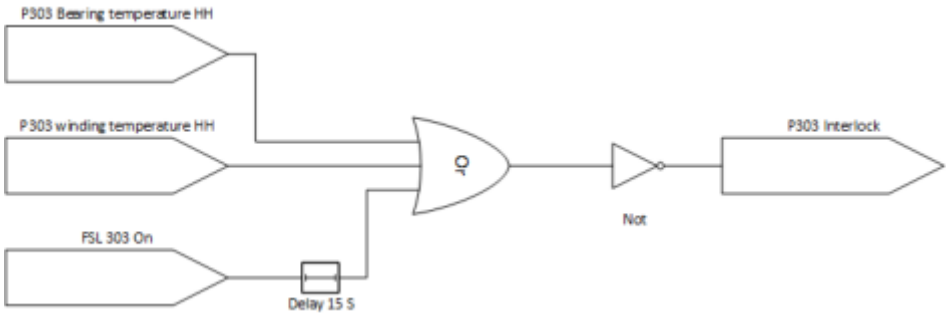

Figure 2: Interlock and control diagram of existing system.

According to the schematic above, the LRVP can trip under three conditions: the bearing motor's high-high temperature, the winding motor's high-high temperature, or the flow switch being active for more than 15 seconds. The LRVP will trip if any one of these conditions is true.

2.2 Reliability

Reliability is the probability of a device performing its purpose adequately for the period intended under the given operating condition. Reliability engineering covers both qualitative and quantitative aspects, aiming for reliable system design to achieve reliability targets (Biniwale & Choudhary, 2023). The quantitative method is developed using maintenance data regarding to each component's time to failure and time to repair. Reliability is calculated using the formula below.

$$R(t) = 1 - F(t) = \int_0^\infty f(t)dt \tag{1}$$

2.2.1 Mean Time Between Failure

Mean Time Before Failure (MTBF) is a measure of the reliability of an asset or an equipment. It is calculated through as follows:

$$MTBF \approx \int_0^T T \times f(x)dx \tag{2}$$

With T as the time to failure of a system. Since the value of MTBF is almost equal to the time that is expected from the failure of an equipment (Calixto, Eduardo et al., 2016) or called Mean Time to Failure (MTTF), we can assume that:

$$MTBF \approx MTTF \tag{3}$$

As MTTF is defined through an arithmetic average, the MTBF can be calculated simply as its best practice through the equation as follows:

$$MTBF = \frac{Operating\ Time}{Number\ of\ Failures} \tag{4}$$

The MTBF can be calculated as the operating time of an asset, divided by the number of failures over time. As an inverse of MTBF, a failure rate can be defined through the following equations:

$$\lambda = \frac{f}{T} \tag{5}$$

With failure rate denoted by Lambda (λ) is a number that is constant for as long as the useful life of an asset (Ramesh, 2013). The failure rate is a very important tool for the reliability of an asset. Some can also expect a variety of failure rates over time, depending on the different times of failure in a system.

2.2.2 Reliability of Exponential Distribution

The Exponential distribution is one of the most widely used in reliability problems. The very reason behind the popularity of this distribution can be attributed primarily to the fact that it is used to model the time to failure of components and systems with a constant failure rate, a situation that is often realistic (Hungund & Patil, 2014). The reliability is given below.

$$R(t) = e^{-\lambda t} \tag{6}$$

2.3 Reliability Block Diagram (RBD)

While calculating the system reliability is necessary to predict the repair time, an evaluation through subsystems is one of the crucial factors when determining the Reliability Density Function. It is important to specify first the boundaries of a system, continued with defining the logic of a system using the Reliability Block Diagram (RBD). The RBD method is divided into two types of systems, with respectively series and parallel block model (Calixto, 2016).

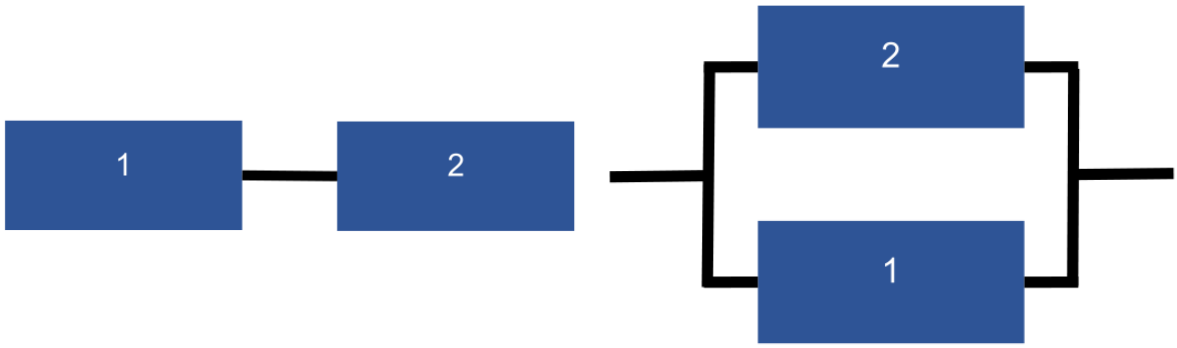

Figure 3: (a) Series and (b) Parallel block model

The series block model explains that when one piece of equipment fails, it causes a system loss of production. Whereas the parallel block model represents that it needs two or more pieces of equipment to fail in a system. Both the series and parallel block models are described mathematically by the following equations:

$$R(T) = R1(T) \times R2(T) \tag{7}$$

$$R(T) = 1 - \Big(\big(1 - R1(T)\big) \times \big(1 - R2(T)\big)\Big) \tag{8}$$

In reliability engineering, using a parallel configuration for system components is a common method to enhance overall system reliability. This approach leverages redundancy, meaning that multiple components perform the same function, thereby increasing the chances of system success even if one component fails (Menčík, 2016)

2.4 New System Implementation

In the new system, a pressure transmitter is added after the flow switch. A pressure transmitter is a device designed to measure pressure in liquids, gases, or fluids and convert this pressure into an electrical signal that can be used for monitoring and control purposes (Volonterio, 2023).

Both the flow switch and the pressure transmitter are placed in the sealing water line that supplies water to the LRVP. If the pressure detected by the pressure transmitter is below the predetermined threshold, the system will identify that the water flow is insufficient.

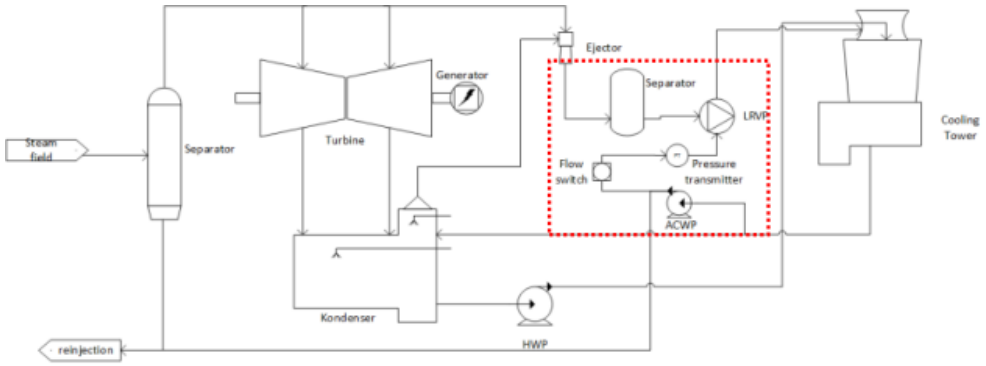

Figure 4: PFD of GPP and new system implementation.

The following is the interlock and control diagram for the new system that causes LRVP to trip.

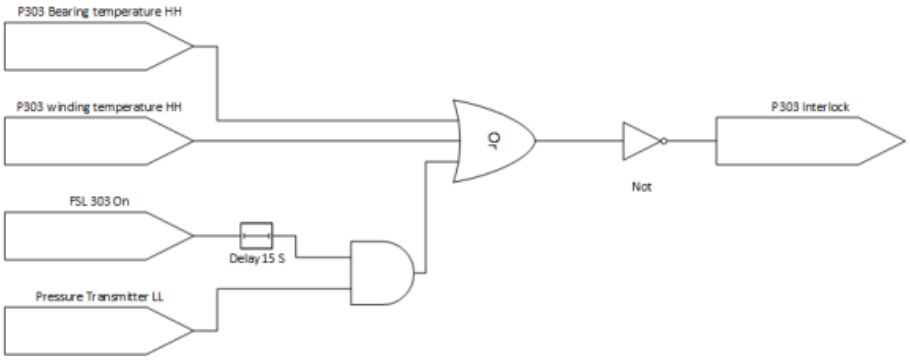

Figure 5: Interlock and control diagram existing system.

According to the schematic above, the LRVP can trip under three conditions: the bearing motor's high-high temperature, the winding motor's high-high temperature, or both of these conditions are met: the flow switch is active for more than 15 seconds and the pressure transmitter reads LL. The LRVP will trip if any one of these conditions is true.

If the pressure transmitter detects pressure below the set limit, the system will activate protection mechanisms. A low pressure reading from the transmitter will send an alarm to operations for further action, while a low-low pressure reading will trigger the LRVP, considering the flow switch is also activated.

3. RESULT AND DISCUSSION

The Power Plant experienced three plant trips between 2016 and 2023, due to false signals transmitted by the flow switch which are as follows,

Table 1: Plant trip by false signal.

Trip date	Repair Duration	Cause
Saturday, 30 January 2016	8 hours	False signal from flow switch
Saturday, 25 August 2018		
Monday, 13 March 2023		

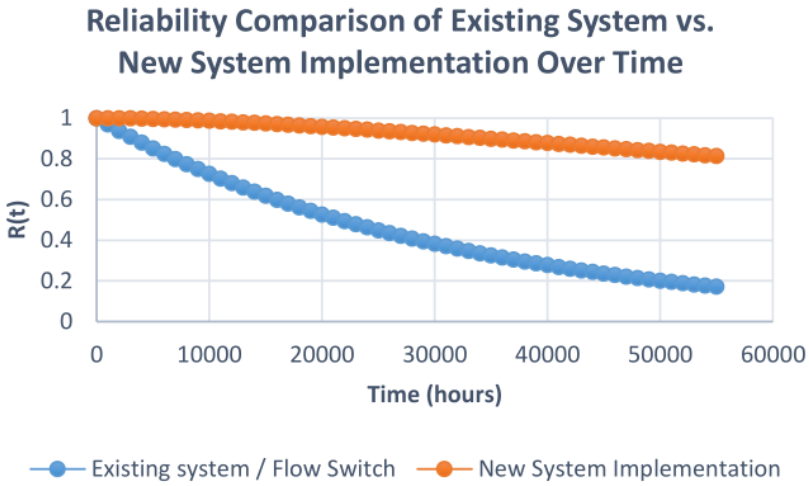

Figure 6: Reliability comparison.

Based on the data above, the Mean Time Between Failures (MTBF) is calculated to be approximately 31188 hours or 1299.5 days or equivalent to 3.5 years. Substitute the value into equation (5) and (6) resulting in the reliability function over time as shown in figure 6 for t = 3.5 years, the reliability value obtained is 0.37.

Reddy et al. (2016) in their research concluded that the smart pressure transmitter has an MTBF of 215509 hours or 8979.5 days. By substituting this value into the equation (5) and (6), reliability over time is obtained. This value is then combined with the reliability of the flow switch over time using a parallel system $R(T)FS//R(T)PT$ to improve the system reliability, resulting in the combined system reliability as shown in figure 6 for t = 3.5 years, the reliability value obtained is 0.92.

The blue line illustrates the reliability of the existing system, which uses a flow switch as the sole component for monitoring the sealing water flow to the LRVP. The orange line represents the new system implementation, which adds a pressure transmitter in parallel with the flow switch to enhance system reliability.

The existing system shows an exponential decrease in dependability with time, consistent with the exponential distribution theory often used to model the time between failures for electronic components. This decay indicates that the system's reliability decreases significantly as time progresses, reflecting a higher likelihood of system failure over an extended period. Initially, the reliability is at 1 (or 100%) but decreases progressively as time increases. This indicates that the probability of the flow switch functioning without failure decreases significantly over time.

The new system implementation also shows an exponential decrease in dependability with time. The reliability also starts at 1 (or 100%) but decreases much more slowly compared to the existing system. The combined system maintains a higher reliability over a longer period. As illustrated in the reliability graph, the new system implementation with the parallel configuration (flow switch and pressure transmitter) shows a much slower decline in reliability over time compared to the existing system with only the flow switch.

4. CONCLUSION

Implementing a highly reliable pressure transmitter in parallel with the flow switch greatly enhances the reliability of the system. The reliability of the existing system and new system implementation of 3.5 years is found to be 0.37 and 0.92 respectively thus, the difference between these values amounts to 0.55. The implementation of a parallel configuration in the cooling water system LRVP (flow switch and pressure transmitter) at the GPP has demonstrated a substantial improvement in system reliability, ensuring more stable and dependable operations over time.

ABSTRACT

The upgrading of condition monitoring systems is crucial for enhancing the performance and reliability of geothermal power plants. This paper presents a case study on the upgrade from Bently Nevada 3300 to Bently Nevada 3500 at Wayang Windu Unit 1 in 2023. The decision to upgrade was primarily driven by the obsolescence of spare parts and services associated with the older system, as well as the desire to leverage the benefits offered by Bently Nevada 3500. The scope of work covered the Turbine-Generator and Hotwell Pump equipment, two critical components of the geothermal power plant.

Moreover, the transition to Bently Nevada 3500 empowered Wayang Windu Unit 1 with advanced monitoring capabilities, improved reliability, and enhanced performance inherent in the newer system. Bently Nevada 3500's outstanding data acquisition and processing capabilities, including increased channel count and faster processing speed, facilitated more comprehensive machine monitoring and fault detection. Furthermore, the upgraded system introduced a modern graphical user interface and sophisticated data management tools, improving the user experience and streamlining data storage, retrieval, and analysis. Additionally, the modular design of Bently Nevada 3500 ensured flexibility and scalability, while its future-proof technology ensured compatibility with emerging advancements.

This paper delves into the benefits and challenges encountered throughout the upgrade process, beside the invaluable lessons learned and best practices identified for future projects. Through a thorough analysis, this case study offers valuable insights into the significance of condition monitoring system upgrades in geothermal power plants. It highlights the importance of transitioning to Bently Nevada 3500 to optimize reliability, efficiency, and operational readiness in geothermal power generation.

1. INTRODUCTION

Star Energy Geothermal operates three different locations of Geothermal Power Plant at West Java with total capacity 886 MW (see Figure 1). Star Energy Geothermal (Wayang Windu), Ltd generates 230.5 MW, consist of two units 1 x 113.5 MW and 1 x 117 MW. Star Energy Geothermal Salak, Ltd (SEGS) generates 381 MW consist of 3 x 67 MW and supply steam to PLN to produce 3 x 60 MW electricity. While Star Energy Geothermal Darajat II, Limited (SEGD) generates 274.5 MW consists of 219.5 MW as well as to supply steam to PLN to produce 1 x 55 MW electricity.

Star Energy Geothermal (Wayang Windu) Limited operates 230.5 MW of electricity capacity. Star Energy Geothermal (Wayang Windu) Limited has exclusive right until 2039 to develop contract area under Joint Operation Contract with PT Pertamina Geothermal Energy (PGE) and sale of electricity up to 400 MW under Energy Sales Contract with PGE & PLN.

SEGWW is located 40 km south of Bandung in West Java and operates a total of 230.5 MW for the Java-Madura-Bali grid. The first Unit (113,5 MW) at Wayang Windu was completed in 1999 and, since 2000, has been producing at full capacity with an availability rate of over 98%. At the time of its installation, Unit 1 was the largest geothermal turbine in the world. On March 2nd, 2009, the then Indonesian Minister of Energy and Resources officially inaugurated Wayang Windu Unit 2, which has a generation capacity of 117 MW from a single turbine.

Three critical assets in Wayang Windu Unit-1 are moniored by supervisory instrument, Turbine, Generator and Hot Well Pump. The FUJI 110 MW steam turbine is directly coupled to the FUJI two-pole 137.5 13.8 kV generator. The steam turbine is a single casing, double-flow, reaction type with eight stages in each flow. Its type is single casing, dual flow, dual exhaust, condensing. It has eight blading stages with rated gross output of 110 MW, its rated steam pressure and temperature are 10.2 bara and 180.7 deg C, its back pressure at exhaust is 110 mbar absolute, its pressure relief device operating pressure is 0.5 barg, the direction of rotation is clockwise

viewed from the generator side. The critical speed of turbine rotor is 1950 rpm and the critical speeds for turbine free standing blades are 2750 and 3230 rpm.

Figure 1: Star Energy Geothermal Plant locations at West Java, Indonesia.

The generator is three phase 50Hz FTLRI type air cooled with forced air-cooling using water. Its terminal voltage is 13,8 kV, its line current 5753 A, its insulation class is F (stator & rotor), its power factor is 0.8 lagging, its rotating speed is 3000 rpm with brushless excitation, it has two poles. Its rotor critical speeds below synchronous speed are 1156 rpm for generator shaft and 1450 rpm for combined unit. Its rotor critical speed above synchronous speed are 3588 rpm for generator shaft and 3950 rpm combined unit.

The condenser cooling water and condensed turbine exhaust steam collects in the condenser hotwell as condensate. Two 50% duty hotwell pumps remove condensate from the hotwell and deliver it to the cooling tower. The hotwell pump is from DMW corporation with vertical centrifugal canned type.

Mechanical failure especially in Turbine-Generator of power plant is what should be avoided, because it is not only can cause loss of production but also can be catastrophic. Continuously monitoring critical asset parameters such as vibration, temperature, speed, and numerous other condition indicators is a proven method for anticipating and preventing mechanical failures – proven in tens of thousands of industrial facilities around the world by delivering tangible benefits such as: Improved protection from catastrophic failures, better machinery reliability/availability, fewer process interruptions, enhanced maintenance/outage planning, lower maintenance and repair costs, longer intervals between outages, reduced insurance premiums. (Baker Hughes -2020) Critical asset parameters at Wayang Windu Unit-1 are supervised by Bently Nevada System, auto shut-down protection is also provided for several conditions which are turbine differential expansion very high, turbine/generator bearing vibration very high, turbine/generator bearing metal temperature very high, and thrust failure. Overspeed in turbine is supervised by six speed sensors, three of them are the input for F/V converter and alarm setter to be the input for overspeed protection, two of the sensors are the input for Woodward, one of the sensors as the input to DCS for indicator.

Before the upgrade, Bently Nevada 3300 was used and below are the detail of the T-G and also HWP supervisory system in Wayang Windu U-1.

Temperature Monitoring

Existing temperature monitoring of WW Turbine-Generator consist of temperature sensors, temperature monitor, and relay module. Refer to Tavle 1,2, and 3.

Turbine Speed Monitoring

Existing turbine speed monitoring of WW Turbine-Generator consist of speed sensors, frequency to voltage converter, and relay module. Refer to Table 3 and 4.

Turbine Keyphasor

Existing turbine keyphasor monitoring system consist of position detector, extension cable, proximitor, system monitor, and DC Power supply. Refer to Table 5 and 6.

Turbine-Generator Bearing Vibration

Existing Turbine-Generator bearing vibration monitoring system consist of 8mm Probe, extension cable, proximitor, dual vibration monitor, and relay modules. Refer to Table 7 and 8.

Turbine Shaft Thrust Displacement

Existing Turbine Shaft Thrust Displacement Monitoring System consist of position detector, extension cable, proximitor, and dual thrust position monitor, and relay modules. The outputs of dual thrust position monitor are connected to DCS through DC4-20mA cable. Refer to Table 9 and 10.

Table 9: Instrument Configuration.

No.	Element	Description	Remarks
1.	Sensor	8mm Probe Sensor Connection	Voltage Bently 330104-00-04-10-02-00 M8
2.	Cable	Extension Cable	Bently 330130-040-01-00

Obsolescence of Bently Nevada 3300

As mentioned above, most of the T-G parameters in Wayang Windu Unit-1 are supervised by Bently Nevada system, before Wayang Windu Unit-1 Shutdown and Turn-Around (SDTA) on August 2023, Bently Nevada 3300 was still used while on March 2014 it is classified as obsolete, meaning the product has no (or limited) support and is not recommended for continued use in a machinery protection application (Phase 5). In fact, limited repairs were possible only until 2017. Before the upgrade, Wayang Windu mitigated the issue if BN 3300 fails with the spare of BN 3300 modules in Darajat site.

BN 3300 was upgraded to BN 3500 on WW U-1 SDTA in 2023, after its commissioning in WW U-1 on September 2023, BN 3500 is still in lifecycle phase 1 and 2, BN 3500 will be in lifecycle phase 1 and 2 until 2024 ~ 2027, then it will be in phase 3 for 5 to 8 years. After this period, the system will transition to phase 4 and it will stay in phase 4 as long as Bently Nevada is able to procure the necessary components to perform repairs. These dates are estimates based on Bently Nevada's current planning and market conditions, actual dates of lifecycle changes may vary depending on industry and business conditions in the future as some components used to manufacture and/or repair systems can become unavailable. Bently Nevada Asset Condition Monitoring hardware utilized a life cycle management program consisting of five phases as described below.

- Phase 1: Product Release

Hardware is released for sale with full support including ongoing enhancements, custom modifications, new spare parts, and full repair capabilities.

- Phase 2: Mature Product

Same as Phase 1 except that no new enhancements are planned. Custom modifications are still available but discouraged. A notification of last time to buy new systems is typically issued several months before transitioning to Phase 3.

- Phase 3: Spares Only

Product is no longer available for new installations and no new custom modifications are available. New spare parts (including those for existing custom modifications) are still available. New spare parts (including those for existing custom modifications) are still available, and repair and support are provided as in Phases 1 and 2. A notification of last time to buy spare parts is typically issued several months before transitioning to Phase 4.

- Phase 4: No Spares, Limited Support

New spare parts are no longer available, and support is limited to repair, exchange, or remanufacture (subject to component availability). Notice of last date to repair is typically issued several months before transitioning to Phase 5.

- Phase 5: Obsolete

The product has no or limited support and is not recommended for continued use in a machinery protection application. Customers are advised to migrate to an appropriate replacement product with the assistance of their Bently Nevada sales professional.

2. UPGRADE OF BENTLY NEVADA 3300 TO BENTLY NEVADA 3500 IN WAYANG WINDU UNIT-1

Wayang Windu Unit-1 (WW-1) had been using Bently Nevada (BN) 3300 to monitor its Turbine-Generator (T-G) parameters since WW-1 commissioning in 2000. In 2017, Bently Nevada announced that Turbine Supervisory Instrument (TSI) BN 3300 is obsolete, and Bently Nevada will no longer support spare parts and services for this model.

In case failure of BN 3300, the turbine and generator will be unprotected and potentially lead to LPO due to spare part unavailability. Lead time for typically new version of TSI is 24 weeks after PO or will potentially result in large financial losses of around USD$47.4 M. Obsolete BN 3300 was upgraded with Bently Nevada 3500 to get full support on the technical and the spare parts from OEM.

This upgrade project covered Bently Nevada 3500 material purchasing, services such as engineering and detail design, setting, testing, installation on Unit 1 during 2023 Shut Down and Turn Around (SDTA) and commissioning.

The procurement process was started in Q4-2022 to meet the schedule for new turbine supervisory instrument installation during WW-1 SDTA in Q3-2023.

2.1 Scope of Upgrade

The supervised parameters of Wayang Windu U-1 T-G and Hot Well Pump (HWP) parameters are Turbine Thrust Bearing Metal Temperature, Turbine Bearing Metal Temperature, Generator Bearing Metal Temperature, T-G Shaft Vibration, Turbine Differential Expansion, Turbine Shaft Thrust Displacement, Keyphasor and HWP Vibration.

The installation service of new rack of Bently Nevada 3500 Vibration Monitor was including panel BN 3300 dismantling, front cubicle panel's modification as the dimension of BN 3300 and BN 3500 is different. BN 3500 vibration monitor installation, configuration & verification, and loop check/signal verification.

2.2 Challenge and Lesson Learnt of the Upgrade

As stated, the upgrade from Bently Nevada 3300 monitoring system to Bently Nevada 3500 monitoring system was done during Outage of Wayang Windu Unit-1 on August 2023. This 2023 Outage has a target of 12 days completion, so the upgrade process is needed to be finished under 12 days. SEG challenged the service contractor to do the installation within 6 days, the mutual understanding of it as a challenge and not for the maximum budgeting for contractor's man-power is needed for both the contract owner and the contractor.

The other lesson learnt from this upgrade project are to ask the contractor to provide a drawing and bill of material even for the smallest modification task. Involve maintenance team since engineering phase, ensure maintenance team is informed of all the details of modification.

2.3 The Advantage of Using Bently Nevada 3500

The 3500 is the result of decades of experience in the condition monitoring & protection field. With features like 1X, 2X, not 1X variables, extensive fault tolerant design, RF immunity, ease of configuration, etc. – the 3500 is an improvement on the 3300 in almost every way. And with a standardized 19" size and 4-channel cards that are less than an inch wide, the channel density possible in a 3500 is far greater than a 3300. Several application-specific monitors are also available (recip compressor, hydro, aeroderivative gas turbine, etc.), making it the ideal solution for all your condition monitoring & protection needs. (Baker Hughes)

The 3500 Series Machinery Monitoring System is also designed to communicate directly with System 1® software for state-of-the-art machinery condition monitoring & diagnostic capabilities. This ensures that along with industry trusted machinery protection, we also have access to effective machinery condition monitoring tools, so you are well informed about the health of your machines. Understanding their condition allows us to more effectively plan maintenance cycles and optimize planned down time for these critical assets. 3500 series is also easy to be configured using configuration software and the modules are hot swappable.

Table 15: The material scope of the upgrade and several differences between modules of BN 3300 and modules of BN3500 also the description of each BN 3500 modules.

No.	Parameter as input	Modules in BN3300	Modules in BN3500	Remarks
1.	Turbine Thrust Bearing Metal Temperature (Front)	3300/35	3500/61 Temperature Monitor	Both 3300/35 and 3500/61 are 6-channel temperature monitor. 3500/61 accepts both RTD and TC temperature inputs. It compares the input against user-programmable alarm setpoints. 3500/61 provides recorder outputs for each of its six channels.
2.	Turbine Thrust Bearing Metal Temperature (Rear)			
3.	Turbine Bearing Metal Temperature (Front)			
4.	Turbine Bearing Metal Temperature (Rear)			
5.	Generator Bearing Metal Temperature (T-Side)			
6.	Generator Bearing Metal Temperature (E-Side)			
7.	Turbine Shaft Vibration (Front 1)	3300/16 Dual Vibration Monitor	3500/42M Proximity Module	3300/16 module provides 2 channels, 3500/42M module provides 4 channels
8.	Turbine Shaft Vibration (Front 2)			
9.	Turbine Shaft Vibration (Rear 1)	3300/16 Dual Vibration Monitor		
10.	Turbine Shaft Vibration (Rear 2)			
11.	Generator Shaft Vibration (T-Side 1)	3300/16 Dual Vibration Monitor	3500/42M Proximity Module	
12.	Generator Shaft Vibration (T-Side 2)			
13.	Generator Shaft Vibration (E-Side 1)	3300/16 Dual Vibration Monitor		
14.	Generator Shaft Vibration (E-Side 2)			
15.	Turbine Thrust Displacement	3300/20 Dual Thrust Monitor	3500/42M Proximity Module	
16.	Turbine Thrust Displacement			
17.	Turbine Shaft Differential Expansion A	3300/46 Ramp Differential Expansion	3500/45 Position Module	3500/45 accepts input from proximity transducers, Rotary Position Transducers (RPTs), DC Linear Variable Differential Transformers (DC LVDTs), AC Linear Differential Transformers (AC LVDTs), and rotary potentiometers.
18.	Turbine Shaft Differential Expansion B			
19.	Turbine Shaft Differential Expansion C	3300/45 Dual Differential Expansion		
20.	NA	3300/14 DC Power Supply	3500/15 Low Voltage DC Power Supply	
21.	NA	(-)	3500/15 AC Power Supply	Back-up Power Supply in BN3500 rack
22.	NA	(-)	3500/22M TDI Module	The interface between 3500 monitoring system and the advanced System 1

				Optimization and Diagnostic Platform.
23.	Keyphasor	3300/03 System Monitor	3500/25 Keyphasor Module	Receives signal from proximity probes or magnetic pickups and converts the signals to digital Keyphasor© signals. Keyphasor© signal is used to measure shaft rotative speed and vector parameters such as 1X vibration amplitude and phase
24.	NA	3300 Weatherproof Housing	3500/05 19-inch Rack	19-inch rack has 14 available module slots. The rack is designed to hold all monitor modules to communicate with one another and for the power supplies to distribute power to each module as required.
25.	NA	(-)	3500/33 Relay Module 16 Channel	Each relay utilized on the Relay Module includes "Alarm Drive Logic". The Alarm Drive Logic is programmed using AND and OR logic (Boolean), and can utilize alarming inputs (alerts and dangers) from any monitor channel or any combination of monitor channels in the rack. This Alarm Drive Logic is programmed using the 3500 Rack Configuration Software to meet the specific needs of the application.
26.	NA	(-)	3500/92 Comm Gateway Ethernet	It provides extensive communication capabilities of all rack monitored values and statuses for integration with process control and other automation systems using both Ethernet TCP/IP and serial (RS232/RS422/RS485) communications capabilities. It also permits Ethernet communications with 3500 Rack Configuration Software and Data Acquisition Software.
27.	NA	(-)	3500/94M VGA Display	Delivers real-time values and current machine status at the machine and in the control room. The 3500/94M provides a real-time window into the machine health and instrumentation condition.
28.	NA	(-)	3500 Rack Config Software	
29.	NA	(-)	Engineering Laptop for Configuration	

3. CONCLUSION

Wayang Windu Unit-1has upgraded its turbine supervisory instrument to Bently Nevada 3500 Monitoring System on August 2023. It is still on lifecycle phase 1 and 2. Bently Nevada 3500 is the monitoring system which can be configured easily, it has better GUI and it can connect to system 1 to provide owner with effective machinery condition monitoring.

Keywords: API, Class G Cement, Cement Quality

ABSTRACT

The industry standard for cement and materials for well cementing in the petrol and natural gas industries is the API Monogram, API Spec 10A / ISO 10426. While the specifications set forth in this document are an excellent benchmark for commonly used oil well cements such as Class G cement, there are limitations to the specification's ability to ensure the desired and necessary level of performance for specific and varying cementing applications encountered in well cementing. Commonly recognized problems and the resulting primary performance factors of concern are early gelation of the cement and poor response to available chemical additives. These concerns are especially true for geothermal cementing operations, which differ from oil and gas operations in multiple ways, such as relatively low placement temperatures for various casing strings but with exceedingly elevated temperature conditions once wells are placed in production mode. Loss circulation while drilling and cementing is also a common and major challenge in most geothermal fields and without acceptable cement properties the cost of curing such losses can be substantial due to consumption of large quantities of cement and chemicals, plus the additional rig time required for such operations. Experience with many of the API Class G cements manufactured in the Asia Pacific suggests that early gelation is indeed a common problem in this region.

Production of oil well cement is a relatively small portion of the cement manufacturing industry and recent pandemic induced supply chain disruptions, coupled with an increasing demand for construction cement as economies reopened, resulted in limited availability of Class G cement in SE Asia. This has been further hampered by the fact that oil and gas operations are more predominate in the region and thus the manufacture of Class G cement is geared more to their needs and well conditions and thus the manufacturers have little incentive to make available Class G cement which is more suited to geothermal cementing operations. Importation of optimal quality Class G cement from other regions is an option but geographically isolated geothermal locations such as the Philippines are subject to significant logistical and economic barriers.

Presented in this paper is a technical background of API Class G cements as well as laboratory data detailing variations in performance of Class G cement available from regional suppliers and variations between batches of cement sourced from the same supplier. This paper documents a case history of the challenges faced by one operator in conducting cementing operations for geothermal wells in the Philippines geothermal environment with regionally available API monogramed Class G cement. This case history also includes the negative impact on performance and cost of cementing operations that less-than-optimal cement can have over a multi-year drilling campaign.

1. INTRODUCTION

1.1 Basics of Cementing

Cement is one of the most important components for drilling and completing a geothermal well. Its applications include cementing the casing strings in position, thereby providing mechanical support, corrosion protection, thermal isolation and long-term zonal isolation within the wellbore. Additionally, it is used for plug cementing operations to shut-off or control lost circulation while drilling, to provide a solid base for sidetracking operations and other remedial operations such as top-up jobs for when the desired top of cement is not achieved or when losses occurs during primary cement job on liners necessitating liner top "squeezes" and for shoe squeezes when the required seal is not achieved on the primary job.

The first application of cement in well drilling industry is recognized to have occurred in 1903 when Frank F. Hill with Union Oil Co. mixed and dumped 50 sacks of Portland cement into a well to shut off a water flow in a California oilwell. Portland cement has remained the dominant type of cement until today. Modern oilwell cementing began in 1910 when A. A. Perkins introduced his 2-plug cementing technique. As drilling became more advanced allowing drilling of deeper wells the increasingly difficult down hole conditions with high temperatures and pressures presented challenges for cementing operations. In the 1920's, techniques were tried, such as adding tons of ice to the drilling mud to cool down the wellbore before cementing. However, these

procedures had limited success which then gave rise to the development of special cement additives that could alter the cement slurry properties to allow placement of cement under the diverse range of well conditions. The use of geothermal resources has been existence for thousands of years for warmth, cleansing and as a mineral source. Use of geothermal surface sources became increasing common in the mid-nineteenth century with transportation of the heat by pipelines with the first geothermal power plant being established in 1904 in Lardarello, Italy. The first drilling and cementing of geothermal wells began in 1921 at The Geysers field in California. Demands for improved performance of the cement in ever increasing difficult down hole conditions such as temperature and pressure as the procedures employed in the 1920's such as adding tons of ice to the drilling mud in attempt to cool down the wellbore were not completely successful. This gave rise to the development of special additives to control the cement slurry properties required for cementing.

1.2 Brief History on API Specifications

Initial methods for testing and evaluating available cements utilized the ASTM (American Society of Testing and Methods) test methods for construction cement. The American Petroleum Institute soon recognized that the ASTM test methods were inadequate for well cementing applications and established the first committee to study cements in 1937. This resulted in the proposed API Code 32 in 1940, later to become API RP10B, adopted as the standard for well cement testing methodology in 1956. The actual Specification for Oilwell Cements (formerly API Standard 10A) was introduced in 1953 and since 1955, any manufacturer wishing to use the API monogram must undertake to make cement according to the relevant specifications detailed in Specification 10A.

Oilwell consumption of portland cement represents only a fraction of a percent of total world cement production, and geothermal consumption of cement is only a fraction of that used in oil and gas operations. Thus, the common well cements are generally derived from the same clinker as construction cements of the appropriate “type”. They may be ground to a different degree of fineness in certain cases so that they pass the additional tests prescribed by the API but, otherwise, they are essentially the same. Thus, most of the major “classes” of API cement are analogous, or very similar, to the various “types” of cement used in the construction industry.

Of the various types or 'classes' of API cement (Figure 1.) the most common one in use outside North America is Class G, a basic sulphate-resistant cement that can be modified with specific additives to perform at the extreme depths typical of today’s oilwells. While API Class G is available in the Asia Pacific region, the number of API Monogram manufacturers is very limited in comparison to construction cement manufacturers which are common and plentiful in most every country in the region due to the high cement demand of the construction market.

This is particularly true in countries such as the Philippines where API oilwell cement must be imported or where local regulations impose heavy tariffs on foreign goods.

1.3 Cement Performance Issues

When water is added to cement a series of reactions takes place that results in the formation of the final set product. These reactions are essentially the same for all Portland cements varying only in the rate at which they occur. This is dependent on the proportions of each phase present and the average particle size of the cement powder.

Class G Specification:
The product obtained by grinding Portland cement clinker, consisting essentially of hydraulic calcium silicates, usually contains one or more forms of calcium sulfate as an interground addition. No additions other than calcium sulfate or water, or both, shall be inter- ground or blended with clinker during manufacture of Class G well cement. This product is intended for use as a basic well cement. It is available in moderate sulfate-resistant (MSR) and high sulfate-resistant (HSR) Grades.

Intended Application:
Intended for use as a neat cement from the surface to 8,000 feet, or to 200F BHST, without additives. When modified with additives, this cement can be used for most well applications both shallow and deep. This cement is manufactured under stringent requirements for chemical content and physical performance tests.

Figure 1: API Classification for Class G Cement.

The chemical reactions involved in setting are complex and still the subject of much conjecture. However, for a simple system like neat cement powder plus distilled water as used for the API Specification test, the setting process is straightforward despite the complex reactions involved. In such circumstances the factors affecting setting time are temperature, chemical composition, including gypsum content and particle size distribution.

Such ideal conditions are never encountered in the field, however, where logistics dictate the use of mixing waters of varying quality, and well status necessitates the use of retarders or other materials to achieve the desired properties of a cement slurry. Mixing energy, shear rates and heat-up rates, due to specific equipment and well configurations, can all influence cement behavior. Also, cements are particularly susceptible to environmental

conditions such as ambient temperature and humidity, so their storage and transportation are key factors in controlling their behavior, particularly in the Tropics. But it is in their response to additives under actual field conditions, that cements display their greatest variation.

One of the more common problems seen in the well drilling industry is that of cement gelation. Gelation can be defined as a premature viscosification or a gel-strength buildup of the cement slurry. This can have significant consequences for field operations and may be so severe as to cause job failure. Due to its often-unpredictable nature, the phenomenon of cement gelation is difficult to deal with, along with the fact that it may occur under a variety of field conditions. It may occur immediately after mixing or as the cement slurry is subjected to temperature increases during pumping. Gelation often occurs under conditions of limited shear or during static conditions such as for planned or unplanned shutdowns during a cement job. The fact that the physio-chemical basis of gelation is complex, it can occur under a broad spectrum of conditions. Some of factors involved include the chemical composition of the cement powder itself, its fineness, its microstructure, the mix water quality, the types (if any) of additive used, the rate of heat flux into the slurry as well as the final temperature to which the slurry is exposed.

2. CEMENT MANUFACTURE

2.1 Manufacturing Process

Cements are industrial products and therefore subject to variations in composition and properties. These variations can be minimized by careful selection and grading of raw materials and by close attention to the proportioning of the raw materials and process control during manufacture. Portland cement is a complex mixture of heterogeneous inorganic compounds. The principal phases that can be identified are Tricalcium silicate (C_3S), Dicalcium silicate (C_2S), Tricalcium aluminate (C_3A) and Tetracalcium aluminoferrite (C_4AF), the proportions of these vary with the class of cement. Associated with these are also relatively minor quantities of Magnesium Oxide (MgO) and gypsum ($CaSO_4.2H_2O$).

The manufacturing process involves the 'burning' of a mixture of calcareous and argillaceous materials in a rotary kiln and subsequently grinding the product to a fine powder. The calcareous materials are usually forms of calcium carbonate (seashells, limestone, chalk) and are effectively the source of lime for the reaction. The argillaceous materials provide silica and may come in the form of clays, shales or silica rock. Bauxite (Aluminum oxide) and iron ore are also added to provide aluminum and iron where the source rocks are low in these elements.

The raw materials are first run through crushers and stored, eventually being transferred to the raw material grinding mills where they are combined in appropriate weight proportions. The mixture is passed through the grinders multiple times until it is ground to the required fineness. Once this fineness has been attained the raw meal is pumped to air-blending silos and from there via a weigh feeder is transported to the cyclone system where it is preheated to approximately 400ºC by the hot gases coming from the kiln. After entering the kiln itself, the raw meal passes through a series of temperature zones as summarized in Table 1.

Table 1: Cement Manufacturing Process.

Zone	Temperature of Material	Physical and Chemical Changes
1.Preheating zone	400 - 550 ºC	Driving off impurities continues
2.Calcining zone	550 - 1000 ºC	Carbonates decompose to oxides
3.Sintering zone	1000 - 1450 ºC	Oxides combine to form clinker minerals and modules of clinker form due to partial melting
4.Outlet zone	1450 - 1200 ºC	Cooling begins

2.2 Variations in Composition and Properties

The rate of movement of the material from inlet to outlet is dictated by the slope and rotation of the kiln. The resultant product called clinker exits at the lower end of the kiln through a grate cooler and is then transported to the clinker storage facility. Once the clinkehas cooled and it is time to proceed with the final processing the clinker is mixed with a specific quantity of gypsum and ground to a fine powder in a ball mill. The output from the ball mill is then fed to an air separator such that coarse particles being recirculated. Cements containing too high a proportion of coarse particles have a reduced rate of hydration, high free water level and a delayed development of compressive strength. Cements which contain excessive quantities of fines typically exhibit poor rheological properties and frequently require the addition of large amounts of additives to provide effective retardation. By proper adjustment of the feed to the mill and air separator, the fineness is controlled.

2.3 Cement Property Issues

During the grinding process, the temperature of the material rises above the boiling point of water. This causes the gypsum (CaSO4.2H2O) added to be partially dehydrated to hemihydrate (CaSO4.½H2O Plaster of Paris) and anhydrite (CaSO4). Such a change can induce a phenomenon known as 'false set' a premature thickening when the cement is mixed with water, which is obviously undesirable. This dehydration of gypsum is reduced by maintaining the temperature of the cement within prescribed limits and by spraying water into the mill. After grinding the meal, the process of cement manufacture is complete, and the product is pneumatically transferred to a silo for storage.

3. CEMENT QUALITY

3.1 API Specifications

All batches of raw materials should be analyzed chemically before use and from the grinders and to the kiln. Such analysis should be carried out on a strict schedule (every 1-3 hours) during manufacture. Analysis of the clinker is more detailed and includes estimations of free lime and sulphate while the final product, the cement itself, must be subjected to additional physical tests such as sieve analysis and specific surface area determine (Blaine fineness). In choosing between available class G cements, the primary performance factors of concern are retarder response and early gelation of the cement. The chemical and physical properties of cement determining these performance factors include tricalcium aluminate (C3A) content, fines content and free lime. For most cement slurry applications, acceptable performance requires minimization of these three properties. In many cement purchase contracts, the cementing service company and/or the operating company specifies an API class G cement of high sulfate resistance with its lower limitation (3.0% maximum) on tricalcium aluminate content. Fines content and free lime concentration contribute to the problems but neither one is addressed directly by API specifications (Table 2.)

Table 2: API Cement Manufacturing Specifications.

Description	API Specification Class G HSR
Silicon Dioxide (SiO3)	n/a
Aluminum dioxide (Al2O3)	n/a
Ferric Oxide (Fe2O3)	n/a
Magnesium Oxide (MgO)	max. 6.0 %
Sulfur Trioxide (SO3)	max. 3.0 %
Tricalcium Silicate (C3S)	max. 65 % / min 48 %
Tricalcium Aluminate (C3A)	max. 3.0%
C4AF+2*C3A	max. 24 %
Loss on Ignition	max. 3.0 %
Insoluble Residue	max. 0.75 %
Total Alkali (%Na2O+0.658*K2O)	max. 0.75 %
Blaine Finness (m2 / kg)	n/a
Autoclave Expansion (%)	n/a

Finally, all necessary API Specification tests (Table 3), including determinations of free water, thickening time per Schedule 5, soundness and compressive strength, must be conducted and this information recorded on a report.

Table 3: API Cement Slurry Performance Specifications.

Description	Summarized API Specification
Thickening Time	More than 90, less than 120 min, tested at 125 F, schedule 5 API, 1.9 SG, 44% water
Consistency	Less than 30 Bc during 15-30 min. of the stirring period, tested at 125 F, schedule 5 API, 1.9 SG, 44% water
Free Water	Less than 3.5ml/250ml @ 80 F
Compressive Strength	> 300 psi after 8 Hours @ 100 F > 1500 psi after 8 Hours @ 140 F

3.2 Potential Problems Not Detected by API Tests

Cements from different manufacturers or even different batches from the same manufacture which even though they may pass the API specifications, often exhibit wide differences in performance when exposed to various mixing, pumping and wellbore conditions in addition to response to various additives and additive concentrations.

Given this fact, it is always preferable to identify and choose the available API cement which best fits operational needs and conditions and then continue to monitor the performance of each new batch. Such an approach helps detect potential problematic batches of cement and allows designs to be modified, if necessary. This strategy can dramatically reduce the number of unsuccessful cement jobs, but it does have limitations.

Table 4: API Cement Slurry Specification Testing.

(2 hour batch mix time)	(2 hour batch mix time) 2 hour decrease in Thickening Time due to new lot of cement

The behavior of cements which pass the API Specification tests may vary greatly when mixed at densities and temperatures different than that specified in the API Specification Tests, and with the addition of chemical additives. Experience with some API cements and most construction cements manufactured in Asia Pacific has found that early gelation is a common problem. At best, the API Class G Specification tests may provide some insight into the gelation tendencies of a given cement. Quite often this problem is not identified until additional testing is conducted as some cement designs may perform as required regardless of the cement being used whereas others can be drastically impacted by differences in the cement supply. Table 4 presents two different batches of

cement which both meet API Specifications. Note that for Lot 3, the thickening time result is approaching the upper limit of the specification and Lot 6 has a shorter thickening time than Lot 3 but well within specification. Table 5 shows how these two different Lots of cement behave differently in an actual cement slurry design. Lot 6 exhibits a two-hour shorter Thickening Time for the exact same slurry design.

Thus, thickening charts become an important record of the cement's potential for problems. Figures 2. and 3. Illustrate types of undesirable setting behavior because of gelation of the cement slurry as observed by the Thickening Time charts and observations of the cement slurry condition after removal from the consistometer and opening of the cement slurry test cup and removal of the paddle assembly.

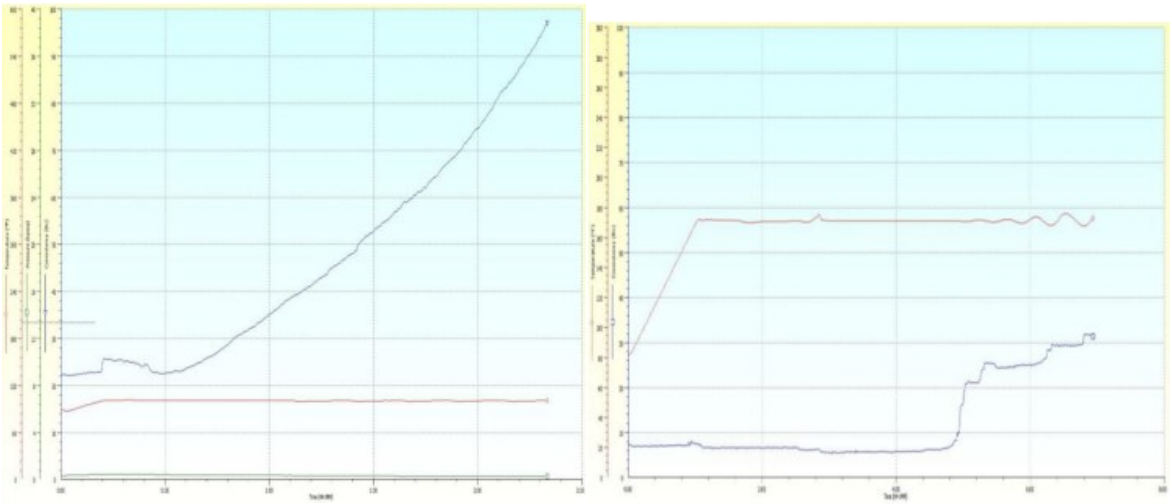

Figure 2: Thickening Time Charts with indication of Cement Gelation.

Figure 3: Slurry Test cup pictures showing gelation as exhibited by cement forming around the center of the consistometer cup paddle due to less mixing energy.

4. CASE STUDY PHILIPPINES

4.1 Cement Availability Issues

The Philippine Geothermal Production Company (PGPC) is engaged in an ongoing well drilling campaign and in addition to the supply disruptions in recent years, the rising demand for construction cement has seemingly impacted the quality of the Class G cement available in the region. Experience with API Class G cements manufactured in Asia Pacific suggests that early gelation of cement for certain cement slurry designs is indeed a common problem in this region. For the regionally predominate oil and gas operations and wellbore conditions that can be quite different than for geothermal operational conditions, the regionally available cement is generally quite acceptable. As geothermal operations are relatively small, it is postulated that the manufacturers have little incentive to produce a separate stock of cement which is more suited to geothermal cementing operations. Currently, there are only three Class G cement suppliers used for most geothermal well cementing operations in the region. Importation of Class G cement has been considered but the high import taxes, transportation costs and logistics present a significant barrier to sourcing Class G cement from outside the region.

From 2020 through most of 2022, the supply of cement provided to PGPC through its cementing services provider came primarily from one supplier. This cement performed reasonably well in both cement additive response and consistency from batch to batch, allowing cement slurry designs to be extended to 14.0 ppg without addition of lightweight additives and to be mixed at 16.0 ppg for Tieback operations and 16.4+ ppg kick off plugs. Reactivity of this cement source was somewhat on the high end for a class G cement but presented no significant gelation

problems. This allowed PGPC to develop very effective lost circulation designs. With the performance of the cement supply remaining fairly consistent between batches cement designs we were able to be further optimized in both performance and cost.

4.2 Performance Issues

A summary of the cement supply is provided in Table 6.

Table 6: Cement Supply and Lot Numbers.

Well No	Cement Source	Lot #	Remarks
1	Supply 1	Lot 1	Meets API specifications, works well with all cement slurry designs and is consistent from lot to lot
2	Supply 1	Lot 1	
3	Supply 1	Lot 2	
4	Supply 1	Lot 2	
5	Supply 1	Lot 2	
6	Supply 2	Lot 1	Cement provides excellent performance, requiring least amount of additives
7	Supply 2	Lot 1	
8	Supply 2	Lot 1	
9	Supply 1	Lot 3	Similar to prior Supply 1 batches
10	Supply 1	Lot 4	More reactive than previous batches, requiring higher concentration of retarder to achieve required Thickening Times
11	Supply 1	Lot 5	Similar to Lot 4, slightly more reactive
12	Supply 1	Lot 6	Very different from previous batch. High gelation tendencies required excessive amount of lab testing and increased chemical additives
13	Supply 3	Lot 1	Less reactive than initial Supply 1 Lots but exhibiting tertiary gelation for lightweight designs. Unable to achieve design requirements with available chemical additives. Fairly consistent between the 2 Lots that were utilized
14	Supply 3	Lot 1	
15	Supply 3	Lot 2	
16	Supply 3	Lot 2	

Towards the end of the first 9 or 10 wells, the cement from Supplier #1 became more reactive and began to cause concerns over gelation issues. This did not significantly impact any of the primary cementing except for the 16.0ppg tieback design which is the most critical cement job as any failure in placement of a 100% continuous cement sheath between casing can range from costly remedial operations and loss of production to complete loss of the well. A shortening of the thickening time with the new cement (Table 5.) was managed by adjustments in additive concentrations. For lost circulation plugs, the gelation exhibited by this batch of cement was beneficial for the desired high early gelation and faster set times. Due to concerns about the cement quality from this supplier, an alternate source was identified, but in the interim while awaiting shipment, the current cement supply was used for the next well(s).

Going to the next field location with plans for three wells, the starting point for cement designs was based on the designs which became standard after the first 11 wells. A new batch of cement from Supply 1 (Lot 6) had been received and tested according to API Spec. 10A. Though this new shipment of cement met API Specifications, given the prior experience with shortened thickening time of the 16.0 ppg Tieback design, it was also tested with the tieback design to confirm performance acceptability. Thickening Time results were found to be consistent with previous cement supplies and thus the new lot was considered acceptable. Operations proceeded accordingly until confirmation testing of the cement blended for the surface casing job with cement design of 14.0ppg revealed that this new Lot was significantly different. This batch of cement, when mixed at the standard 14.0ppg density for the standard surface casing design, exhibited both early and latent gelation problems. Thickening times would not build while mixing and the cement slurry would quickly become unpumpable with any shutdown in mixing. As shown in Fig 4 and Fig. 5 below, the thickening time charts did exhibit the typical and expected increase in viscosity as measured in the standard cementing measurement of bc. (Bearden Units). Upon opening of the slurry cup, it was found that the cement had gelled up around the paddle which is a clear indication of a gelation problem.

Multiple slurry design changes were made in attempt to correct the gelation problem, but no solution was found in time and to not delay operations it was decided to forego the fluid loss control and just focus on obtaining a design with acceptable pump time and rheological properties.

Cement designs for subsequent liner jobs were similarly impacted by the cement quality (Figs 6 and 7) but in attempting to correct the gelation problem resulted in an additional problem of slurry instability.

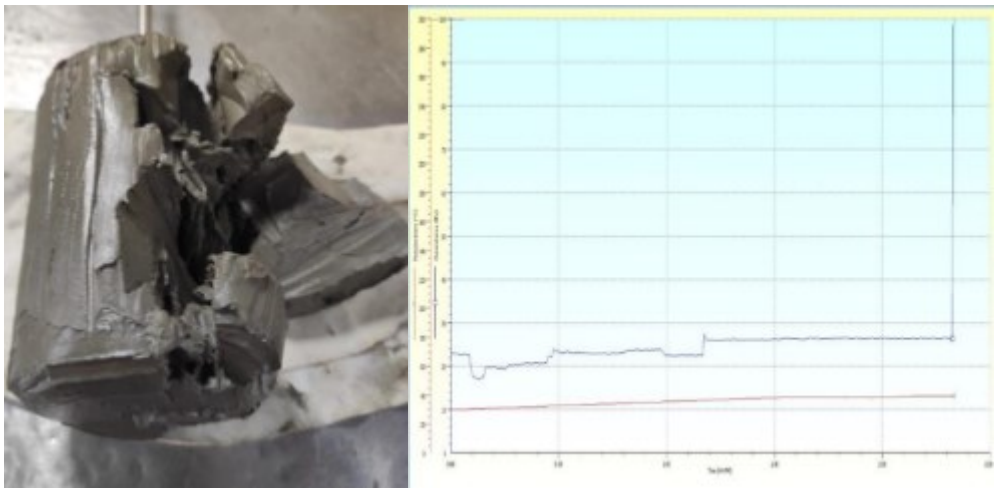

Figure 4: Surface Casing - Thickening time chart and picture after removal from slurry cup.

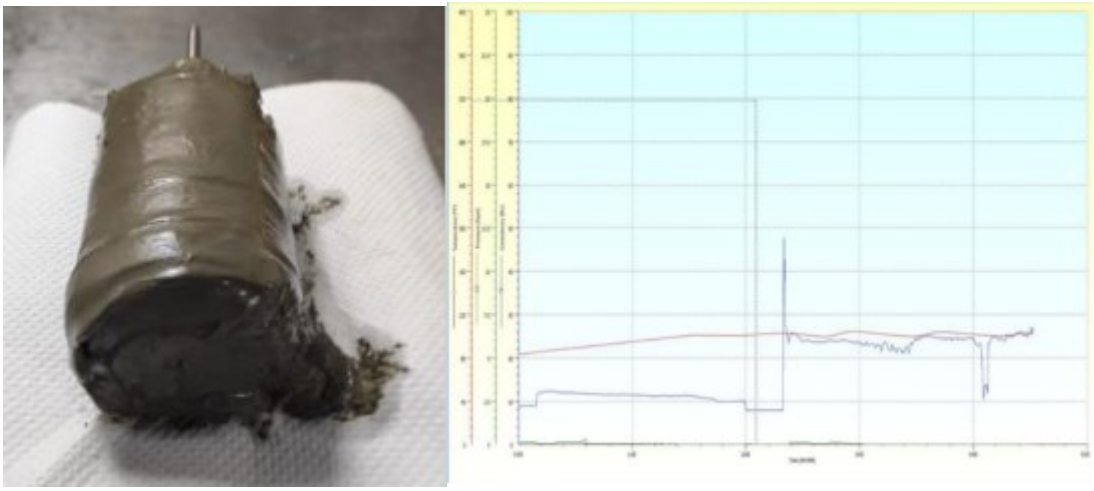

Figure 5: Surface Casing - Attempts to correct this gelation resulted in unstable cement slurries.

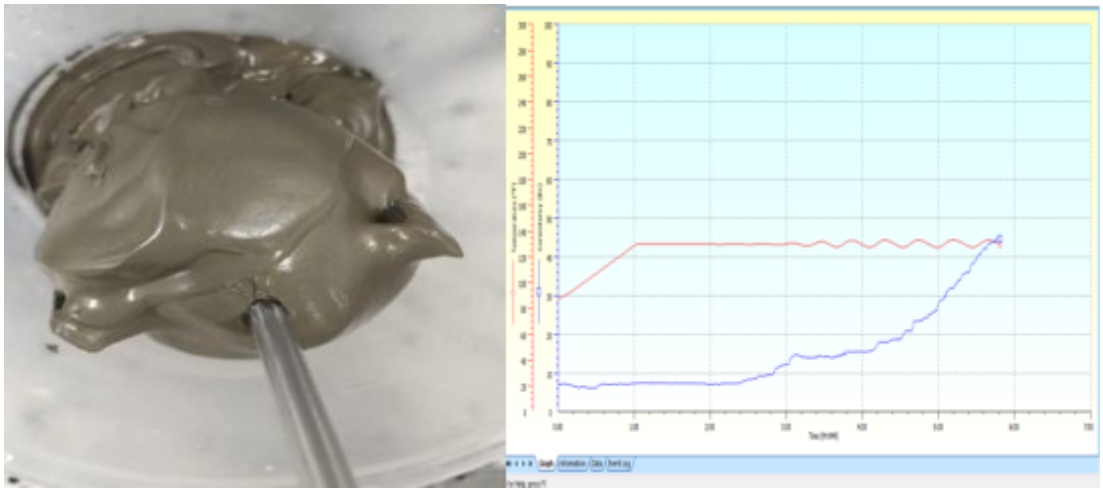

Figure 6: Intermediate Liner – Temperature oscillation caused by slurry gelation.

It was possible after a significant amount of lab testing to meet specifications and achieve manageable though less than desirable designs for the Liner jobs by incorporating a costly amount of microsilica additive to help stabilize the cement slurry. In total, over 100 lab designs had to be tested in search of acceptable cement slurry designs with this batch of cement. Based on the performance of this batch of cement from Supplier #1 and the fact that a

new supply of cement from Supplier #3 was now in stock, it was decided not to use this Lot#7 cement for any primary cement jobs on the next wells and to discontinue sourcing any cement from Supplier #1. Before placing the order for Class G cement from Supplier #3, API specification testing and confirmation testing of the 16.0ppg Tieback design found that this cement supply would be acceptable. Unfortunately, this was before the experience that a cement that would be acceptable for a cement slurry density of 16.0ppg may not be acceptable at all for a 14.0ppg cement slurry density.

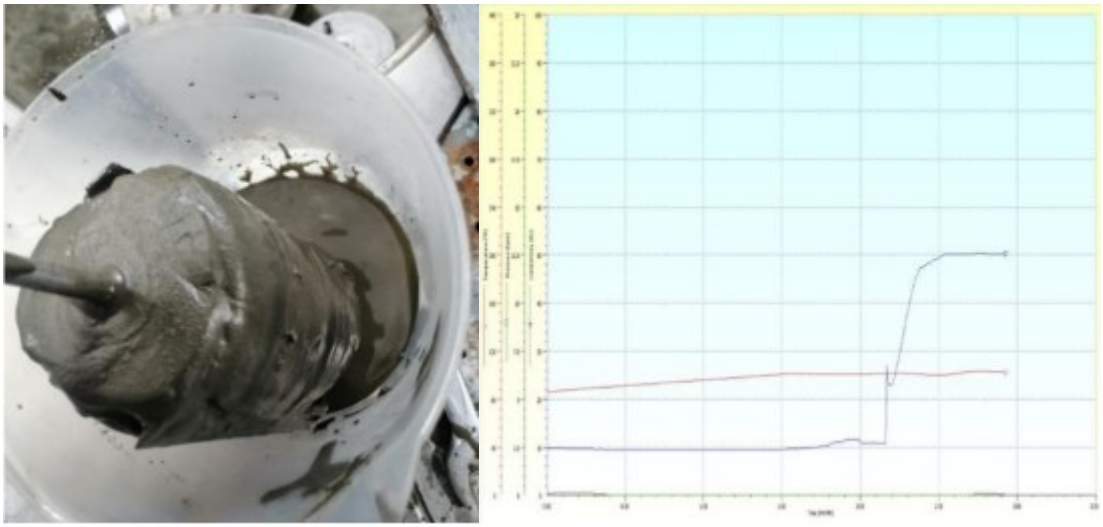

Figure 7: Deep Liner – slurry unable to set evenly.

Testing of this newly arrived cement supply #3 for the 14.0ppg surface casing, 14.0ppg liners and 15.0ppg lost circulation plugs found that this cement behaved exactly opposite of the previous cement supply. This new supply of cement exhibited low reactivity at lower temperatures and had some latent gelation issues. Placement temperature for the surface casing cement operations is typically 100oF to 110oF due to relatively shallow setting depth, continuous pumping of fluids downhole to combat loss circulation and the fact cementing is done via inner string method. Intermediate liner cementing temperatures are typically 130oF to 150oF. Even with the addition of accelerators it was not possible to get 14.0ppg designs that exhibit proper thickening time curves. In general, the normal gelation in the cement hydration process did not take place while being stirred in the HPHT consistometer and attempts to cure this problem ended with the cement setting around the shaft of the mixing paddle but remaining liquid towards the outer edge where the mixing energy was somewhat less (Fig. 8).

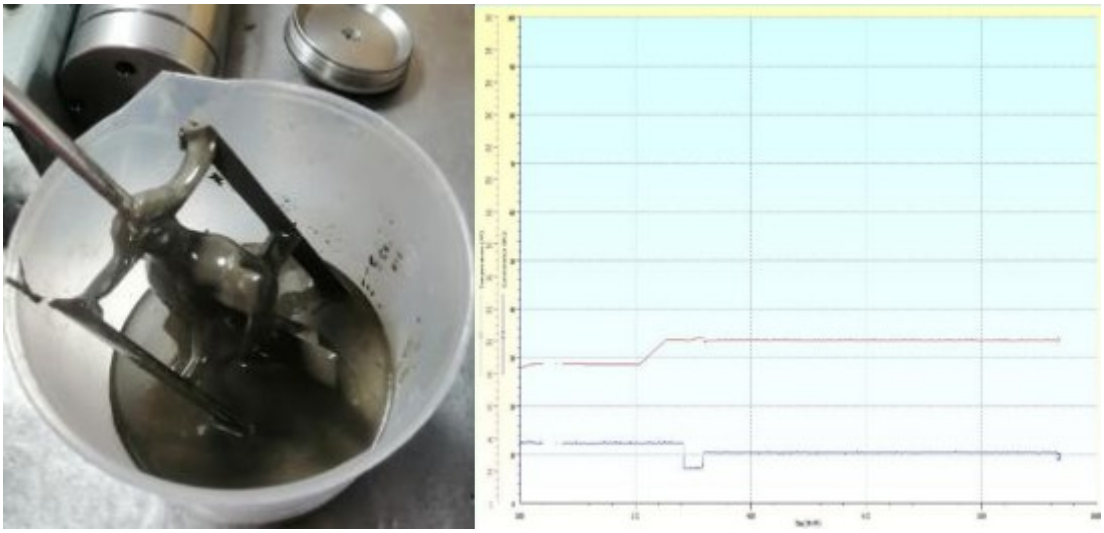

Figure 8: 14.0ppg Surface casing Pilot test using samples of Supply #3.

After a multitude of tests of using currently available chemical additives, the only effective means to accelerate and stabilize the hydration process was to increase the densities of the 14.0ppg cement designs to 14.5ppg and to add a costly stabilizer type additive. The remaining cement Supply #1 was kept on hand for lost circulation plugs however this became an operational risk to keep two very different cements on location given the possibility that field crew may inadvertently use the wrong cement for a given job.

Given the performance of cement supply #3, samples of the latest batch of Class G cement were obtained from supplier #2 as that cement had previously proven of acceptable quality. Unfortunately, even though it met API Specifications, it was found that the cement from that source had also become very reactive with gelation problems similar to Lot 6 from supplier #1. The exact reason for the change in quality of Class G cement from both Supplier #1 and Supplier #2, is not known but it is most likely due to a change in the raw materials. Also, it is worth noting that faster setting cement with shorter gel times is generally desirable for construction cement and as previously stated, construction cement is the primary product of cement manufacturers.

4.3 Cost Impact

Upon the successful completion of the 16 well drilling campaign, the cementing cost per job per well was compiled and organized for comparison of the different cement supply. Do take note that the first 11 wells were drilled in a different field from an earlier campaign (2020-2022) and the latter was most recent (2022-2023)

A discernible trend emerges during the first 11 well drilling campaign, a gradual decline in pricing signifying a favorable cost-effectiveness for the cementing process. As mentioned in Table 4, wells 1 - 5 came from supplier 1, and wells 6 - 8 is from supplier 2. The reason for getting cement from supplier #2 was due to supply chain disruption and with supplier 1 being unable to manufacture on time, nonetheless, the cement from supplier 2 behaved similarly to the prior supplier. Wells 9 – 11 is from supplier 1 as well and no significant changes in cost were observed. In the following campaign starting with Well 12, operations switched to a fresh supply of cement from supplier #1. This led to a notable rise in costs, largely attributed to the quality of the cement. Transitioning to a newly arrived G Cement provided by supplier #3 starting from Well 13 did not alleviate the cost concerns, as this time, the cement proved to be less reactive compared to previous batches. Consequently, despite the change in suppliers and cement batches, the cementing costs for the second campaign significantly exceeded those of the first 11 wells, with some costs even doubling. The most evident case in this drilling campaign for the cost impact of the cement supply is during the cementing of the liner strings. This is best exemplified by the 13-3/8" intermediate liners as this casing string were run in every well (Fig.11).

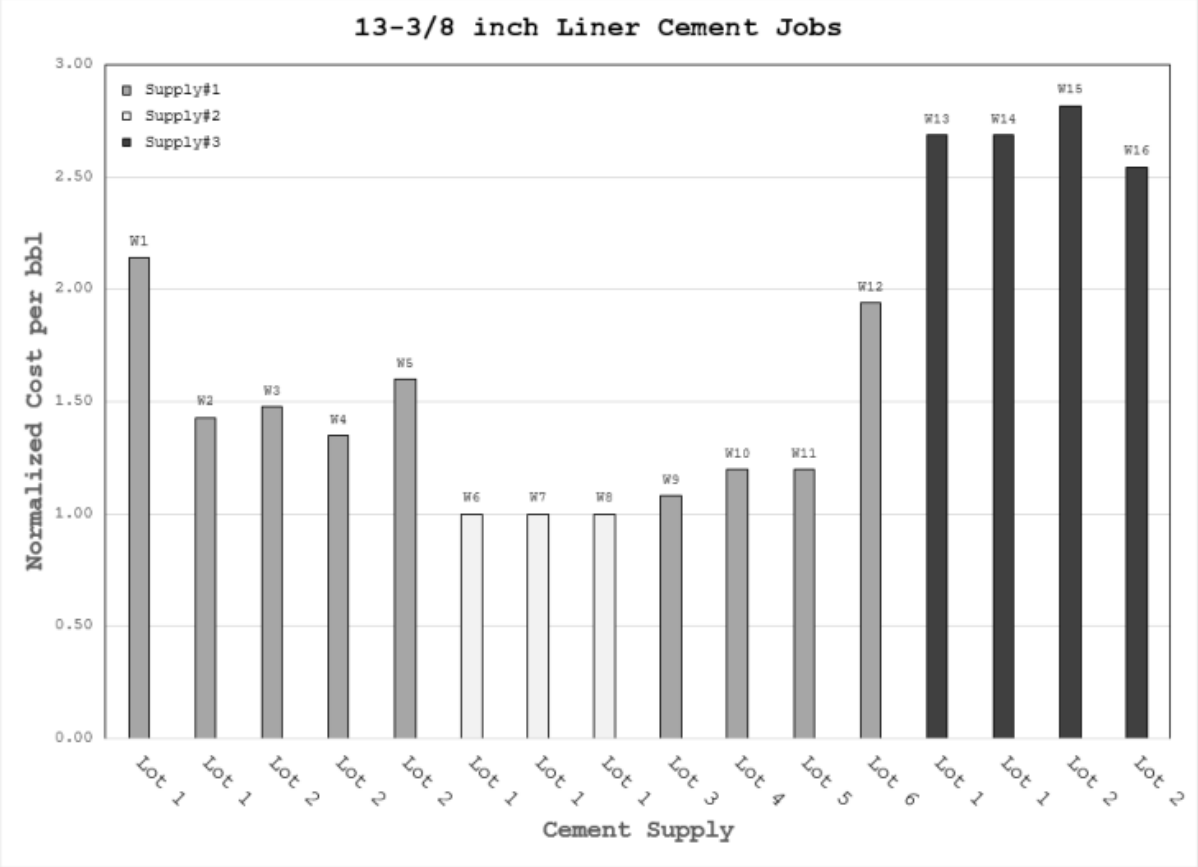

Figure 9: 13-3/8" Intermediate Casing (Wells Vs. Cost/Barrel).

5. CONCLUSION

Production of cement is one of the main and most important industries worldwide. Its primary use as a binding agent for concrete that is one of the most frequently used materials for civil construction projects, can be

considered the backbone for development. While its application for well cementing is equally important, the fact remains that this usage of cement is relatively minor in comparison especially for geothermal cementing operations which are small compared to oil and gas operations. This is further complicated by the fact that the raw materials vary in chemical make-up and what may be acceptable for use in concrete, may not be as suitable for geothermal well cementing. API standards have long provided a benchmark for ensuring cement manufactured to its specifications are generally suitable for well cementing. However, as observed in PGPC's geothermal operations, there can be a significant distinction between cement that is merely adequate and that of which delivers exceptional performance for any given supply and batch.

To better ensure a cement supply which is optimal and to improve cement consistency from lot to lot, one recommendation is to engage an open line of communication with the cement manufacturer to convey the cement properties that are needed for geothermal operations. This would ideally include witnessing API specification testing conducted at the cement manufacturing facility as a first step in the screening process for acceptance of any lot of cement. In addition to API specification tests, testing of actual cement designs planned for all casing strings should be conducted by the cementing service provider to ensure that the cement meets not only the API specifications but is applicable for the intended geothermal operations. Aside from the manufacturing process, packaging, shipping, handling and storage should be considered to ensure the quality of the cement from point of manufacture to point of use. Procedures should minimize the risk of exposure to contaminants, environmental factors (moisture, etc.) and ensure that the cement is delivered and maintained in the same condition as it was at the point of origin. Furthermore, additional tests may be taken per new batch that has arrived to confirm consistency with the tests from the point of origin.

In summary, cement quality is a critical factor that dictates the success of a cementing operation. High-quality cement is essential to ensure the ability to formulate cost effective cement slurry designs that are mixable, pumpable and meets all performance requirements to ensure the formation of a strong, stable, and impermeable barrier in the wellbore, particularly in demanding applications such as geothermal operations. Conversely, poor cement quality may result in costly cement designs or the inability to design a slurry which meets performance requirements and thereby increase the potential for job failures requiring costly remedial operations and the potential for failures in well integrity and long-term performance. All in all, API specifications may serve as an overall guide in controlling quality and acceptability of well cements, but additional controls as suggested in this paper are often necessary to further prevent cement quality issues for geothermal operations.

Keywords: Debottlenecking, Steam Supply

ABSTRACT

Pertamina Geothermal Energy Area Geothermal Ulubelu supplies steam to PLN - Indonesia Power plants and its own power plants with a total installed capacity of 220 MW (4X55MW). There are a total of 30 production wells owned by PGE Ulubelu to fulfill the steam demand. Based on production test data and well histories, if all potential production wells can supply the system, the expected power generation can reach at least 4 x 50 MW. Steam supply shortages are due to decreased production well capacity and wells that cannot supply into the system due to various reasons. One of them is a bottleneck on the pipeline side. A study and simulation are conducted before the debottlenecking process. Debottlenecking is done by changing the configuration in the system supply to the plant by adding new pipeline and separator so that the steam supply provided is optimal. The wells that previously couldn't supply steam to the system (UBL-38 and UBL-45) can now supply steam to the system again and additional steam supply of a total of 18 MW was obtained after debottlenecking. From the series of processes conducted, it can be concluded that increasing steam supply can be achieved not only by drilling new wells but also by optimizing production well facilities from upstream to downstream, considering various aspects and utilizing well data owned with relatively lower costs.

1. INTRODUCTION

Indonesia continues to strive for net zero emissions, a situation where the amount of carbon released does not exceed what is absorbed by the earth, as part of its efforts to maintain the earth's climate balance (Nabila, 2022). This is being pursued through various strategic steps, one of which is increasing the utilization of new and renewable energy (NRE). The target for NRE's share in the national energy mix is to reach 39% by 2040 and 66% by 2060. One potential energy source is geothermal energy, where Indonesia possesses about 40% of the world's geothermal energy or approximately 28,617 MW, although its utilization is still very low. The low utilization of geothermal energy is due to several factors such as high exploration risks, varying economic feasibility of geothermal power plants, locations intersecting with conservation areas, issues in setting electricity sale tariffs, and social issues (Anindya, 2023).

PT Pertamina, through its subholding Pertamina Geothermal Energy, actively contributes to maximizing Indonesia's geothermal potential by harnessing geothermal energy to produce electricity. One of Pertamina Geothermal Energy's working areas is the Ulubelu area in Lampung province, with a total installed capacity of 4 x 55 MW. Units 1 and 2 belong to PT PLN with a steam sale business scheme, while units 3 and 4 operate on an electricity sale business scheme. A total of 186 MW out of 641 MW (29%) of the generation capacity in Lampung province is supplied by steam and electricity produced by Pertamina Geothermal Energy Ulubelu Area. Although the energy contribution percentage in Lampung province is relatively high, this capacity has not reached the target of installed capacity due to several factors that need to be analyzed to take the most appropriate action.

PT Pertamina Geothermal Energy began steam production in 2012, which was then supplied to PT PLN's power plants units 1 and 2 to generate electricity. In 2016, PGE started independently producing electricity at unit 3, followed by unit 4 in 2017. During the early steam production period from 2012-2015, there was a decrease in production capacity at units 1 and 2. From 2016 to 2022, total generation increased with the addition of new power plant units 3 & 4, but the maximum production capacity of each individual plant decreased. Out of the installed capacity of 55 MW, the highest generation per unit only reached 4 x 50 MW in 2019, with 20 operational wells out of a total of 28 production wells. This condition could be influenced by both internal factors such as upstream (steam supply) and downstream (plant performance) issues, as well as external factors like climate change due to global warming. Rising temperatures each year affect generation because the power plant type is condensing pressure, meaning temperature increases impact cooling and the achievable vacuum.

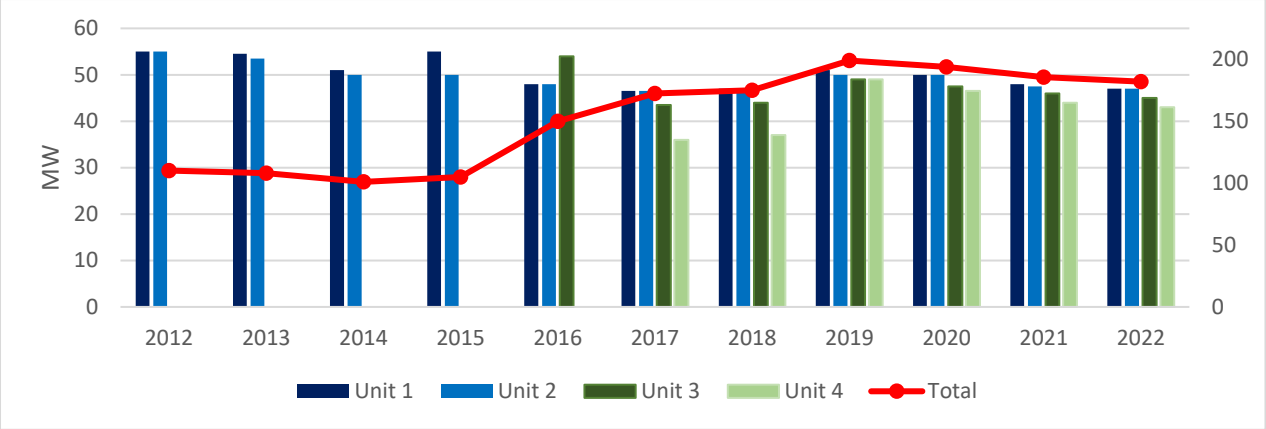

Figure 1: Power Plants Capacity from 2016-2022.

On the upstream side, it was found that with the same number of production wells, the capacity achieved decreased. Production well declines occur over time and can vary significantly (Sanyal, 2000). In the Ulubelu geothermal field, production well capacity declines at a rate of 5%. To compensate for this, new wells are drilled to achieve maximum production capacity. There were an additional 2 production wells by 2022, but this was not sufficient to meet the steam supply needs. Even with these additional wells, total generation in 2022 was lower than in 2019.

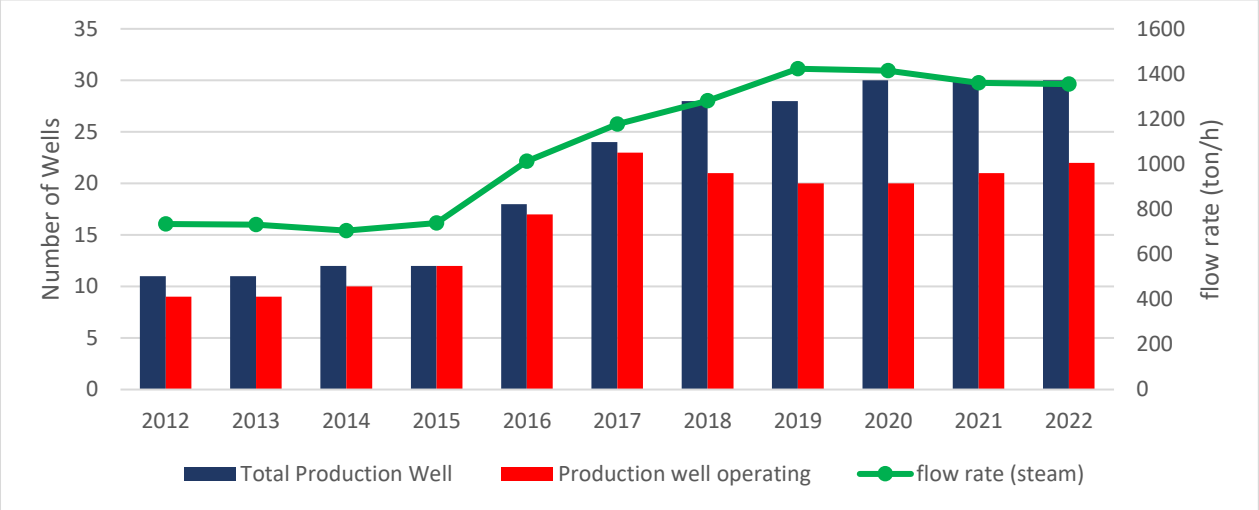

Figure 2: Production Well from 2016-2022.

2. METHOD AND RESULT

PGE monitors production and reinjection wells through Tracer Flow Tests (TFT). These tests are crucial not only for subsurface studies but also for measuring the flow rate of geothermal two-phase fluids, which is then used to determine the capacity of geothermal production wells through various approaches (Axelsson, 2013). The latest test results indicate that the total capacity of all production wells is equivalent to 206.84 MW. This shows that the plant's capacity can still be optimized through certain steps to at least reach the highest generation ever achieved, 4 x 55 MW or 200 MW.

In 2022, PGE Ulubelu had a total of 30 production wells, but only 22 could be connected to the system. Wells UBL-12, UBL-16, UBL-29, and UBL-30 were shut-in due to low pressure and could not enter the system, while well UBL-27 was tentatively connected due to its interference with UBL-56. When both wells were operated simultaneously, a pressure drop occurred in UBL-56, and the pressure in UBL-27 progressively decreased from the initial system entry until it fell below the header pressure. Wells in cluster I could not enter the system because the flow pressure in the pipes from cluster J was much higher than the flow from cluster I at the tie-in point between clusters J and I, preventing cluster I from entering the central separator. This condition was considered a bottleneck that needed to be addressed.

Table 1: Well Production Capacity of Ulubelu Field.

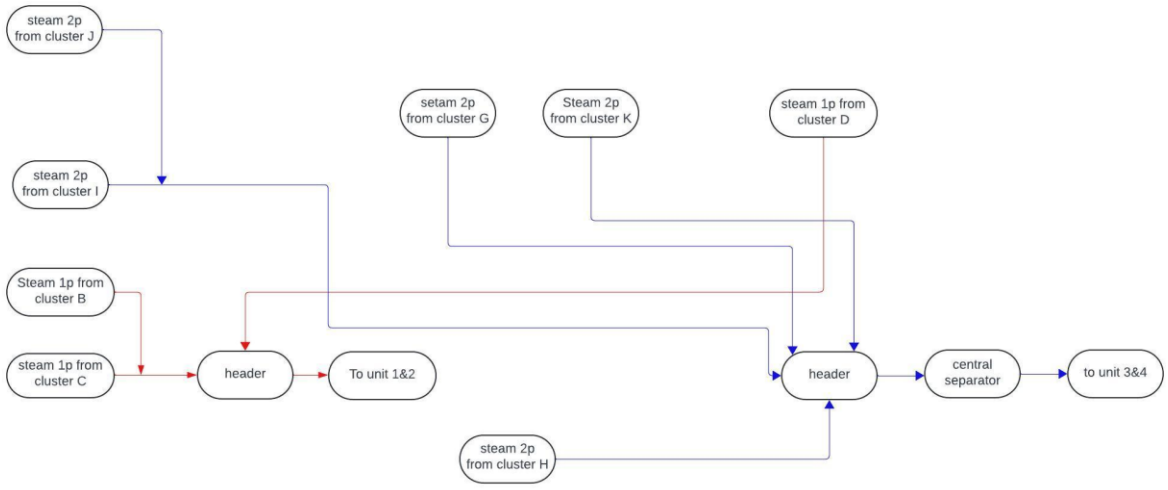

Figure 3: SAGS Configuration before Debottlenecking.

Debottlenecking efforts began with simulation modeling using Aspen Hysys software with the NRTL (Non-Random Two-Liquid) fluid package. This choice was made because the simulation involves not only water but also carbon dioxide as a non-condensable gas. The NRTL fluid package was selected to provide the best correlation for this complex system. The simulation was conducted under conditions where wells in cluster I could enter the system. The simulation results required changes to the production system route and the addition of a separator.

Wells from cluster I would re-enter the system to supply steam to units 3 and 4, while steam from cluster J, initially using the cluster I route, would be redirected to a new separator and through a new route supplying units 1, 2, 3, and 4, with a dominant supply to units 1 and 2. The addition of a separator is necessary for the wells in cluster J due to the limited design capacity of the separator in units 1 and 2, which could create new issues for the wells in clusters B and C if they are combined through a two-phase flow route. With the new route specifically created for the wells in cluster J, there will be a pressure reduction in the cluster I route, allowing the wells in cluster I to re-enter the system and flow towards units 3 and 4. However, on the other hand, the steam supply to units 3 and 4 decreases because the flow from cluster J wells is no longer maximized towards units 3 and 4, and there is an increase in flow to units 1 and 2. Additionally, a new route was added so that steam from cluster D could flow to

supply units 3 and 4, helping to compensate for the steam shortfall due to the route changes in the cluster J wells. Dividing the flow and adding new routes would reduce pressure in the existing routes, allowing wells to optimize their supply to the system.

The simulation results were implemented and completed in early February 2023. Post-debottlenecking, generation increased by 18 MW. This increase was due to wells in cluster I entering the system as per the simulation results, bringing the total number of production wells in the system to 24. Comparing post-debottlenecking generation with TFT analysis results, the actual plant capacity reached 97%.

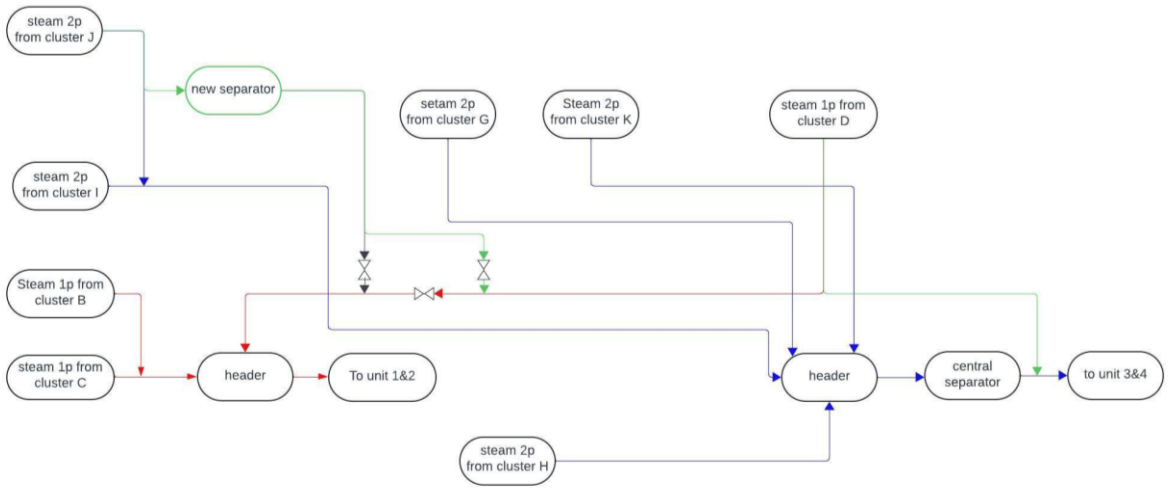

Figure 4: SAGS Configuration After Debottlenecking.

Table 2: Comparison of Before and After Debottlenecking.

Component	Before Debottlenecking	After Debottlenecking
Total Capacity (MW)	182	200
Total Production Well	30	30
Operated Production Well	22	24

3. CONCLUSION

The bottleneck in the Ulubelu geothermal field was due to the SAGS configuration, preventing all potential wells from supplying the system. Debottlenecking involved reconfiguring the SAGS by modifying the steam route and adding a new separator. The occurrence of bottlenecks in steam configuration can be prevented by utilizing more comprehensive data related to the geothermal field and the production wells that will be operated, as well as through a comprehensive approach and operational planning. However, in practice, geothermal development is often carried out in stages due to high costs, which means that the necessary data is not always available in full during the early construction phase. Additionally, changes in production well conditions and discrepancies between estimated well potential and actual conditions after drilling often require adjustments in approach and planning to maximize the available potential. Therefore, the implementation of predictive technology and scenario-based planning becomes crucial to addressing these challenges, with the aim of optimizing resources and preventing operational bottlenecks in the future.

ABSTRACT

This paper discusses the lessons learned from a forced outage (FO) incident experienced at Geothermal Power Plant (GPP) Lumut Balai Unit 1 on April 14, 2024. The FO was triggered by a lightning strike on the 150 kV transmission lines from the GPP to the Tanah Abang Substation (owned by PLN) used to deliver electricity production to customers. The strike occurred at 16.7 km and 19.8 km from the GPP and activated the 87L protection relay which triggered Auto-reclose 150 kV CB operated on phase R. This, in turn, caused all motors on the medium voltage 6.3 kV system (HWP A & B, LRVP A & B, CT FAN A to F) to trip due to an unbalanced system on the Grid detected by its negative sequence current (46) relay.

Through detailed analysis of the event, including root cause analysis and examination of system protection settings, valuable lessons were identified to improve system reliability and prevent similar incidents in the future. The focus was particularly on motor protection during unbalanced system faults on the Transmission Line.

It was found that the delay time of the unbalance relay for the medium voltage (MV) motors in GPP Lumut Balai Unit 1 had been set for 1 second. However, according to IEEE Std C37.96-2012, the recommended standard value should be 10 seconds with a pickup value of 15%. This deviation caused the unbalanced relay protection in the GPP to operate prematurely during single phase grid disturbances or during Auto-reclose 150kV CB Operated, where the deadtime of recloser is only 1 second. When the unbalance system was detected, the relay operated within 1 second, causing all motors on the medium voltage 6.3 kV system to trip, resulting in the turbine trip and the opening of Circuit Breaker 52G. The 3-hour forced outage at PLTP AG Lumut Balai resulted in an Equivalent Availability Factor (EAF) loss of 0.07% and an Equivalent Forced Outage Rate (EFOR) increase of 0.034%.This overly sensitive unbalance relay protection setting caused unnecessary trips. Evaluating the delay time according to IEEE standards for the unbalance relay is essential to prevent the unit from experiencing unnecessary protection trips. This paper emphasizes the importance of proper relay settings and adherence to industry standards such as IEEE Std C37.96-2012. Recommendations for enhancing system protection and reliability in power generation plants are provided.

1. INTRODUCTION

Protecting induction motors in power plants is paramount to maintaining operational reliability and efficiency. According to IEEE Std C37.96-2012, a critical protective relay used is the motor unbalance relay, which safeguards equipment against current and voltage imbalances. This relay ensures that motors operate within acceptable operating limits, preventing potential damage and outages.

This study focuses on identifying the root cause of a forced outage that occurred at the Lumut Balai Geothermal Power Plant on April 14, 2024. The objectives are to determine the underlying issues, propose solutions to prevent recurrence, and evaluate whether the relay setting and coordination are in compliance with IEEE Std C37.96-2012. By addressing these aspects, the study aims to enhance not only reliability of the motor but also reliability and availability of the Lumut Balai's Geothermal power plant.

2. TRANSMISSION LINE PROTECTION SYSTEM

Transmission lines are the backbone of the power grid, whose main function is transferring electricity power from a source to a load point over long distances. The role of transmission line protection is to detect and isolate faults with high selectivity, so that faults in one line are isolated without causing disruption to the rest of the system. The necessity for precise transmission line settings arises from the need to maintain the stability and efficiency of the power grid, preventing issues such as voltage drops, power outages, and energy inefficiencies since transmission line protection failure is one of the leading causes of power system collapse, and blackout.

Distance and differential relays are the two most commonly used transmission line protection methods. Traditionally, both use fundamental-frequency voltages and/or currents to protect transmission lines as shown on Figure 1. Two sources represent the grid on the sending and receiving sides. There are distance and differential relays in each bus with a voltage transformer (VT), current transformer (CT) and circuit breaker (CB). The relays get the relevant measurement from the VT and CT, take decisions based on the available data and send the trip signal to the CB. In the case of the differential relay, there is necessarily a communication channel between the two line terminals.

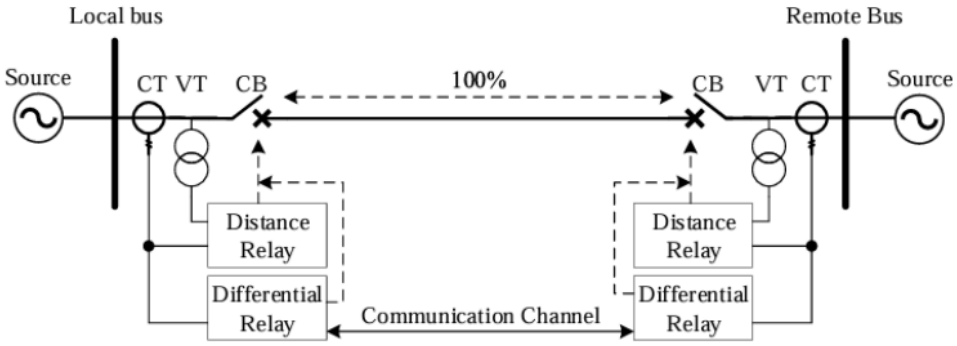

Figure 1: Single Line Diagram Protection of Transmission Line.

2.1 Distance Relay Protection

Distance relay protection is a widely used method for protecting transmission lines. It can work with measurements from the relay's location, without communicating with the other line terminal, and is relatively simple to implement in numerical relays. A distance relay calculates fault impedance from the local measurement of voltage and current, and compares this with a preset impedance to determine whether the fault is within its operating region or not as Figure no 1. The fault distance is inferred from the impedance, as the electrical characteristics of a transmission line relate its length to its impedance, hence the name distance protection.

Distance relay protection is a non-unit type of protection, its protection zone is not strictly limited within the protected line segment. Distance relays are designed to operate with different zones. The zone 1 is usually set at around 80% of the line length, usually set to be instantaneous (no deliberate delay). The zone 2 and the zone 3 are usually set at 120% and 220% of the line length, with added delay. Zone 2 ensures that the protected line is entirely covered, in case of faults beyond zone 1. Its delay gives time for a fault just beyond the line end to be cleared by protection relays closer to the fault. Zone 3, where used, provides a backup to other protection relays.

2.2 Differential Protection

Differential protection operates on Kirchhoff's current law, that the total current entering the protected zone should be equal to the current leaving it under normal conditions. As shown on Figure 1, differential protection, therefore, requires fast communication between two terminals of the protected line for transmitting measurement data. It is a unit-type protection, provides excellent selectivity, and is immune to many different system changes. However, practically, differential protection always needs backup protection due to the possibility of communication channel failure.

2.3 Transmission Line Setting

For the protection system of the Transmission Line, we use Micom P545 Agile as the brand and type of the relay. This protection relay has 2 activated functions, which is Distance Relay (21) and Line Differential Current (87L). Furthermore, the autoreclose function is set on this relay based on the sending of 87L.

2.3.1 Distance Relay Setting

The 150kV Lumut Balai substation is connected to the 150kV Transmission line Tanah Abang Substation by using two (2) lines, line 1 and line 2. The estimated length of the transmission line around 19.3km as shown in Figure 2.

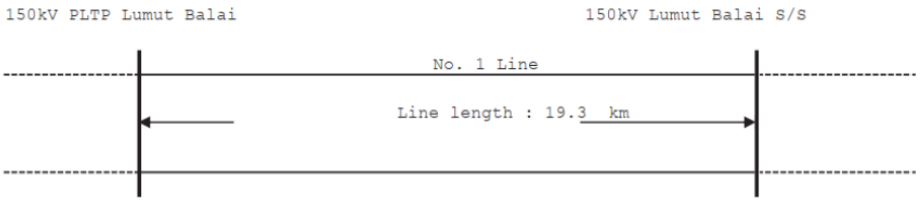

Figure 2: 150kV Transmission Line Lumut Balai unit-1.

Line impedance of 150kV Lumut Balai unit-1 to the 150kV Transmission Line Tanah Abang :

- Z1 (Positive sequence impedance): 4.67 ∠ 74.73842883 Ω
- Z0 (Negative sequence impedance) : 28.88 ∠ 72.18920452 Ω
- Zm (Mutual impedance) : 6.07 ∠80.98023335 Ω
- Source impedance (Zs) : 2.75 Ω
- Minimum fault current : 5589.66A

These setting was programmed to the Micom P545 Agile as shown on Table 1.

Table 1: Line Parameters.

Address	Name	Value
GROUP 1 LINE PARAMETERS		
30.02	Line Length	19.3 km
30.03	Line Impedance	4.7 Ohm
30.04	Line Angle	74.7 deg
30.05	kZN Res Comp	1.71
30.06	kZN Res Angle	-3.04deg

2.3.2 Line Differential Current Setting

On a per-phase basis, the current inputs at each protected terminal are measured and communicated to devices at the other protected terminals. This allows for fault detection and tripping initiation, if necessary. At each device in the scheme, the remote current measurements received through the communication links are processed and compared with the local signals. This comparison allows the derivation of the differential current and bias current values on a per-phase basis.

The differential and bias currents are then compared against a tripping criterion defined by a dual-slope characteristic, as shown in Figure 3.

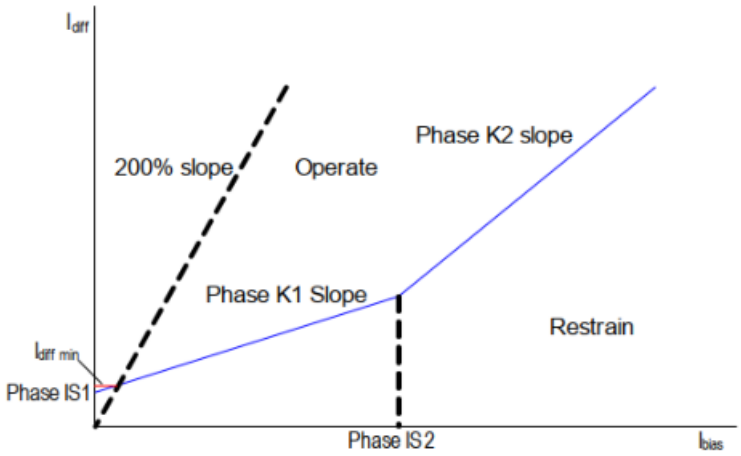

Figure 3: Dual slope current differential bias characteristic.

Refer to Figure 3 above, the phase current differential characteristic is defined by four settings:

- **Phase Is1**: The basic differential current setting which determines the minimum pick-up level of the protection.
- **Phase k1**: The lower percentage bias setting used when the bias current is below the Phase Is2 setting. This provides stability for small CT mismatches, while ensuring good sensitivity to resistive faults under heavy load conditions.
- **Phase Is2**: A bias current threshold setting, above which the higher percentage bias setting Phase k2 is used.
- **Phase k2**: The higher percentage bias setting used to improve protection stability under heavy through fault current conditions.

The tripping criteria is defined by the bias characteristic graph. Basically if the differential current is above the line, the protection will trip. If it is below, the protection will restrain. Final setting of line differential current protection can be found on Table 5.

Line Circuit Breaker (CB). After the temporary fault is cleared, then the 150kV Line CB will close again. If the fault is not cleared or if a permanent fault is detected then the 79 Final trip will trigger Lockout relay (86-1) to work and open permanently 150kV Line CB. These two functions will give some event on the Sequence of Event (SOE) on the Distributed Control System (DCS) as shown on Table 6.

Table 5: Line Differential Current Setting.

3. MOTOR UNBALANCE PROTECTION

3.1 Working Principle & Type of Relay

The most common cause of unbalance for three-phase motors is the loss of phase resulting from an open fuse, circuit breaker, connector, or damaged conductor. Unbalances in other connected loads can also affect the motor. A voltage unbalance of 3.5% can produce a 25% or greater increase in motor temperature. This results primarily from negative sequences produced by the unbalance.

Unbalanced currents cause excessive heating in motor rotors due to opposing magnetic fields in parts of the rotor of either synchronous or induction motors that can result from excessive unbalanced (negative-sequence) currents. This current produces flux in the motor air gap rotating in the opposite direction to the actual motor direction. The relative effect is essentially double-frequency current in the rotor. Higher resistance in the rotor further increases heating, and negative-sequence impedance remains essentially at locked-rotor value. Thus, high current and high resistance compound the heating effect. Derating guidelines for unbalanced voltage are provided in NEMA MG-1, Part 20 and Part 21, respectively. Negative-sequence currents reduce the available accelerating torque.

Several types of relays are available to provide phase unbalance protection, including single phasing. Most of these relays are described in Chapter 4 of IEEE Std 242-2001 (IEEE Buff Book™) and in IEEE Std C37.96™-2012. list common protection relay that being used as follows :

a. Phase current unbalance (Device 46).

   This relay protects against unbalanced currents in a polyphase circuit. Mechanical phase current unbalance relays are induction disk devices that detect unbalance in the currents in the three phases. These relays inherently have a time delay. Occasionally, a timer is used to obtain additional delay. Because this relay cannot protect for unbalances less than 25%, its selection is questionable except for complete loss of one phase. Unfortunately, this device shares the same device number as the negative sequence overcurrent relay (Device 46) in item d).

b. Phase current unbalance high resistance ground (HRG) (Device 46).

   In high-resistance grounded (HRG) systems, setting a current unbalance relay (Device 46) to trip can cause unwanted tripping during ground faults. While some low-voltage (LV) protection relays have a blocking function to prevent this, if the Device 46 lacks such a function, it's recommended to use it for alarm only.

c. Reverse-phase (Device 46).

   This relay protects aganninst reversed phase sequence in a polyphase circuit. This relay is rarely used for motor unbalance protection.

d. Negative sequence overcurrent (Device 46).

A negative sequence overcurrent relay is a time over-current relay with extremely inverse characteristics that operates at very small levels of negative sequence current. Settings are available to alarm before trip and to trip upon a limit of I22t.

e. Negative sequence voltage (Device 47).

Because negative sequence voltage relays operate instantaneously on negative sequence overvoltage, some external time delay might be necessary.

f. Voltage balance (Device 60).

The voltage balance (60) element compares voltage sources to determine if there is a difference in voltage, i.e., for VTs determining if both input sources are present or if there is an open fuse losing one source. If a source is not present, then the output of this element blocks (removes permission) from tripping or starting elements. The voltage balance 60 relay is an older method than voltage-unbalance 47 protection, which is based on sequence components

3.2 Relay Selection & Setting

Geothermal Power Plant Lumut Balai unit-1 is designed to use the negative sequence current (46) as the unbalanced protection of the Medium Voltage (MV) motor. The negative sequence current is contributed by the motor or system when :

1. An unbalance voltage condition exist (e.g., open-phase conditions, single-phase faults, or unbalance load)
2. Stator coil cutout occurs during a repair
3. There are shorted turn in the stator winding

These negative-sequence currents induce double line-frequency current that flow in the damper or rotor parts. Final setting of 46 Relay protection of the MV motor are shown on Figure 4.

46 : Negative sequence current / unbalance

Element activity : On

Setting group
- Tripping curve : Definite time
- Threshold current : 15 % of IB
- Delay : 1000 ms

Tripping behavior

Output O1 - Type : Normally Open

Output O1 - Mode : Pulse

Activate output O1 : Yes

Trigger fault recording : With

Activate indicators : L9

Figure 4: Parameter setting of relay 46 (negative sequence current).

The setting curve has a definite time, when the negative sequence current is exceeding its setting value (15% of Ib) then the relay will work after 1 second as its delay time of the protection relay.

4. RELIABILITY AND AVAILABILITY OF POWER PLANT

The reliability and availability of power plants, as indicated by metrics like EAF and EFOR, are crucial for ensuring consistent and efficient power generation. By focusing on these metrics, power plant operators can improve performance, reduce costs, and ensure a stable supply of electricity.

4.1 EAF (Equivalent Availability Factor)

The Equivalent Availability Factor (EAF) for a power plant is a measure of the reliability and availability of the plant to generate electricity over a specific period of time. It is typically expressed as a percentage and is calculated based on the actual availability of the plant compared to its maximum potential availability under ideal conditions.

$$EAF = \frac{Availabe\ Hours}{Period\ Hours} \text{x } 100\% \quad (1)$$

- Available Hours = The total number of hours during which the power plant is ready to operate (Total hours in the period - Production loss hours).
- Period Hours = Total hours in the observation period.

4.2 EFOR (Equivalent Forced Outage Rate)

EFOR is Equivalent Forced Outage Rate. It is a metric used in the energy and power generation industry to measure the reliability and availability of a power plant or a specific unit within the plant. EFOR specifically focuses on the rate of forced outages experienced by the unit or plant

$$EFOR = \frac{Forced\ Outage\ Hours}{Total\ Available\ Hours} \text{x } 100\% \quad (2)$$

- Forced Outage Hours = Total hours during which the unit or plant was unavailable due to forced outages.
- Total Available Hours = Total operational hours during the same period.

5. PLANT INTERLOCK

The steam turbine and steam turbine generator are provided with the protection system to prevent unsafe conditions during normal or emergency operation. To ensure the safety operation of the plant, interlock between the steam turbine control system and steam turbine generator control system is designed to shut the plant down automatically. The basic concept of interlock between steam turbine control system and steam turbine generator control system is as shown below :

5.1 Initiation of steam turbine generator protection system

When the Generator Protection System is initiated, the steam turbine and generator are automatically tripped immediately.

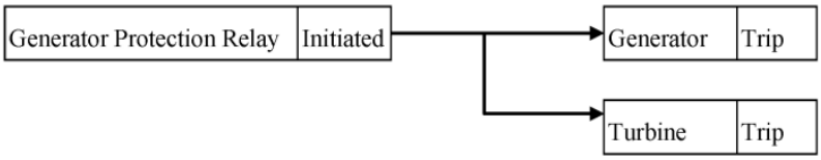

Figure 5: Generator Protection Trip Command.

As shown in Figure 5, both Generator and Steam Turbine will automatically trip when the Generator Protection Relay detects any internal or external fault that might cause damage to the Generator. List of Generator Protection Relay Function is refer to the electrical interlock diagram which is consist of several relay like Generator Differential (87G), 3rd Harmonic Neutral Undervoltage (27TN), Neutral Overvoltage (59N), VT Fuse Loss (60F), Generator Loss of Field (40G), Generator Reverse Power (32G), Generator Out of Step (78G), Generator Negative Sequence (46G), Generator Over Excitation (24V/F), Generator Overvoltage (59G) and AVR Protection.

5.2 Initiation of steam turbine protection system.

When the turbine protection system is initiated, the steam turbine generator is automatically tripped immediately.

Figure 6: Turbine Protection Trip Command.

As shown in Figure 6, when turbine protection detects any anomalies that exceed its operation limit then the turbine will trip and then this signal will be sent as input for the generator trip. The turbine protection consists of following protection such as D-EHC Heavy fault, Turbine overspeed, Both Hot Water Pump trip, Condenser vacuum low low, etc.

6. FORCED OUTAGE REPORT AND ANALYSIS

Forced Outage Report & Analysis delves into the critical process of documenting and analyzing these unplanned outages. By systematically recording and scrutinizing forced outages, power plant operators and engineers can identify underlying causes, assess the impact on plant performance, and develop strategies to prevent future occurrences.

6.1 Sequence of Events turbine trip

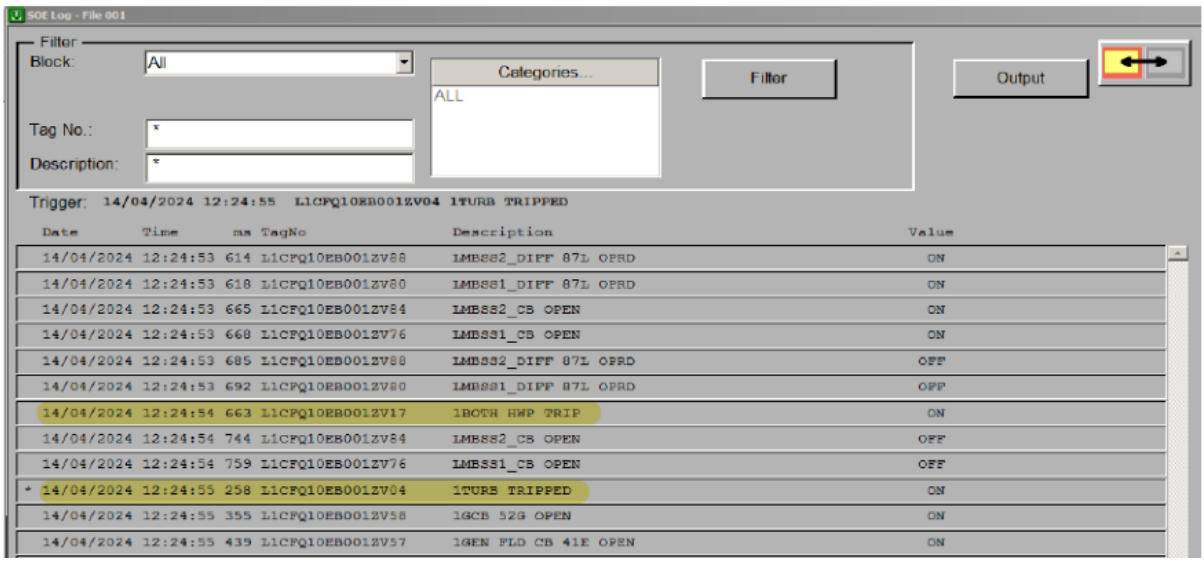

Figure 7: Tosmap SOE (Sequence Of Event) Turbine tripped.

The Sequence of Events (SOE) log in Figure 7 indicates that on April 14, 2024, at approximately 12:24:55, there was a disturbance on phase R of the 150V transmission line, as evidenced by the actions taken by the protection systems (87L operated) and 150kV CB line open. The specific event "1TB TRIPPED" signifies a major issue that triggered a series of protective measures. In response to the detected anomaly, the corresponding 150kV line circuit breakers (LMBSS1_CB and LMBSS2_CB) were opened to isolate the fault and protect the system. The repeated switching of these circuit breakers due to activation of the reclosure function caused further protective actions, including the "BOTH HWP TRIP" Ultimately, these protective measures culminated in the "1TB TRIPPED" event, signifying that the turbine was tripped to prevent damage and maintain the integrity of the whole system.

6.2 Root Cause Analysis

Lumut Balai Geothermal Power Plant experienced a turbine trip due to an external disturbance on the both phaseR of 150kV Transmission Line 1 and 2, this 1 phase fault caused by lightning strike produced a voltage drop and a current spike on the 150kV side phase R and neutral side. This triggered the operation of the Line Differential (87L) relay, leading to the tripping of all motors on the 6.3kV medium voltage side (HWP, LRVP, CT FAN) due to motor unbalance. Consequently, the tripping of both HWP motors caused the MSV and MCV to fully close, resulting in a turbine trip and the opening of breaker 52G as per Plant interlock diagram and PLTP Unit 1 entered a backfeeding condition.

When the lighting strike happened, voltage drop happened and automatically high current occurred on phase R of both transmission line 1 and Line 2. The Line Differential Relay on Line 1 and Line 2 detected the fault and attempted to mitigate the anomaly in the grid by activating the auto-reclose function.`

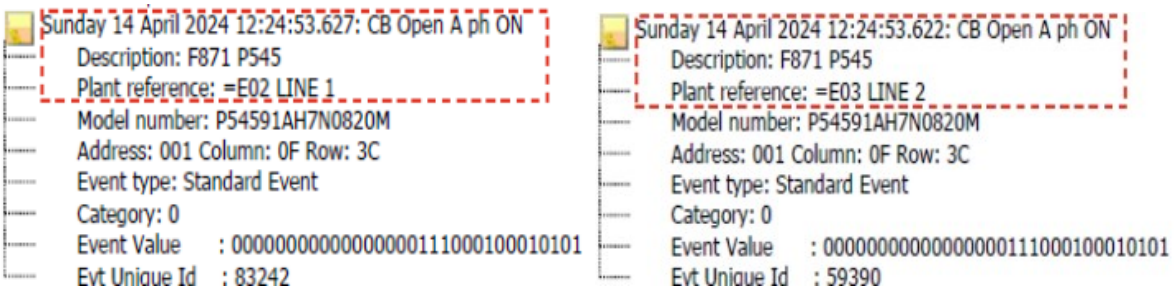

Figure 8: Auto reclose at line 1 and line 2.

As shown on Figure 8, the autoreclose is working to open 150kV Line CB Phase R on Sunday April 12, 2024 at 12:24:53:627 for line 1 and 12:24:53:622 for line 2. The autoreclose worked due to the external fault that was detected by the 87L relay.

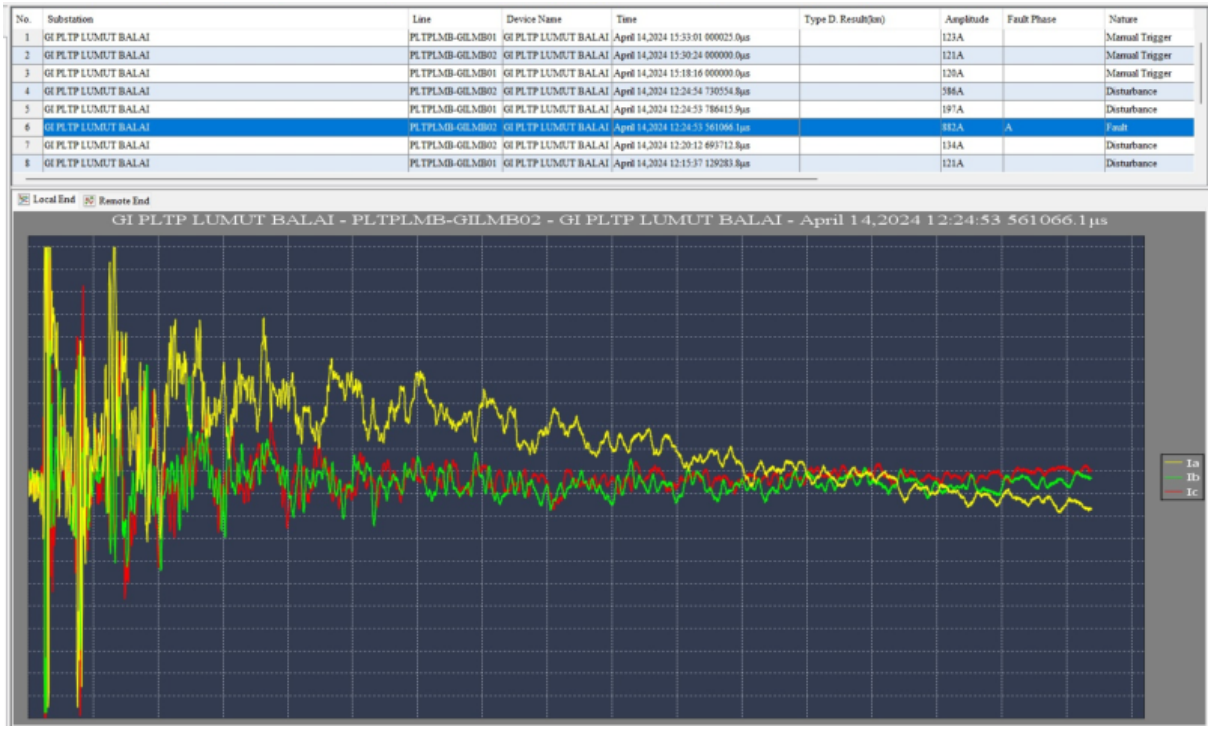

Figure 9: True Travelling Wave - failed in Phase A.

Based on Figure 9, it can be seen that there is an anomaly in phase R, with the value of the current spiking significantly at 12:24:53.

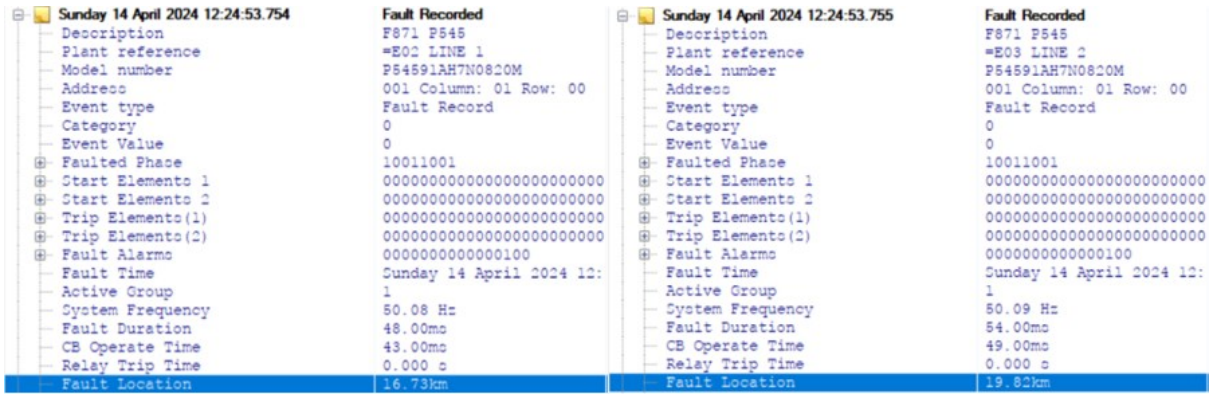

Figure 10: Fault Location.

In the Figure 10, From the data analysis of Micom Agile 150 kV line, auto reclose occurred on Line 1 due to a fault on phase R (CB Open A ph ON) at 12:24:53.627 with a fault location at km 16.73. Similarly, on Line 2, auto reclose also occurred on phase R (CB Open A ph ON) at 12:24:53.622 with a fault location at km 19.82. Based on the fault location, the distance relay protection also detects this fault, however since the location is not in Zone 1 for both lines then it needs additional time delay for the protection relay to be operated.

During the operation of the line differential (87L) protection system, which attempted to clear the fault by activating auto reclose on single phase R, the recloser's dead time setting is 1 second as shown on Figure 11.

Therefore, the auto-recloser waits for 1 second after detecting the first fault to determine if it's temporary or permanent. However, during this waiting period, an anomaly (unbalanced current) occurs on the medium voltage (MV) system. This anomaly is detected by the negative sequence current (46) relay protecting the MV motor. Since the unbalanced current reaches the relay's setting value and the 1-second time delay elapses, all motors on the MV side trip abruptly due to the motor unbalance protection.

Subsequently, tripping of both hot water pumps triggers the turbine to trip as well. This chain reaction results in an undesired forced outage at the Lumut Balai Geothermal Power Plant (PLTP). This outage could have been avoided if the time delay setting for the negative sequence current (46) relay on the MV motor had been longer than the dead time of the auto-recloser.

Figure 11: Setting Group of Autoreclose.

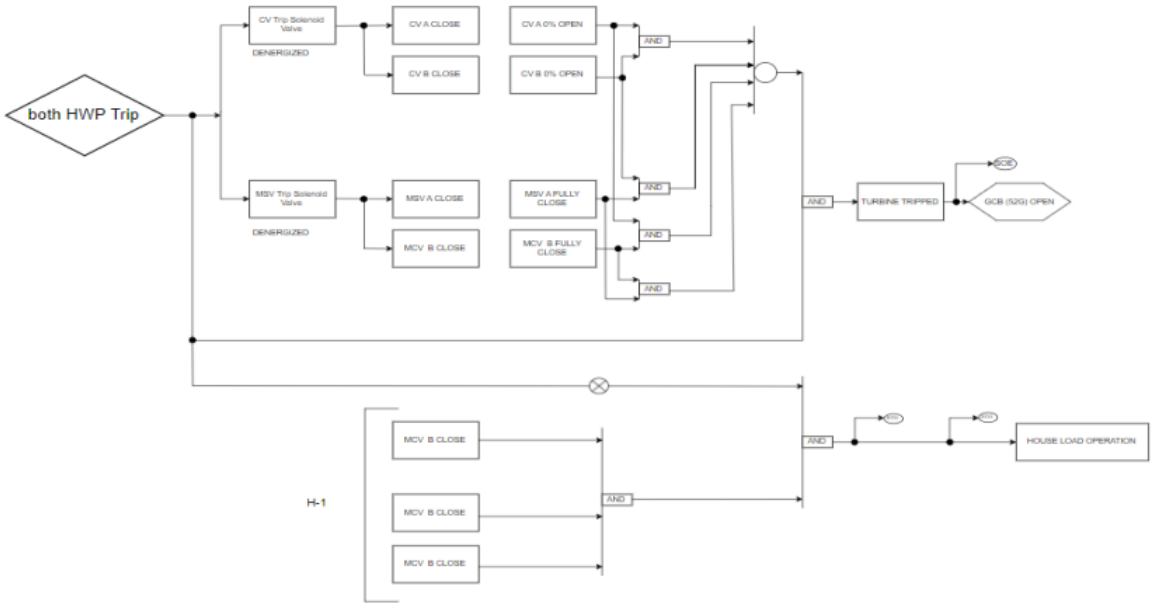

Figure 12: Plant Interlock both HWP trip.

According to the IEEE standard C37.96-2012, a delay time of 10 seconds is recommended for the motor unbalance relay. Ensuring proper coordination and setting alignment between upstream protection relays, such as the auto-recloser and the motor unbalance relay, is crucial to minimize unnecessary outages and ensure reliable operation of the power system.

From the plant interlock in Figure 12, it can be seen that when both hot water pumps trip, it will de-energized the main stop valve (MSV) and main control valve (MCV). This subsequently causes the turbine to trip and the opening of 52G, resulting in the Lumut Balai Geothermal Power Plant experiencing backfeed due to the disturbance.

Figure 13 shows a graphical representation of the simultaneous operation of auto reclose and the motor unbalance relay. When the line differential protection activates auto reclose to address the disturbance, the motor unbalance relay simultaneously detects the disturbance and begins its countdown.

As shown in Figure 13, a disturbance occurred on phase R Line 1 on Sunday, April 14, 2024, at 12:24:53.627 and auto reclose was active for a duration of 1.128 seconds. The differential currents, particularly IA Differential, exhibit a very high peak value (5476.385), indicating a significant imbalance or fault in phase R. The differential currents for phases B and C are relatively low, signifying that the primary issue lies within phase R.

As shown in Figure 14, a disturbance occurred on phase R Line 2 on Sunday, April 14, 2024, at 12:24:53.624 and auto reclose was active for a duration of 1.118 seconds. The differential currents, particularly IA Differential, exhibit a very high peak value (5259.318), indicating a significant imbalance or fault in phase R. The differential currents for phases B and C are relatively low, signifying that the primary issue lies within phase R.

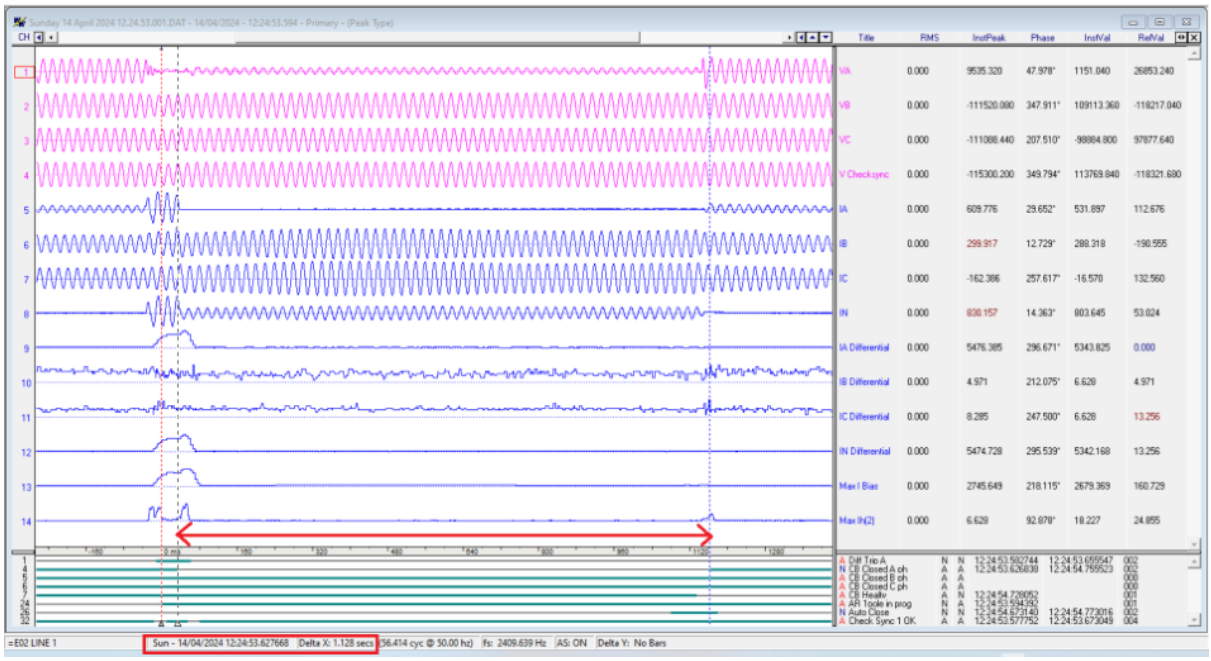

Figure 13: Auto reclose at Line 1 (87L).

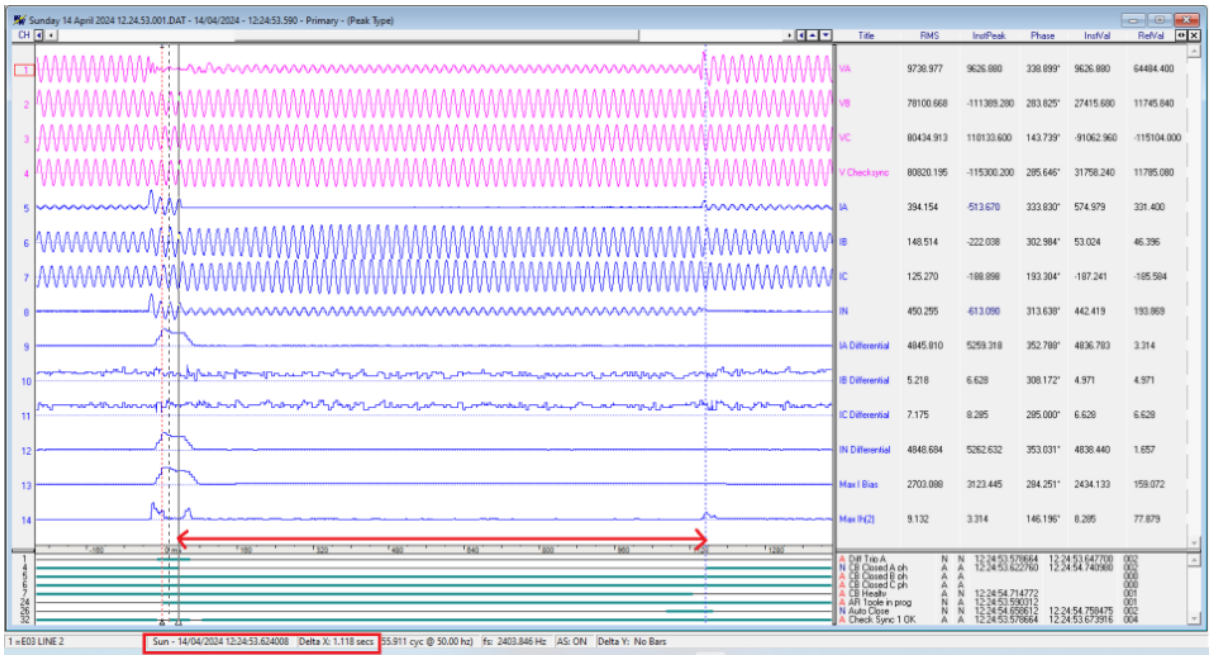

Figure 14: Auto reclose at Line 2 (87L).

As shown in Figure 15 of Hot Well Pump A, it appears there is unbalanced current in the system due to auto reclose on the phase R of the Transmission Line. The current on each phase R, S and T are uncontrollable at that time, unbalanced currents cause excessive heating in motor rotors due to opposing magnetic fields in parts of the rotor of induction motors that can result from excessive unbalanced (negative-sequence) currents. This current produces flux in the motor air gap rotating in the opposite direction to the actual motor direction. However, we need to understand that the condition will damage the motor if only the negative sequence current is high and also occur in a long duration exceeding the limit from the Manufacturer or any International Standard.

Similar to Figure 15, the HWP motor B also experiences the same condition (unbalance current on the MV system) during auto reclose on the 150kV Transmission line in Figure 16..

From the waveform data for Transmission Line 1 & 2, HWP A & B, we can conclude that when a lightning strike occurs and a disturbance happens on the grid, the protection relays, including the line differential relay and the motor unbalance relay, operate almost simultaneously. The line differential relay attempts to clear the disturbance

on the grid by activating the auto-reclose function, while the motor unbalance relay works to secure the equipment by responding to the motor unbalance condition setting.

Figure 17: Table event of auto reclose and unbalance.

6.3 Business impact of the outage

As a result of this incident, the Lumut Balai Geothermal Power Plant experienced a total downtime of 3 hours. This downtime reduced the Equivalent Availability Factor (EAF) by 0.07% and increased the Equivalent Forced Outage Rate (EFOR) by 0.034%. The estimated lost revenue amounted to IDR 191,472,442. This event underscores the critical importance of maintaining robust and reliable systems. By swiftly addressing such

challenges, we reinforce our commitment to operational excellence and uphold our company image as a dependable and resilient energy provider dedicated to sustainability and customer satisfaction.

7. IMPROVEMENT PROGRAM

The current setting for motor unbalance protection on the medium voltage (MV) motors is 15% of rated current (Ib) with a delay time of 1 second (definite time curve). and after conducting an extensive literature review , about relay coordination, sequence of events, O&M also According to the IEEE C37.96-2012 standard, the pick-up current setting already meets the requirement. However, the 1-second time delay is too fast and cannot accommodate any temporary voltage or current imbalances on the grid (known as "swing") that can occur during single-phase auto reclose operations. This overly sensitive unbalance relay protection setting caused unnecessary trips. The new value for the delay time is set to 10 seconds (definite time curve) based on the recommendations from the IEEE C37.96-2012 standard. This new time delay will provide proper protection for the motors in case of any real unbalanced condition (e.g., broken circuit components like cables, windings, or fuses) while preventing unnecessary tripping due to grid swings, unbalanced current transformer burdens, etc.

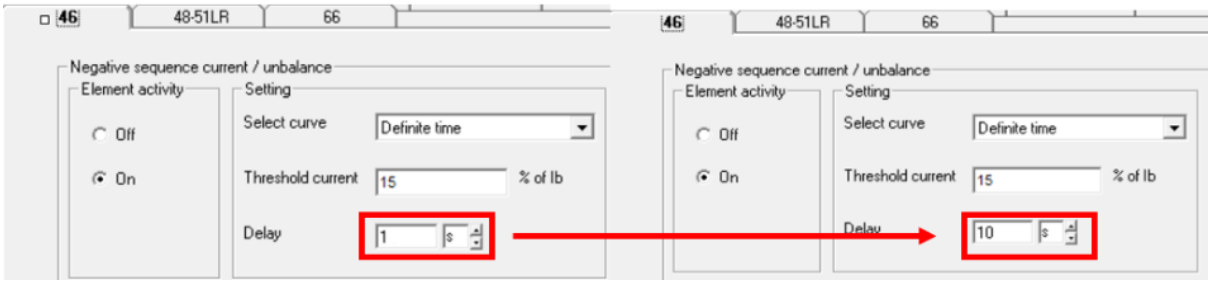

Figure 18: Delay time motor unbalance from 1s to 10s.

As shown in Figure 18, we modify the time delay of the negative sequence current (46) relay on the MV motor from 1 second to 10 second. Evaluating the delay time according to IEEE standards for the unbalanced relay is essential to prevent the unit from experiencing unnecessary protection trips and miss coordination with the upstream protection relay.

8. CONCLUSION

The unplanned outage at the Lumut Balai Geothermal Power Plant (PLTP) resulted from the simultaneous operation of the line differential relay's auto-reclose function and the motor unbalance relay, both configured with identical delay times. During the auto-reclose cycle, the motor unbalance relay detected phase differences, triggering unnecessary tripping of the motors even though the line fault had been cleared by the line differential relay. This unnecessary tripping can lead to increased downtime and potential equipment stress.

To prevent future occurrences and improve overall system reliability, we implemented a staggered delay time strategy between the line differential relay and the motor unbalance relay. This enhanced coordination between the protective devices minimizes the likelihood of unnecessary motor trips.

Following the IEEE C37.96-2012 standard, we adjusted the motor unbalance relay's delay time from 1 second to 10 seconds. This change ensures proper coordination, preventing unnecessary trips and enhancing system reliability. We expect this adjustment to eliminate similar incidents in the future, leading to a projected increase in Equivalent Availability Factor (EAF) by 0.07% and a reduction in Equivalent Forced Outage Rate (EFOR) by 0.034%.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to Pertamina Geothermal Energy Lumut Balai for granting permission to share the data used in this study.

ABSTRACT

Indonesia has 40% of the world's potential geothermal resources, estimated at 28,000 megawatts (MW). Patuha Geothermal Power Plant is one of the power plants that have been established in Indonesia and operated under PT. Geo Dipa Energi (Persero). Patuha Geothermal Power Plant has a capacity of 1 x 60 MW. One of the factors that contributes to power plant efficiency is Non Condensable Gas (NCG) content, like CO2 and H2S that can commonly can be found at steam compositions coming from geothermal wells. Patuha Geothermal Power Plant uses Gas Removal System that consisting of an ejector and liquid ring vacuum pump (LRVP). Gas Removal System has the function to extracting NCG accumulation and exhaust it into the atmosphere. Current operational condition at Patuha GRS system is a combination of 60 % ejector and one Liquid Ring Vacuum Pump in service. Meanwhile, on daily operating condition of Patuha power generation on each day can fluctuate depending on several factors, such as demand that has been determined by the grid dispatcher or production well capabilities producing steam, so that here Patuha Power Plant can operate in fluctuate condition and not always in full load capacity considering Patuha Power Plant is a power generation system that is following system in the national grid. So this condition is an opportunity for Patuha Geothermal Power Plant to increase energy efficiency by reducing the use of motive steam on the ejector system which is controlled based on the load conditions of the generator without affecting the ejector design. The consumption of motive steam used in ejector has the potential to be excessive because there is no control system that can regulate the steam motive flow to the ejector using a control valve. In general, the impact that occurs from the current operating base of the gas removal system consist of a 60% ejector in service without using a flow control valve (FCV) on motive steam line, is the excess of motive steam, which the motive steam should be able used to help the generation load on the generator turbine when there is not much steam production from the well. The solution for Patuha Geothermal Power Plant is to add a flow control valve to the motive steam line in the 60% ejector.

1. INTRODUCTION

Geothermal energy is a renewable energy with a stable characteristic for generating electricity and is used as the base load for power generation on national grid electricity. Geothermal power plants operate like other thermal power plants, using the rankine cycle principle. Steam as the working fluid will expand through turbines, which are coupled with generators to convert kinetic thermal energy to electrical energy. Indonesia has 40% of the world's potential geothermal energy resource, estimated at 28,000 MW. Patuha Geothermal Power Plant is one of those commercially operated by PT Geo Dipa Energi (Persero) with an installed capacity of 1 x 60 MW. Patuha Geothermal Power Plant is a dry steam power plant with characteristic vapor dominance, and there is little gaseous content such as carbon dioxide, hydrogen sulfide, methane, and others (Dipippo 2016). Non-condensable gas in geothermal power plants is one factor contributing to plant performance efficiency; otherwise, the NCG needs further handling to dissipate to prevent increasing condenser pressure and affecting turbine output. The influence Non Condensable Gas caused reduce geothermal fluid can be extracted in energy conversion, for each 1% NCG increase turbine losses 0,86% at inlet due to decreasing turbine inlet temperature (Gocken and Yildrim, 2008). Commonly, geothermal power plants use a gas removal system consisting of an ejector and a liquid ring vacuum pump (LRVP). Before the production well was completely drilled, the GPP surface facility design had already started due to the uncertainty of geofluid properties during the early stages; therefore, the sizing equipment gas removal system (GRS) used two to three times the actual condition (Yamin W et al., 2020). The principle operation ejector-based Bernoulli is that the accelerating high-pressure motive steam through the nozzle will be converted to velocity energy and sucking NCG at the lower pressure suction side. Currently, the Patuha Geothermal Power Plant GRS system is using a combination hybrid system operation with a 60% ejector and one liquid ring vacuum pump (LRVP) in service. The NCG content in the Patuha geothermal field, based on analysis during initial operation, was about 1.09%–1.14% by weight of total steam supply, and there was a decline to 0.68% by weight average NCG content in 2022. The daily operation flow consumption of steam as motive steam to gas removal system is 7.01 t/h and the inlet pressure is 7.79 bar. This condition means the means the motive steam pressure is

too high from the minimum inlet pressure and could potentially be reduced. Reducing the waste of disposed energy is significantly important to improving geothermal power plant performance (Pambudi et al., 2014). The motive steam to get the optimum point was to be set as close to the critical pressure limit (choked flow) as possible and obtain the highest efficiency (Hanafi et al., 2015). The suction load of the ejector will decrease if the motive steam supply pressure is greater than 20%–30%. In the above design, this condition causes too much steam to expand across the nozzle (Lines and Smith, 2000). This study aims to present a potential improvement in plant performance efficiency at the Patuha Geothermal Power Plant based on the current operating mode. To maximize potential excessive motive steam at 60% ejector, existing optimization will be carried out by installing an additional flow control valve (FCV).

2. METHOD

2.1 Research Methods

This study was conducted to determine the potential reduction of flow motive steam consumption that can be used in ejector 60% on gas removal systems (GRS). Research methods start with identifying the current pattern of the operating mode gas removal system (GRS), then conduct data collection to find the data design and operating ejector 60%, after that conduct a literary study to find the best methods to calculate related current ejector 60% steam consumption end ejector 60% design steam consumption. In this study we use data comparison between design steam ejector and operation data, the result of the literary study are applied to the determine the potential to reduce of motive steam consumption ejector 60%. After the data is obtained, the next step is to analyze minimum steam flow rate on motive steam ejector 60% and analyze opening flow control valve (FCV) on motive steam to obtain desired minimum motive steam flow rate. The flow diagram show on the Figure 1.

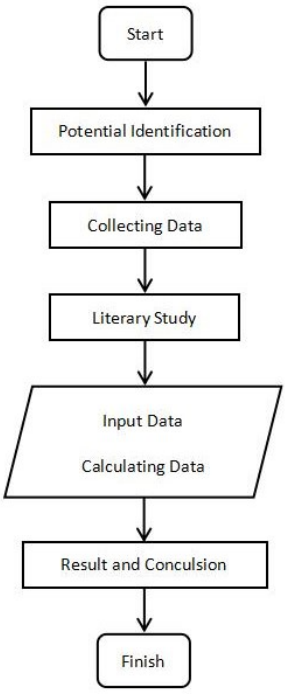

Figure 1: Research Methods Diagram.

2.2 Data Collecting Methods

2.2.1 Overview Gas Removal System

To remove NCG from the condenser and discharge it to atmosphere the most commonly Geothermal Power Plant used steam jet ejector, two or more stage ejectors can be arranged to get greater compression. In two stages system to condense the first stage motive steam and prior to ensure in the second stages only handles non condensable gas an inter condenser are used. A hybrid system operation are used to increase efficiency and reduce motive steam consumption, the gas removal system used Liquid Ring Vacuum Pump combiner with steam jet ejector (R.B. Swandaru, 2006). Figure 2 show the simplified process flow diagram gas removal system are used patuha geothermal power plant. The ejector is designed to operate at a specified steam pressure, ejector manufacturers summarize critical data on a ejector data design and performance curve. Table 1 shows ejector data design for a single stage ejector and figure 3 shows on a performance curve for a single stage ejector. On the y-axis of this curve is suction pressure bar absolute (bar A). On the x-axis is the water vapor equivalent load (kg/hr).

2.2.2 Operating Data Ejector

Currently operating mode gas removal system at Patuha Geothermal Power Plant is using hybrid combination system, depend on vacuum condenser with one 60 % ejector and one liquid vacuum pump (LRVP).The initial sampling result of NCG content based on first performance test at 2014 is about 1.09% - 1.14% by weight of total steam supply show on table 2 and there was decline to 0.68 % by weight average NCG content at 2022 show on table 3.

Table 2: NCG Analysis Result On Initial Performance Test 2014.

Date Time	GSA/Steam Ratio (ppm by Weight)
24/09/2014 12:00	1.14%
24/09/2014 15:00	1.12%
24/09/2014 19:00	1.09%

Table 3: NCG Analysis Result at 2022.

Date	GSA/Steam Ratio (ppm by Weight)
31/12/2012	0.68%

The current daily operation flow rate steam as motive steam to ejector 60% is average 7.019 t/h at 2022 show on table 4 and consumption of motive steam used in ejectors in service has the potential to be excessive due to there is a decrease in the total of Non Condensable Gas (NCG) and the flow motive steam required for the ejector potentially to be reduced.

Table 4: Average Steam Flow Rate at 2022.

Month	Steam Flow (t/h)

September	6.77
October	7.8
November	7.62
December	7.62

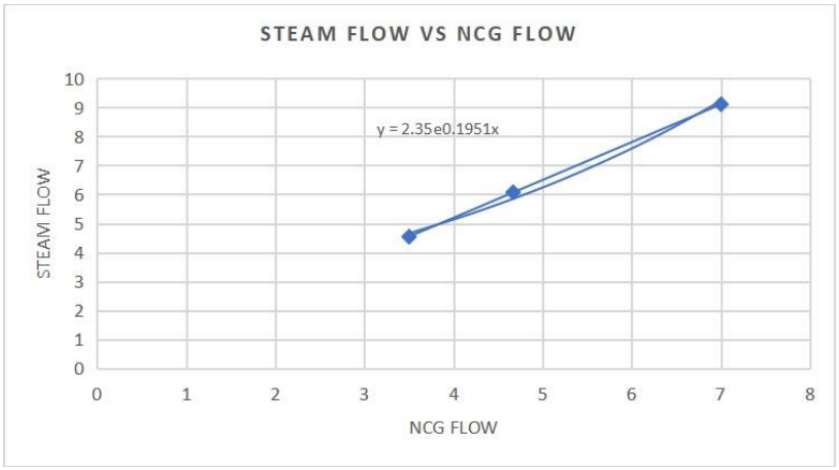

Figure 4: Function Relation Ratio Steam Flow and NCG Flow.

3.RESULT AND DISCUSSION

To analyze and calculate the motive steam flow rate required for the 60% steam ejector, are using the procedure of a function equation ratio based on the total suction load called the non-condensable gas (NCG) flow rate design and the motive steam flow rate design shown in Figure 4. In line with the decrease in NCG content average in 2014, the steam flow rate will also decrease. The steam consumption of a single-stage ejector is dependent on the mass flowrate (and molecular weight) of the gas to be handled (Bandoro, 2006). Meanwhile, also have to consider that the minimum suction pressure should not decrease below the minimum operating steam pressure of the ejector. Thus, the ratio between a suction load and motive steam flow rate can be determined by the equation.

$$y=2.35e0.1951x \quad (1)$$

Condition operation motive steam consumption was higher than the process requirement based on design, manufacture, and NCG content conditions. Based on the result of the study comparison design on steam ejector 60% with actual condition operation to obtain plant performance, we suggest the Flow Control Valve is possible to install to reduce excessive motive steam and give the optimum startup operation to control steam flow to ejector 60% depend on vacuum condenser and prevent over vacuum that cause turbine rolling when vacuum up operation and give the optimum startup without use ejector 30% or 40% to initial build up vacuum on condenser. Optimum operation flow control valve between 65% and 70% considered NCG content from steam. In this condition, we can reduce motive steam to 2.6-3.2 T/h as shown in figure 5. Based on the assumption that all excessive steam will flow through the steam turbine, the increased output of the steam turbine is approximately 300–400 KWH with the current steam-specific consumption (SSC).

ABSTRACT

Darajat Unit-1 steam supply comes from North Sector (60%) and South Sector (40%) areas. As some of the South sector wells have repetitive wellbore issues, Unit-1 steam supply dependency on North Sector is growing. This dependence intensified following a landslide in the South Sector (Cikupakan) on November 19, 2021, disrupting steam flow from Pad 4. Backup from Unit-2 wells (Pad-18) was required, potentially jeopardizing Unit-2's steam buffer and generation capacity in the long run.

To maintain steam supply to Unit-1 without interrupting Unit-2 steam supply, One of the mitigations is by reactivating the currently inactive wells i.e. DRJ-31 well. The well was put offline after latest sampling performed in May 2018 shows that the dryness possible was 95.37%.

Additional steam-liquid separation process is required in DRJ-31 pipeline to remove 4.63% liquid content from the produced steam. The separated steam would be directed to Unit-1, while the separated liquid would be flowed into the zero discharge condensate reinjection system. A dedicated separator was chosen due to its scheduling flexibility (not requiring Unit-1 shutdown for installation) and cost-effectiveness.

The dedicated separator was designed according to ASME Sec VIII Div 1 (2019 ed.) standards. Unlike typical wellpad separators, the DRJ-31 separator utilizes a fast-acting LCV (level control valve) to ensure a minimal liquid level inside the vessel. This approach obviates the requirement for a loop seal, which conventionally necessitates a vessel skirt height of up to 7 meters. Fabrication, installation, and commissioning of the separator were completed over a span of 10 months, from June 2021 to March 2022. Performance testing was conducted to find optimum delta pressure which resulted in highest possible steam quality (min 99%) and the most optimum steam flowrate, with dryness reaching up to 99.8% at specific wellhead pressure and flow rate.

Since its reactivation in February 2022, DRJ-31 has consistently delivered an average steam flow rate of 10.9 kg/s, equivalent to the production of approximately one makeup well. As of the latest operation report, DRJ- 31 is currently producing 15 kg/s of steam at WHP of 13 barg. This successful re-activation enhances Unit- 1's steam supply security and reduces reliance on Unit-2 wells.

1. INTRODUCTION

Darajat unit-I steam supply is maintained by group of wells in North and South Sectors, i.e. DRJ-7, DRJ-9, DRJ-10, DRJ-11, DRJ-31 in North area and DRJ-8, DRJ-13, DRJ-34 in South area. North area wells supports around 60% of steam delivered to Unit-1, while the rest (40%) comes from South area wells. As most of the Southern wells are known to have repetitive wellbore issue (e.g. scaling), Unit-1 steam supply dependency on Northern wells production is growing over time.

Since 19 September 2021, steam supply from South Sector has been significantly reduced due to landslide at Cigupakan area, damaging some south sector's steam pipeline and cut off steam supply from Pad 4. This has caused redirection of around 32 kg/s Pad-18 steam (normally fed into Unit-II) to Unit-I via Pad-9 junction line (north sector). This condition impacts in reduction of Unit-II steam buffer which can threaten Unit's capability to fulfill long term business plan target.

To maintain steam supply to Unit-1 without interrupting Unit-2 steam supply, One of the mitigations is by reactivating the currently inactive wells i.e. DRJ-31 well. The well was last opened for production to Unit-I in July 2016, supplying 7 kg/s steam (equal to 3.5 MW) at 10% valve opening. The well was then put offline after latest steam quality sampling performed in May 2018 shows that the dryness possible was 95.37%.

Additional steam-liquid separation process is required in DRJ-31 pipeline to remove 4.63% liquid content from the produced steam. The separated steam would be directed to Unit-1, while the separated liquid would be flowed into the zero discharge condensate reinjection system. A dedicated separator was chosen due to its scheduling flexibility (not requiring Unit-1 shutdown for installation) and cost-effectiveness.

2. PROJECT COMPLETION DATA

DRJ-31 separator installation project was started in Q3 2021 and finished in Q1 2022. Scope of project include separator fabrication, pipeline & pipe support modification, electrical & instrument work, and commissioning of DRJ-31 separator. The dedicated separator was designed according to ASME Sec VIII Div 1 (2019 ed.) standards with design basis for separator capacity of: 15 kg/s (WHP 14.2 barg) inlet fluid flowrate at 95.37% steam quality, while the pipeline was designed according to ASME B31.3.

2.1 Facility Arrangement

Before installation DRJ-31 separator, steam from well DRJ-31 flows directly to Pad-3 steam header to supply to Unit-1 Darajat. After installation DRJ-31 separator, in normal operation, wet steam from well DRJ-31 flows through Separator. The outlet steam flows to Pad-3 header to supply to Unit-I Darajat, while separated liquid flows to condensate reinjection system, as shown in Fig.1.

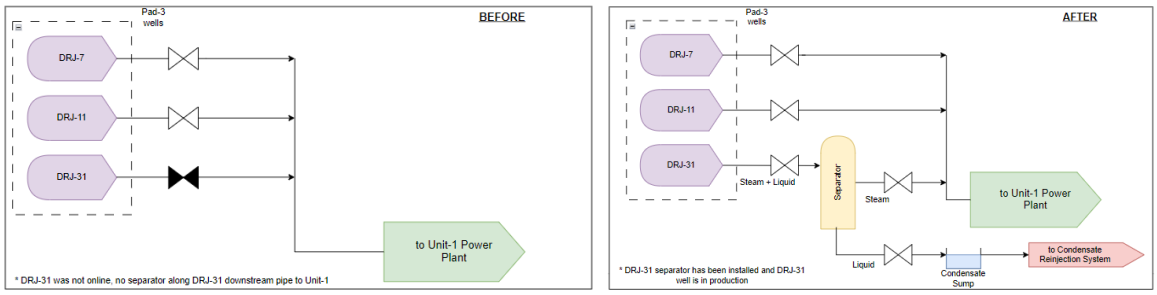

Figure 1: Schematic diagram of Pad-3 Steam Pipeline Arrangement (Before and After DRJ-31 Separator Installation Project).

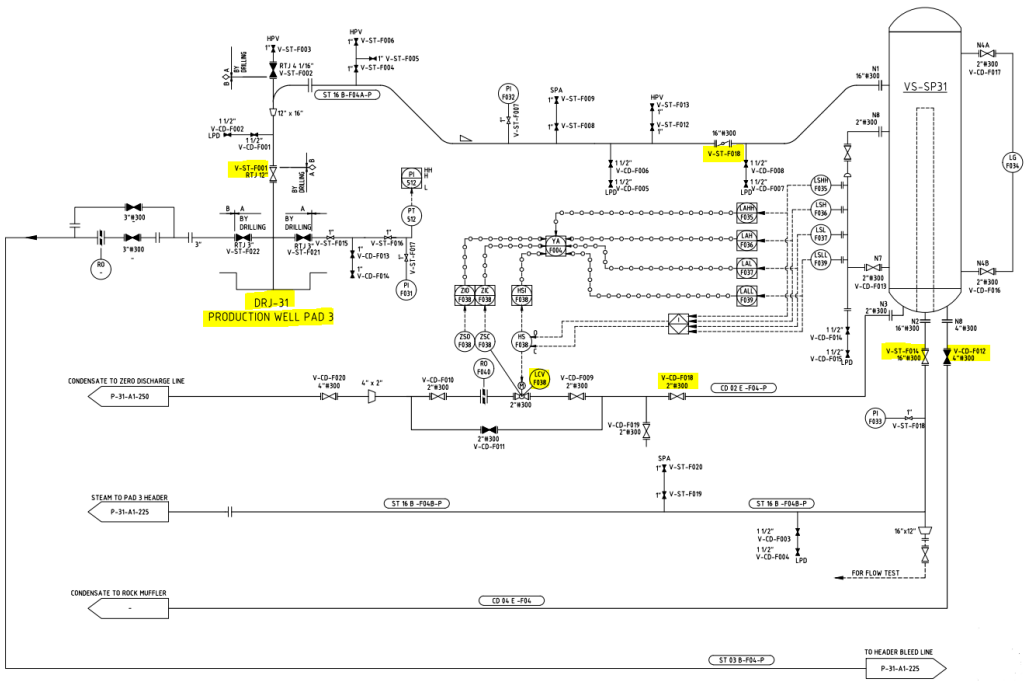

Figure 2: P&ID DRJ-31 Production Well.

2.2 General System Description

DRJ-31 wellhead separator (VS-SP31) is Vertical Bottom Outlet type separator. Separation process works by using centrifugal force of fluid spinning inside the separator. Steam-liquid mixture in contact with vessel's wall causes vapor-liquid separation where liquid drops to the bottom of the vessel, while vapor/steam and gas exits through a standpipe extending up inside the vessel.

As shown in Fig.2, the wellhead separator receives mixture of steam and liquid from the wellhead production flowline. A manually operated FCV (V-ST-F018) located in the flow line controls the flow rate from the well to the separator. The manual operated valve is 16-in butterfly valve and normally is set at certain opening to maintain wellhead pressure based on reservoir management team requirement.

The FCV has a master valve on its upstream side (V-ST-F001) so that the FCV and vessel can be shut-down for maintenance. Downstream of the vessel is also equipped with isolation valves (V-CD-F018, V-ST-F014, and V-CD-F012) to allow for vessel inspection/maintenance.

The FCV has a master valve on its upstream side (V-ST-F001) so that the FCV and vessel can be shut-down for maintenance. Downstream of the vessel is also equipped with isolation valves (V-CD-F018, V-ST-F014, and V-CD-F012) to allow for vessel inspection/maintenance.

Liquid level inside the vessel is controlled/maintained by LCV-F038. During normal operation, liquid level shall be maintained between LSL-LSH. Liquid level control is needed to seal the liquid (condensate) system from steam system. This is to allow small pressure change during operation without affecting the separation efficiency of the separator, or causing risk of hammering due to gas/vapor blow-by to liquid line.

LCV-F038 operates in "on/off" mode by motorized actuator that functions open and close the valve to maintain separator loop seal liquid level between LSL-LSH in about 340 mm. Level switches LSH-F036 and LSL-F037 are provided to detect/sense liquid at low and high level for LCV activation. When the condensate liquid level in the separator reaches the high level switch (LSH-F036), the relay circuit de-energizes the CLOSE command and energizes the OPEN command to the LCVF038 which holds it open and allows the condensate to drain from the separator liquid loop seal.

The level control valve is also used for start-up of the separator system. During this operation, the LCV is controlled locally by the operator, who monitors separator level on the level gauge and adjusts the LCV position to suit. During vessel startup, mixture of steam and liquid from the well is discharged from the separator, through the valve V-CD-F012, to existing rock muffler in Pad 3.

3. DRJ-31 SEPARATOR PERFORMANCE TEST

Performance testing was conducted to find optimum delta pressure which resulted in highest possible steam quality (min 99%) and the most optimum steam flowrate, with dryness reaching up to 99.8% at specific wellhead pressure and flow rate. The work steps is to test separation performance in several wellhead pressures: 14, 16, 18, and 20 barg, by maintaining separator pressure at 12 barg, slightly higher than Pad-3 header pressure, then measuring steam quality outlet separator at each wellhead pressure. WHP is set by adjusting V-ST-F018 (flow line BV) and separator pressure is set by throttling 16" BV at temporary flow test line to Rock Muffler. Steam flowrate is measured by using orifice installed at temporary flow test line between 1-½" LPD and the 16" BV. Steam quality will be measured on temporary flow test line (separator outlet).

Separation performance (in term of outlet dryness) as a function of pressure difference (ΔP) between well head and separator is shown in the following chart:

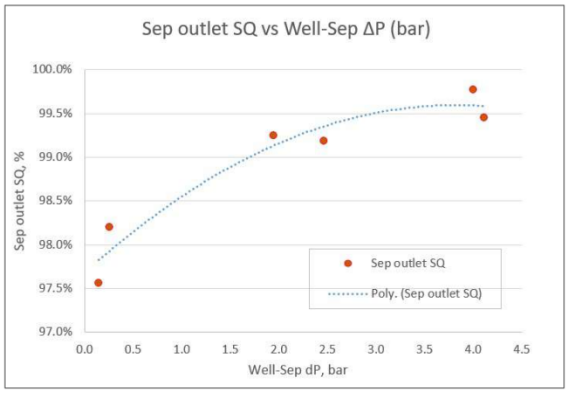

Figure 3: DRJ-31 Separator Outlet Steam Quality vs Well-Separator dP.

The plot shows that higher ΔP impact in higher steam dryness outlet separator which indicating substantial effect of flashing across FCV to the decrease of steam wetness. Although high ΔP requires higher wellhead pressure (i.e. with ΔP 4 bar and Separator Pressure 12 barg, WHP will be 16 barg), wherein it means wetter steam from well, flashing (JT effect) combined with separation process is able to compensate it and produce higher SQ steam from separator. DRJ-31 Separator predicted performance within 12-16 barg wellhead pressure range, at 12 barg operating pressure, is summarized in Table 1.

Steam quality higher than 99% can be obtained by operating the well at 14 barg and separator 12 barg pressures, with steam flowrate 11.12 kg/s. The steam flowrate is 4 kg/s (~ 2MW equivalent) higher than it is at WHP 15.75

barg. Test results evaluation suggest that DRJ-31 Separator is ready for service in support of Unit-I steam supply management.

Table 1: DRJ-31 Well and Separation System Predicted Performance at 12 barg Separator Pressure.

WHP, barg	SQ Steam from Well, %	SQ Sep Outlet, %	Steam from Separator Flowrate, kg/s
12	93.4%	98.2%	13.01
12.25	93.5%	98.3%	12.93
12.5	93.5%	98.4%	12.81
12.75	93.6%	98.6%	12.65
13	93.6%	98.7%	12.44
13.25	93.5%	98.8%	12.18
13.5	93.5%	98.9%	11.87
13.75	93.4%	99.0%	11.52
14	93.2%	99.1%	11.12
14.25	93.0%	99.2%	10.68
14.5	92.8%	99.3%	10.18
14.75	92.6%	99.4%	9.65
15	92.3%	99.5%	9.06
15.25	92.0%	99.6%	8.43
15.5	91.6%	99.7%	7.75
15.75	91.3%	99.8%	7.03
16	90.8%	99.8%	6.26

Since its reactivation in February 2022, DRJ-31 has consistently delivered an average steam flow rate of 10.9 kg/s, equivalent to the production of approximately one makeup well. As of the latest operation report, DRJ- 31 is currently producing 15 kg/s of steam at WHP of 13 barg. This successful re-activation enhances Unit- 1's steam supply security and reduces reliance on Unit-2 wells.

4. CONCLUSION

DRJ-31 separator installation was done with design basis of 95.37% and total steam flowrate from well at 15 kg/s (WHP 14.2 barg). In normal operation, wet steam from well DRJ-31 flows through separator. Outlet steam flows to Pad-3 header to supply to Unit-1 Darajat, while separated liquid flows to condensate reinjection system header line in Pad-3. From the performance test, highest steam quality achieved was 99.8% obtained at DRJ-31 WHP 15.8 barg and separator pressure of 11.8 barg; while the lowest WHP to get steam dryness outlet separator > 99% is at 14 barg. Test results evaluation suggest that DRJ-31 separator is ready for service in support of Unit-1 steam supply management.

Keywords: SIL, LOPA, Geothermal, Steam Field, Operational Risk

ABSTRACT

In 2021, geothermal utilization in Indonesia was approximately 9% of the total geothermal potential capacity in the country. PT XYZ is one of the geothermal industries in Indonesia that operates water-dominated geothermal fluids. Geothermal fluids operate in monitoring of pressure, temperature, flow, and enthalpy, which create operational risks that need to be addressed and developed in a safe manner. One of the risk mitigation developments is Safety Integrity Level (SIL).

This study aims to evaluate the Safety Integrity Level (SIL) at the two phases of Geothermal Steam Field Facilities PT XYZ by using the Layer of Protection Analysis (LOPA) method. A quantitative method was used to evaluate the design and actual operation using LOPA in 2023. As a result, information on the SIL value can be used to determine an improvement program to enhance the SIL value according to the company's needs and provide information for the development of new facility designs if necessary.

1. INTRODUCTION

Electrical power is one of the most important needs since it is potentially utilized in a variety of applications, including manufacturing, healthcare, and other daily needs. Currently, fossil fuels are the most common source of electric power. In Indonesia, electricity accounts for 69% of total fossil energy use, while Renewable Energy used for 31% (CNN Indonesia, 2022). Geothermal energy is one of the renewable energy sources that can be used to generate electricity in Indonesia. Indonesia is located in the Ring of Fire region, which is marked by numerous volcanoes and high seismic activity, gives it significant geothermal potential. Indonesia's geothermal potential is 11,073 MW, with reserves of 17,506 MW scattered across 331 places from Sabang to Merauke (no date). With its enormous geothermal potential, it can be used to generate electricity to fulfil increasing demands. One of geothermal fields in a certain area produces a fluid consisting of a two-phase fluid, steam and brine. The two-phase fluid must first be separated into steam and brine using separator and other supporting equipment to power the turbine. The two-phase steam field facilities operate at high temperatures, pressures, and flow rates, which increases the potential of failure or accidents. Steam production facilities must consider aspects of safety and workplace security. As a result, efforts are required to reduce the risk of failure by improving the Safety Integrity Level (SIL). SIL is a safety level that reduces the risk of failure, which can be determined using the layer of protection analysis method. The LOPA method can identify and evaluate the existing protection layers in a two-phase steam field to mitigate risk. LOPA can quantitatively evaluate the efficiency of each protective layer using the Probability Failure on Demand (PFD) value, which helps in determining the SIL classification of geothermal facilities in two-phase steam fields (Marszal & Scharpf 2002). Currently, there are two-phase steam field geothermal facilities that have not concern about SIL because the geothermal field still apply the proven methods or are manually operated by operators. As a result of using proven methods, there are many instances of failure that can lead to production interrupts and loss production due to maintenance activities. In the two-phase steam field, the system is evaluated to determine which SIL values can be improved. By evaluating and implementing SIL in geothermal facilities of the two-phase steam field, it is expected to enhance safety levels and reduce production losses due to failures.

2. LITERATURE REVIEW

2.1 Safety Integrity Level (SIL)

The Safety Integrity Level (SIL) is a safety level of a Safety Instrumented System (SIS) used to reduce process risk. SIL is separated into four levels, each of which describes the amount of safety protection provided by a procedure. SIL 1 is the lowest level; SIL 4 is the highest. A process's SIL value indicates how accurate a component's security level is. SIL is often assessed using a risk analysis approach known as Layer of Protection Analysis (LOPA).

SIL is confirmed by computing the Probability Failure on Demand average (PFDavg) for each system component. PFDavg is the average likelihood that a SIF will be unable to execute a security function. The failure rate (λ), or the number of failures in a unit of time, influences the value of PFDavg. Once the PFDavg value of a component has been obtained, the SIL level may be derived using IEC 61508 as stated in Table 1.

Tabel 1: Safety Integrity Level (IEC 61508).

Safety Integrity Level (SIL)	Average Probability Failure on Demand (PFD_{avg})
4	0.00001 – 0.0001
3	0.0001 – 0.001
2	0.001 – 0.01
1	0.01 – 0.1

2.2 Hazard and Operability Studies (HAZOP)

Hazard and Operability (HAZOP) is the study of equipment dangers in real-world production operations. HAZOP seeks to detect possible adverse events that might endanger or disrupt operations, such as hazards to people's safety and potential harm to assets, the environment, and reputation. The discovered threats are reported on the HAZOP worksheet, together with any actions for further investigation and appropriate supporting information (Salaheldine Darwish et al. 2020).

A team of specialists with expertise, experience, and responsibility for the processes and components to be studied conducts HAZOP analysis. When evaluating the study, the facilities to be examined are separated into different sections with specific limits known as nodes, based on the complexity of the system and the natural separation in ratings, pump absorption, drainage pipelines, tanks, and so on.

In the study, HAZOP employed a guide word to assist the design team in identifying failure scenarios in a process that might lead to risk and operational issues. Following a node-based identification using a guide word, a review will be performed by looking at the cause, which is the cause of the deviation, the consequence, which is the result of a process, and the safeguards, which are the layer of protection that prevents the occurrence of a consequence.

2.3 Layer of Protection Analysis (LOPA)

Layer of Protection Analysis (LOPA) is a risk analysis approach that uses basic criteria to define and analyze hazards semi-quantitatively, as well as to create a layer of protection to deal with process risks. LOPA is a risk assessment that necessitates the identification of additional risks, namely the Hazard and Operability Study (HAZOP). LOPA is used to assess if the protective layer and other measures necessary are enough to address the probability of failure and to establish the layer's degree of safety (Studi et al., n.d.).

The major goal of the LOPA approach is to verify that a proper protection layer is in place, reducing the possibility of an accident and calculating the safety level of the protective layers. In a hazard scenario, one or more protective layers are necessary, depending on the complexity of the industrial process and the severity of the danger. The layers on the LOPA are structured like onion structure, as seen in Figure 1.

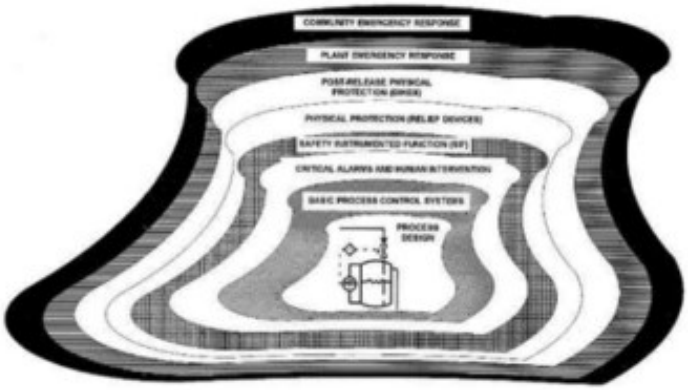

Figure 1: Protection Layer Against Possible Accidents (American Institute of Chemical Engineers. Center for Chemical Process Safety. 2001).

The protective system on the LOPA has the following protective layer:

1. Basic Process Control System
2. Critical Alarms and Human Intervention
3. Safety Instrumented Function (SIF)

4. Physical Protection (Relief Devices)
5. Post-release Physical Protection
6. Plant Emergency Response
7. Community Emergency Response

3. RESEARCH TYPE AND METHOD

3.1 Independent Protection Layer (IPL)

IPL are identified from two-phase steam field geothermal facilities to determine the Probability Failure on Demand (PFD) value for each protection layer. Without protection layers, the PFD value will be set to 1. If there are protection layers, the PFD value for that layer can be determined using existing references. One reference that can be used to determine the PFD value when there is protection layer is the CCPS 2001. However, there are some data within the company that can be used to determine the PFD value. Table 2 below shows the PFD value of each IPL.

Tabel 2: PFD Value for IPL (American Institute of Chemical Engineers. Center for Chemical Process Safety. 2001).

No.	IPL	PFD
1	Basic process control system, if not related to the initial cause considered	0.1
2	Alarm operator with enough time to respond	0.1
3	Relief valve	0.01
4	Rupture disk	0.01
5	Flame/detonation arrestors	0.01
6	bund/dike	0.01
7	Underground drainage system	0.01
8	Open vent	0.01
9	Fireproofing	0.01
10	Blast-wall/bunker	0.001
11	Redundant	0.01 (maximum credit)
12	Different backup tool	0.01 – 0.001
13	Other event	Based on experience
14	SIS with SIL 1	0.1 – 0.01
15	SIS with SIL 2	0.01 – 0.001
16	SIS with SIL 3	0.001 – 0.0001
17	Internal mechanical security trips independent of SIS	0.1 – 0.001
18	A Non-Return Valve (NRV) or check valve	0.1
19	"Inherently Safe" Design	0.01

The equation for determining PFD based on SIS may be configured in different ways. There is a system 1oo1 having one source (Willey & Sons 2010), as illustrated in the following equation 1.

$$PFD_{avg} = \lambda^{DU} \times T_i/2 \quad (1)$$

Where:

λ^{DU} = Failure Rate Dangerous
T_i = Time Interval
PFD = Probability Failure on Demand

3.2 Target Mitigated Event Likelihood (TMEL) Identification

In the LOPA method, first find the TMEL value to determine the PFD value. The TMEL is a value determined by the management of the company to reduce the likelihood of hazard emerging as a result of a consequence. TMEL values are shown in Table 3.

3.3 Initiating Event Frequency (IEF)

Determining the Initiating Event Frequency (IEF) is a necessary step to calculate the LOPA GAP value. The events that occur must result in consequences affecting all safeguards. The frequency of an event must consider background aspects such as the frequency of the operation mode corresponding to the scenario. Generally, the frequency of IEF is expressed in events per year, although other units such as per 106 hours are also used. Initiating events are grouped into three categories: external events, equipment failure, and human failure.

External failures include natural phenomena such as earthquakes, tornadoes, floods, and events originating from fires or explosions at adjacent facilities. Equipment failures can be further classified into control system failures

and mechanical failures, which include software bugs, corrosion, and defects. Human failures encompass operational errors, maintenance errors, and program errors. Table 4 below shows the IEF values used to determine the LOPA GAP.

Tabel 3: Target Mitigated Event Likelihood Value.

Severity Level	Safety Consequence	Target Mitigated Event Likelihood
CA	Single first aid injury	0.03
CB	Multiple first aid injuries	0.003
CC	Single disabling injury or multiple serious injuries	0.0003
CD	Single on-site fatality	0.00003
CE	More than one and up to three on-site fatalities	0.00001

Tabel 4: Initiating Event Frequency Value (American Institute of Chemical Engineers. Center for Chemical Process Safety. 2001).

Initiating Event	Frequency Range from Literature (per year)	Example of a Value Chosen by a Company for Use in LOPA (per year)
Pressure vessel residual failure	10^{-5} to 10^{-7}	1 to 10^{-6}
Piping residual failure—100 m—Full Breach	10^{-5} to 10^{-6}	1 to 10^{-5}
Piping leak (10% section)—100 m	10^{-3} to 10^{-4}	1 to 10^{-3}
Atmospheric tank failure	10^{-3} to 10^{-5}	1 to 10^{-3}
Gasket/packing blowout	10^{-2} to 10^{-6}	1 to 10^{-2}
Turbine/diesel engine overspeed with casing breach	10^{-3} to 10^{-4}	1 to 10^{-4}
Third party intervention (external impact by backhoe, vehicle, etc)	10^{-2} to 10^{-4}	1 to 10^{-2}
Crane load drop	10^{-3} to 10^{-4} per lift	1 to 10^{-4} per lift
Lightning strike	10^{-3} to 10^{-4}	1 to 10^{-3}
Safety valve opens spuriously	10^{-2} to 10^{-4}	1 to 10-2
Cooling water failure	1 to 10^{-2}	1 to 10^{-1}
Pump seal failure	10^{-1} to 10^{-2}	1 to 10^{-1}
Unloading/loading hose failure	1 to 10^{-2}	1 to 10^{-1}
BPCS instrument loop failure Note: IEC 61511 limit is more than 1×10^{-5}/hr or 8.76×10^{-2}/yr (IEC, 2001)	1 to 10^{-2}	1 to 10^{-1}
Regulator failure	1 to 10^{-1}	1 to 10^{-1}
Small external fire (aggregate causes)	10^{-1} to 10^{-2}	1 to 10^{-1}
Large external fire (aggregate causes)	10^{-2} to 10^{-3}	1 to 10^{-2}
LOTO (lock-out tag-out) procedure failure overall failure of a multiple-element process	10^{-3} to 10^{-4} per opportunity	1 to 10^{-3} per opportunity
Operator failure (to execute routine procedure, assuming well trained, unstressed, not fatigued)	10^{-1} to 10^{-3} per opportunity	1 to 10^{-3} per opportunity

3.4 Target Mitigated Event Frequency (TMEF)

Target Mitigated Event Frequency (TMEF) is a target of the probability of the occurrence of a hazard. The value can be determined on the basis of the severity of the hazardous event that can be defined using the following 2 equation.

$$TMEF = UEF_1 \times PFD_{tot1} + UEF_2 \times PFD_{tot2} + \cdots \quad (2)$$

Where:

TMEF = Target Mitigated Event Frequency

UEF = Unmitigated Event Frequency
PFD = Probability Failure on Demand

TMEF can be determined by knowing the UEF and PFD_{total} values of each initiating cause.

3.5 Determine Safety Integrity Level (SIL)

SIL is a safety level of the Safety Instrumented System (SIS) as an attempt to reduce risk in a process. SIL can be determined by reviewing SIL classification using the LOPA method, determining TMEL values, and determining the TMEF values to obtain a gap. The gap obtained is used as the primary reference for the SIF to be designed and evaluated. Target SIL guidelines require a gap specified with the PFD LOPA gap. The value of the PFD on the LOPA gap can be determined using the equation 3 as follows:

$$PFD_{gap} = TMEL/TMEF \quad (3)$$

After determining the PFD_{gap} value, the level of SIL can be determined according to IEC 61508 according to Table 1. After performing SIL classification using the LOPA method and determining the degree of SIL, SIL verification was undertaken to verify if the current instrument meet the SIL classification level.

4. MODELLING, CALCULATION, AND ANALYSIS

Figure 2 is a flowchart that explains the workflow of SIL evaluation on Geothermal Steam Field using the LOPA method.

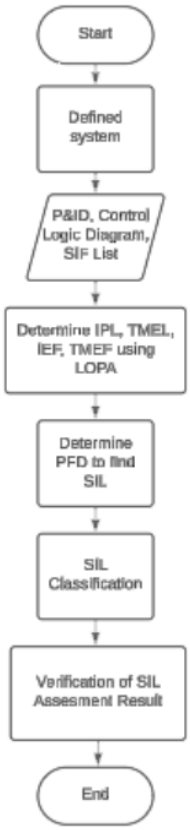

Figure 2: Flowchart SIL Evaluation on Geothermal Steam Field using LOPA Method.

4.1 SIF List Determination

To perform SIL classification processes on geothermal field steam facilities, two phases are selected based on the highest HAZOP risk and the failure in the field based on discussions and interviews. The SIF list was derived from the P&ID and Control Logic Diagram by analyzing the sensor, logic solver, and final element components in the two-phase steam field. Figure 3 shows the P&ID used to define List 1 SIF as a sample.

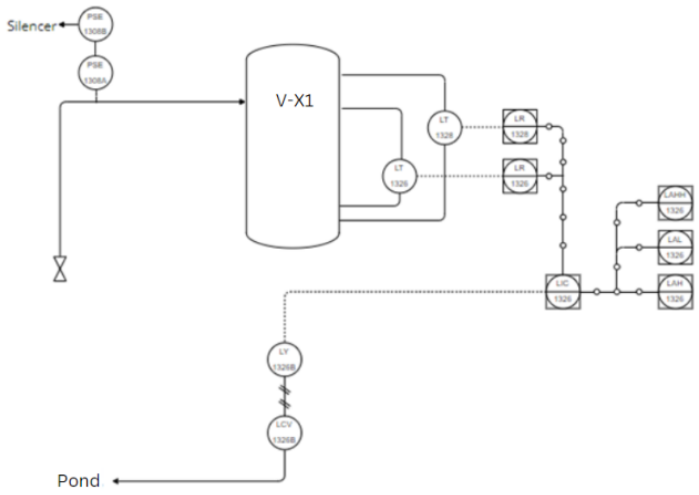

Figure 3: P&ID V-X1.

Based on the P&ID in Figure 3 can be determined SIF List as in Table 5.

Tabel 5: SIF List.

No.	SIF	Design Intent	Initiator
1	[SIF] High High Level in Wellhead Separator V-X1	To prevent overfilling of Wellhead Separator V-X1	01-LAHH-1326
2	[SIF] High High level in Wellhead Separator V-X2	To prevent overfilling of Wellhead Separator V-X2	01-LAHH-1426
3	[SIF] High High Level in Wellhead Separator V-X3	To prevent overfilling of Wellhead Separator V-X3	01-LAHH-1726
4	[SIF] High High Level in Wellhead Separator V-X4	To prevent overfilling of Wellhead Separator V-X4	01-LAHH-1826
5	[SIF] High High Level in Wellhead Separator V-X5	To prevent overfilling of Wellhead Separator V-X5	01-LAHH-1926
6	[SIF] High High Level in Wellhead Separator V-X6	To prevent overfilling of Wellhead Separator V-X6	01-LAHH-2012A
7	[SIF] High High Level in Wellhead Separator V-X7	To prevent overfilling of Wellhead Separator V-X7	01-LAHH-2112A
8	[SIF] High High Level in Wellhead Separator V-X8	To prevent overfilling of Wellhead Separator V-X8	01-LAHH-2212A
9	[SIF] High High Level in Wellhead Separator V-X9	To prevent overfilling of Wellhead Separator V-X9	01-LAHH-2312A
10	[SIF] High High Level in Wellhead Separator V-X10	To prevent overfilling of Wellhead Separator V-X10	01-LAHH-4012A
11	[SIF] High High Level in Wellhead Separator V-X11	To prevent overfilling of Wellhead Separator V-X11	01-LAHH-4112A
12	[SIF] High High Level in Wellhead Separator V-X12	To prevent overfilling of Wellhead Separator V-X12	LAHH-6001
13	[SIF] High High Level in Wellhead Separator V-X13	To prevent overfilling of Wellhead Separator V-X13w	LAHH-5012

4.2 SIL Classification

SIL classification is use to conduct SIL approaches to two-phase steam field geothermal facilities in order to obtain SIL values from the LOPA gap. The process of SIL classifications is based on cause and consequence in the HAZOP. To determine the SIL value of the Lopa gap, the Target Mitigated Event Likelihood (TMEL) values obtained from consequences, Initiating Event Frequency (IEF), Probability Failure on Demand (PFD) on initiating cause, and Independent Protection Layer (IPL) based on the Center for Chemical Process Safety (CCPS) to determine PFD_{Avg} values. After determining the PFD_{Avg} value, the SIL value can be calculated for the LOPA gap.

Take a sample for the calculation of SIL classification which is SIF list 1. In doing SIL Classification this is done determination of consequence of HAZOP first to determine the value of TMEL. Which is obtained TMEL on SIF

List 1 obtains 0.00001. After determining the TMEL value, the Unmitigated Event Frequency (UEF) value of each initiating cause is obtained as in Table 6.

Tabel 6: IEF Value and UEF from Initiating Cause.

No.	Initiating Cause	IEF (Event per yr)	Conditional Modifiers		UEF (Event per yr)
			Description	Prob	
1	More flow from upstream (Wellhead) due to increasing productivity of reservoir	1	Operation mode	0.1	0.1
2	High Silica scale formation at separator (for prolonged time)	0.4	Operation mode	0.1	0.04
3	LCV accidently close due to instrument air off due to compressor off	0.1	Operation mode	0.1	0.01

From Table 6, it is known that the value of IEF can be determined based on Table 3. The value of the IEF at the initiating cause of the first is worth 1 because at the time of production produced on SIF list 1 increases is a natural cause, which is the case naturally from the reservoir.

$$UEF = IEF \times Prob$$

$$UEF_1 = 0.1$$

Then the IEF rating on the second initiating cause is 0.4 because based on the data obtained from the agency during the interview, silica-related interference occurs as many as 4 times a year. So, the UEF value can be determined with the completion as follows.

$$UEF = IEF \times Prob$$

$$UEF_2 = 0.04$$

Then the IEF value on the third initiating cause is 0.1 according to Table 6. So, the UEF value can be determined by completion as follows.

$$UEF = IEF \times Prob$$

$$UEF_3 = 0.01$$

The total PFD value for each IPL is then determined to establish the SIL classification by adding all IPLs from each starting cause, as shown in Table 7.

Tabel 7: PFD Value from each IPL.

No.	Initiating Cause	Independent Protection Layers (IPLs)			
		IPL Description	Type of IPL	PFD	IPL Description
1	More flow from upstream (Wellhead) due to increasing productivity of reservoir	Rupture Disc (e.g. PSE-1308A, PSE-1308B)	Physical Protection	0.01	1E-07
		[SIF] High High level alarm on separator V-X1 (e.g. LAHH-1326)	SIF	1	
		[Alarm] High Level alarm on separator V-X1 (e.g. LAH-1326) to alert operator for opening bypass valve	Alarm and Operator Response	0.1	
		Rupture Disc (e.g. PSE-1332)	Physical Protection	0.01	
		Condensate Drain Port	Physical Protection	0.01	
2	High Silica scale formation at	Acid Injection available	Human Intervention	0.1	1E-03
		Automatic Condensate Drain Port	Physical Protection	0.01	

No.	Initiating Cause	Independent Protection Layers (IPLs)			
		IPL Description	Type of IPL	PFD	IPL Description
	separator (for prolonged time)				
3	LCV accidently close due to instrument air off due to compressor off	[SIF] High High level alarm on separator V-X1 (e.g. LAHH-1326)	SIF	1	1E-01
		[Alarm] High Level alarm on separator V-X1 (e.g. LAH-1326) to alert operator for opening bypass valve	Alarm and Operator Response	0.1	

Based on Table 4, the PFD_{total} value of each initiating cause is obtained, so the TMEF value can be determined using the equation 2 as follows.

$$TMEF = 0.00104$$

Once the TMEF value is known, then the PFD_{gap} value can be determined by dividing the TMEL value by the previously specified TMEF using the equation 3 as follows.

$$PFD_{gap} = 0.0096$$

By knowing the PFD_{gap} value of SIF list 1, then the level of SIL can be classified according to Table 1. The PFD_{gap} value obtained is 0.0096 so the SIL level is SIL 2.

Then the calculation is done in the same way up to the 13th SIF list to determine the SIL classification. Table 8 shows PFD_{gap} values obtained from 13 SIF surveys.

Tabel 8:Table PFD_{gap} for 13th SIF Review.

No	SIF	Probability Failure on Demand (PFD) Lopa GAP	SIL Classification
1	Separator V-X1	0.0096	SIL 2
2	Separator V-X2	0.0096	SIL 2
3	Separator V-X3	0.0096	SIL 2
4	Separator V-X4	0.0096	SIL 2
5	Separator V-X5	0.0096	SIL 2
6	Separator V-X6	0.0096	SIL 2
7	Separator V-X7	0.0096	SIL 2
8	Separator V-X8	0.0096	SIL 2
9	Separator V-X9	0.0096	SIL 2
10	Separator V-X10	0.0096	SIL 2
11	Separator V-X11	0.0096	SIL 2
12	Separator V-X12	0.0096	SIL 2
13	Separator V-X13	0.0096	SIL 2

4.3 SIL Verification

After doing SIL classification, perform SIL verification by determining the type of sensor, logic, and actuator used on each separator and arrangement of PFD sensors. Then determine the architectural constrain and carry out certification from manufacturing based on the sensor used so that SIL values on SIL verification can be determined and compared with the SIL value obtained on LOPA gap.

PFD SIL calculation is performed to determine the SIL level in order to verify whether the SIL classification value requires additional components, replaces the component with the corresponding PFD value, or there is a problem with redundancy. Table 9 shows the data obtained from the search for certification and manufacturing data based on the components used.

Based on Table 9, the average PFD value for the Rosemount transmitter level sensor is obtained using the equation 1 with a time interval of 1 year.

$$PFD_{avg} = 0.000018396$$

Here is a calculation of PFD_{avg} for logic solver using equation 1 with time intervals of 1 year.

$$PFD_{avg} = 0.0001752$$

Here's a calculation of the PFD_{avg} for the LCV actuator using equation 1 with a time interval of 1 year.

$$PFD_{avg} = 0.00097674$$

After obtaining PFD_{avg} values from each sensor, logic solver, and actuator, the overall PFD_{avg} value may be determined the following formula.

$$PFD_{avg} = 0.0013359$$

A total PFD_{avg} value of 0.0013359 is obtained, which is based on the provisions of IEC 61511 and CCPS 2001, the SIF review list 1 is included in SIL 2. This means that the SIL value between SIL classification and SIL verification is the same so that no component needs to be replaced with the corresponding PFD value.

The steps subsequently continue up to SIF list 13, determining SIL verification. Table 10 The following table shows the PFD_{gap} values obtained from 13 SIF evaluations.

Tabel 9: PFD SIL Calculation SIF 1.

Component	Brand	SIL Certificate	Configures SIF	Failure Rate	PFD

4.4 Verification of SIL Assessment Result

The SIL evaluation, which included SIL classification based on CCPS SIL standards calculations and SIL verification based on certification of each sensor, actuator, and final element component, resulted in SIL 2 for 13 SIF reviews. This SIL 2 can be validated against existing literature, such as CCPS, and compared to the institution's P&ID, which has been updated to meet the necessary criteria. In addition, a field expert verified the SIL evaluation results.

Achieving SIL 2 for 13 SIF evaluations in the two-phase geothermal steam field was considered adequate. SIL levels depend on operational patterns, and geothermal systems cannot have identical operations to those in oil & gas or petrochemical industries. At the institution where the SIL evaluation was conducted, the system classification is SIL 2, but some components used are certified SIL 3. Thus, SIL 2 is sufficient for the operational pattern, but the geothermal industry has not yet made SIL mandatory. Therefore, SIL requirements still depend on the needs of each company or institution.

5. CONCLUSION

Based on the data analysis and discussions conducted to evaluate the SIL level at the two-phase steam field geothermal facilities, the following conclusions can be drawn:

1. Based on the analysis performed for the SIL classification process using the LOPA method, it was determined that the target safety level for the two-phase steam field geothermal facilities in the 13 SIF evaluation is SIL 2.
2. With the SIL evaluation conducted, the proposed improvement program is to perform maintenance at least once a year, as estimated by the SIL analysis. This includes maintenance of sensors, actuators, final elements, and the wiring system in the two-phase steam field.
3. SIL evaluations using the LOPA method can be utilized in the geothermal industry to consider process safety and continuous improvement, consequently improving operational safety using logic control technology and reducing the probability of failure that impacts opportunity loss.

ABSTRACT

SIL1-2, an exploration well drilled in 1997, is in Silangkitang Geothermal Field. With minor reservoir pressure and enthalpy drop, the wellbore-size constrained SIL1-2 was initially produced at a stable mass rate in the first three years of production. The well performance showed a significant decline trend in the following years due to a combination of wellbore and near-wellbore calcite scaling. Several trials of wellbore clean-out have been done since 2020 to recover well performance, one of which left the presence of fish in hole. The inaccessible wellbore of SIL1-2 creates complexity, from minimum downhole information to limited options of any well intervention options. Through risk assessment, the acid bullhead stimulation method was considered the only viable option to restore well capacity, considering the presence of fish, feed zones that are located below the top of the fish, the uncertainty of fishing job due to slim hole completion, good wellbore and wellhead integrity. Bullhead stimulation was aimed to dissolve the scale deposits in both wellbore and near wellbore; sweep out the solution to formation, bind, and prevent the dissolved Ca^{2+} ions from being redeposited, expecting permeability improvement in formation. The rock formation (core sample), as the only solid sample reference, underwent laboratory testing with acid and alkali-based chemicals. The bullhead stimulation at SIL1-2 has successfully improved the production capacity, while it also practically reduced equipment needed and loss generation as compared to other well-stimulation methods ever tried.

1. INTRODUCTION

The Silangkitang (SIL) geothermal field, one of four known geothermal prospects within the Sibualbuali Working Area, is in Pahae Jae, North Tapanuli Regency, North Sumatera Province, Indonesia. SIL is a fault-controlled geothermal system that is situated along the Great Sumatera Fault (GSF). A 110 MW Geothermal Combined Cycle Power Plant, consisting of a backpressure steam turbine and binary units, is operated by Sarulla Operation Ltd. (SOL). This technology allows nearly 100% reinjection, maintaining the sustainability of the field. The current production and injection strategy is maintained by four production wells, located in the center of the field, and seven injection wells, distributed in the northwestern and southeastern parts of the field (Figure 1). UNOCAL, who was initially granted to conduct the exploration and development, drilled five exploration wells in the late 1990s. SIL1-2, one out of three wells drilled relatively perpendicular to the GSF, encounters good permeability with a fluid temperature of more than 300°C. SIL1-2 well deliverability is categorized as wellbore-size limited, and it's actively being used as a production well to date. It initially produced ~ 420 t/hr of the total mass rate at 22barg operating WHP, with an average enthalpy of 1360J/g. The well generated approximately 18MWe stably supplied to the power plant, from early commissioning in March 2017 to December 2019, before continuously showing a high decline rate of ~45-50%/ year. A high decline rate is not expected as the reservoir pressure shows relatively minor pressure drawdown since early production. The well has been continuously operated at minimum allowable Wellhead Pressure (WHP) to sustain the generation.

During a regular static Pressure Temperature (PT) survey performed in early 2020, the well was observed to have shallower accessibility by ~1900 ft as compared to its total depth of 7644 ft.MD, indicating the presence of an obstruction. An attempt to clear the obstruction was run by using Coil Tubing (CT) mechanical cleanout within the same year. The scale deposit was observed around the top of the 7" production casing. Unfortunately, after clearing the whole 7" casing, ~3750ft long of 1 ¾" CT was lost in hole. The well intervention activity was categorized as unsuccessful, with CT fish left in hole and zero production recovery. An additional well intervention was continued by performing fishing in March 2021. Nearly half of the CT length was retrieved and well performance recovered temporarily to its ideal capacity, before the new high declining trend (Figure 2).

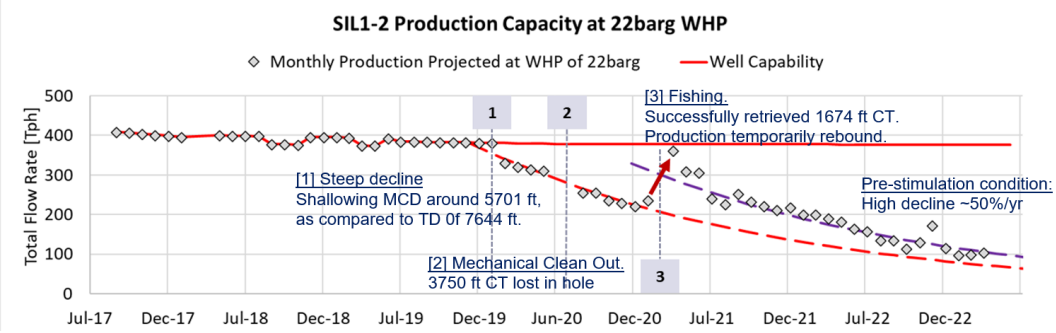

Figure 2: SIL1-2 normalized production capacity at minimum allowable WHP and its sequential observation.

2. PRE-STIMULATION ASSESSMENT

2.1 Geochemistry Assessment

Sets of geochemistry data were taken regularly as part of well monitoring activities. To complete the well performance evaluation and the scaling potential assessment, the geochemistry data were simulated with the WATCH aqueous speciation program (Arnorsson, et al., 1982) to identify the type of scale (mineral). The initial flowing chemistry data of SIL1-2 was collected during December 2017 and this is assumed to be the baseline and equilibrium condition of the well. The simulation was focused on the retrograded solubility minerals such as calcite and anhydrite. The SI (log Q/K) of calcite from the baseline data is 0.21 and it's slightly above the theoretical SI (log Q/K = 0). This information, however, strongly indicates the calcite scaling potential. Years after the well was in production, the SI of calcite was observed to be higher than the initial, suggesting the likelihood of calcite deposition over time starting from the reservoir or near wellbore conditions (Figure 3). On the other hand, anhydrite remains undersaturated over time. The possible causes of scaling deposition may be attributed to factors such as low operating pressure conditions that create deeper flashing points. The equilibrium state of the fluid is disturbed and the dissolved CO_2, when it flashes, degassing and causing the calcite to be precipitated (Kaya et al., 2010; Satman et al., 1999).

2.2 Wellbore Assessment

The wellbore accessibility of SIL1-2 was restricted by two objects, i.e., scale deposit and CT fish left in hole. The top of fish was estimated at ~5667ft.MD and assumed to be extended irregularly to the bottomhole. The identified feedzones of SIL1-2 are located below the top of the fish, at 6383 and 6883ft.MD, both lie in 5" and 3.5" perforated liner, respectively (Figure 4). Considering the presence of fish, running any PT/PTS log to assess the wellbore dynamics is a non-viable option. The pre-acid stimulation flow rate based on the tracer flow test in December 2023 yields about 89 t/hr total at a minimum allowable WHP of 20barg.

These two conditions imply that the possibility of conducting conventional downhole acid treatment becomes impractical and an immediate cleanout treatment must be performed before the FZ is blocked by scale. The only feasible option to recover the well performance is by bullhead stimulation, where all chemicals are pumped from the surface through the wellhead.

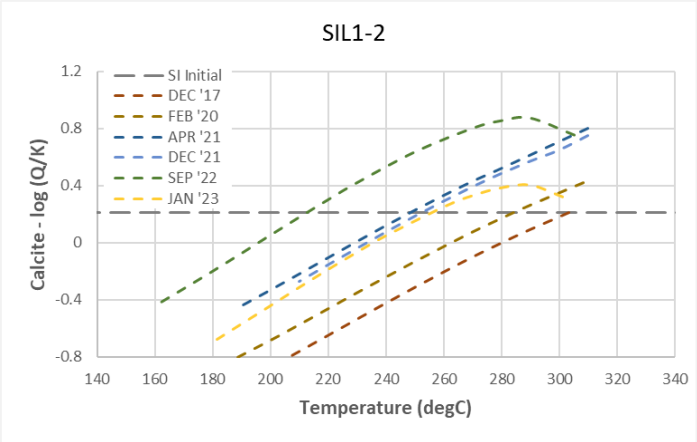

Figure 3: Calcite oversaturation in the wellbore of SIL1-2 based on monitoring data simulated in adiabatic cooling conditions.

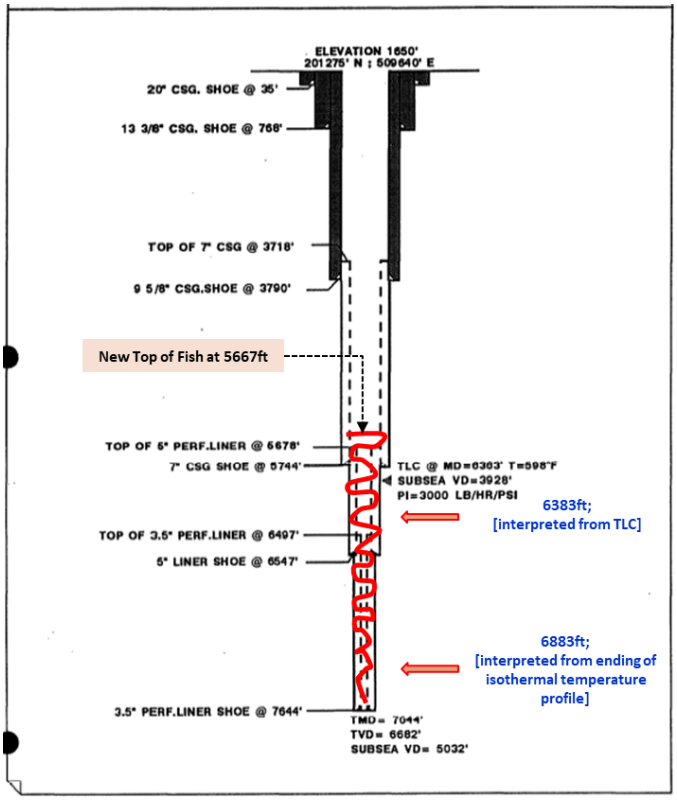

Figure 4: Well casing configuration and accessibility.

3. BULLHEAD ACIDIZING PROGRAM

3.1 Chemical Selection and Delivery

Due to the inaccessibility of the wellbore, there was no scale sample retrieved from SIL1-2 well. The type of scale was estimated by chemical simulations and references from nearby well that showed similar behavior, i.e., calcite oversaturation, drop pressure and mass flow, and possible injection breakthrough. In the nearby well case, the calcite scale deposit was successfully cleaned out with acetic acid. It is also well known that HCl is suitable and applied for dissolving calcite deposits in geothermal production wells (McLean et al., 2021; Kaya et al., 2010).

The bullhead acidizing method is demonstrated in other fields, solving and treating both calcite and silica(te) deposits. In Domo San Pedro, the implementation of acid bullhead was used successfully to treat calcite and silica

scaling in the wellbore and formation, improving about 351% of well performance (Rodriguez, et al., 2021). The chemicals they used as dissolver are HCl and formic acid (calcite), and alkaline solutions (silicate). A similar case was also demonstrated in the Wairakei geothermal field where a combination of acid and caustic was used to remove both calcite and silica in the production well. The chemical treatment can deliver 100% well capacity recovery (McLean et al., 2021). The bullhead acidizing method was also successfully demonstrated in Kawerau injection well, dissolving the silica scaling in near wellbore formation with Hydrofluoric Acid (HF) and formic acid, resulting in higher injection capacity (Goh et al., 2020).

Corresponding to the above examples, an idea was raised to improve in situ permeability by conducting solubility tests on the (deposited) secondary minerals in fractures/veins/veinlets. Two core samples, which were described as having mainly silica (quartz) and minor calcite in fractures, analog as SIL1-2 feedzone depths underwent dissolution test with repeated steps of alkaline – acid – alkaline- acid solutions. The acid solution is mainly composed of hydrochloric acid, and the alkaline solution is mainly composed of caustic. The weight loss (%solubility) of the two rock samples was 9 and 12.3%, respectively. Although the main dissolution agent is the acid, the result allowed permeability improvement by enhancing the dissolution rate. This, however, determined the type of chemicals used for the cleanout program, which are a combination of acid, alkali, and chelating agents. The acid solution, as developed by SOLENIS, is blended with a food-grade base corrosion inhibitor that would work up to 200°C and it is safer from an environmental perspective.

The bullhead acidizing method has several benefits as compared to the CT method, including but not limited to the following:

- Simplification of the whole job sequence: no high-pressure pumping unit, no lifting equipment during the job, etc.
- Increasing the pumping rate, having higher pumping rate could:
    - Prevent the well from being heated up which consequently reduces the corrosion inhibitor failure (exceed temperature rating).
    - It may increase the formation coverage, more chemical-scale reactions.
    - When a chelating agent is used, a higher rate may improve the dissolution rate. Rose et al. (2010) studied that a higher injection rate can improve the dissolution rate by 4.5% and extend the radial penetration.
- No downhole equipment, no lost-in-hole risk.

3.2 Executed Program

The bullhead acid stimulation program was divided into four steps and completed successfully within three days of operations. The first step is to quench the well with fresh water to create a vacuum condition before acid injection. The second step is to inject the acid solution of GS1127 to dissolve and flush the scale in the wellbore. This second process concluded with condensate displacement and continued with overnight quenching to allow further soaking time. The third step involves alkaline treatment with alkali GS1014 and additive of GS1824. This phase attempts to improve the formation's permeability and bind the dissolved Ca^{2+} ions by adding the additive (redeposition prevention). The fourth and last step is to inject the GS1127 which aims to dissolve the remaining calcite in the reservoir. The executed program is summarized as follows (Figure 5):

4. RESULT AND DISCUSSION

4.1 Well Capacity Improvement

After four days of shut-in, the well SIL1-2 flowed back to the plant system. To increase measurement accuracy, the single-phase flowmeter at the outlet of the separator is set as the main parameter. At stabilized ~27 barg WHP of SIL1-2, the total mass rate in the separator was increased by 292 t/hr (Figure 6). Figure 7 shows the deliverability curve of SIL1-2 pre- and post-bullhead acidizing. The total flow rate of SIL1-2 post-acid stimulation is ~420 t/hr at 22 barg WHP or equivalent to its initial capacity. The target generation of SIL is recovered post-acid stimulation of SIL1-2, and even better, can be optimized to slightly above the initial power plant design. Considering less operational complexity, minimum operational downtime, and removal risks of downhole intervention, the bullhead acidizing method offers a more attractive solution than the other past successfully applied chemical well stimulations in SIL, i.e., CT, rig.

Step One - Well Killing
- Killing the well with 160 – 320 lpm fresh water. Vacuum condition prior acid injection.
- Well turned to ~0 barg in 6.5 hours.

Step Two - Treatment within the Wellbore (Acid Dosing)
- To dissolve and flush scale in the wellbore, GS1127 was injected thru crown valve.
- 30 m^3 at high rate of 1200 lpm, another 30 m^3 with lower rate of 360 lpm.
- Displaced with 240 lpm condensate for 20 mins to push remaining acid in wellbore to formation.
- Switched and quenched the well with 240 lpm of river water from backside, allowed overnight reaction/soak time.

Step Three - Treatment within the Formation (Alkaline Dosing)
- Injected the 20 m^3 of GS1014 with GS1824 at 2666 lpm, attempted for formation permeability improvement and bind Ca^{2+} ion, prevent redeposition, i.e., calcite, possible silica/quartz dissolution.
- Displaced with condensate for 1 hr before moving the third step.

Step Four – Treatment within the Formation (Acid Dosing)
- Tuned to 1800 lpm (condensate + acid) and injected remaining 40m^3 of GS1127. Attempted to push away the acid out to the formation and dissolves remaining calcite in reservoir.
- Displace with 3x wellbore volume at 2500 lpm for 1 hr.
- Well shut-in and heating up.

Figure 5: Summary of the executed chemical cleanout program.

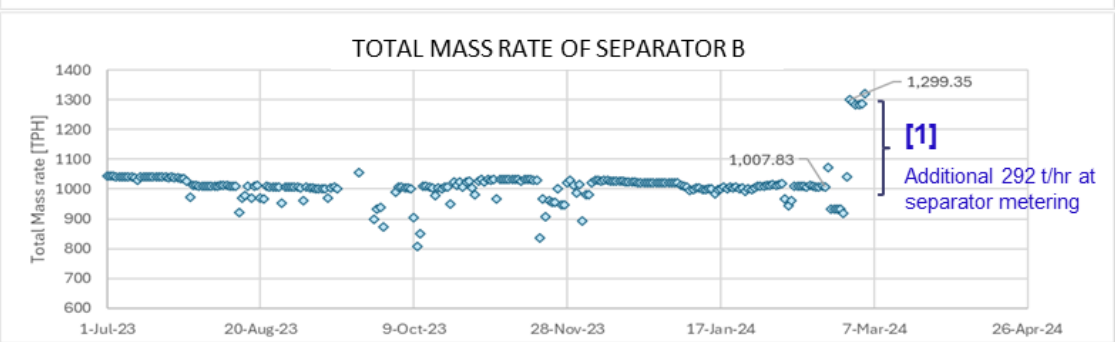

Figure 6: The observed mass rate increment at the production separator after the stimulation is completed.

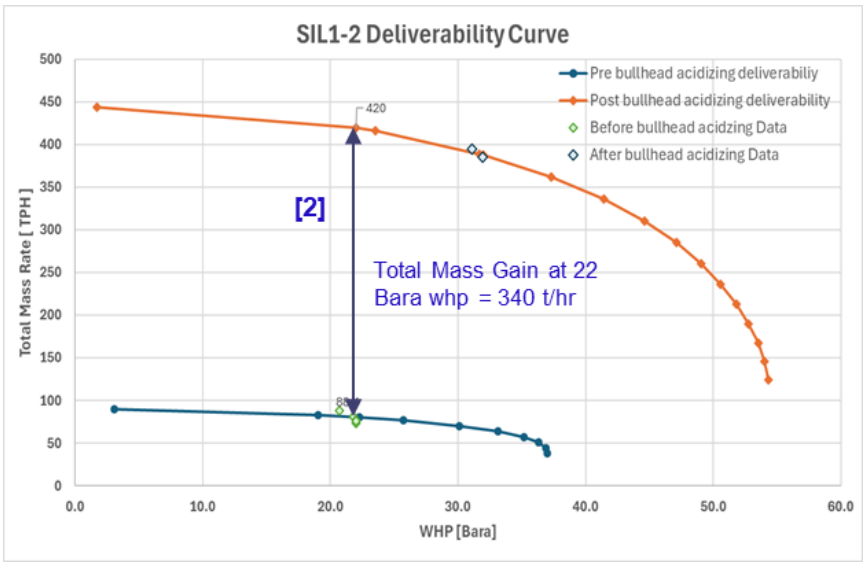

Figure 7: Post-acidizing updated deliverability curve of SIL1-2 which shows a 340 t/hr improvement (normalized to 22 barg).

4.2 Well post-stimulation Observation

Regardless of the methodology, chemical selections, and capacity improvement, the repetition of scaling deposition in SIL's production well is unavoidable. The repetition of deposition may be caused by the nature of the fluid that is oversaturated with respect to calcite and/or the consequences of the operating conditions. Confirmed by the latest chemistry data (April 2024) of SIL1-2 and exercised using different degassing coefficients in the WATCH program, suggesting the oversaturation of the fluid to calcite above 280°C or starting from the reservoir condition (Figure 8). After a cumulative four months of production, the well already shows a declining trend in mass rates. At 22 barg, SIL1-2 delivers about ±300 t/hr (Figure 9). Although the decline trend may be flattened, the well is expected to require similar well stimulation in the future.

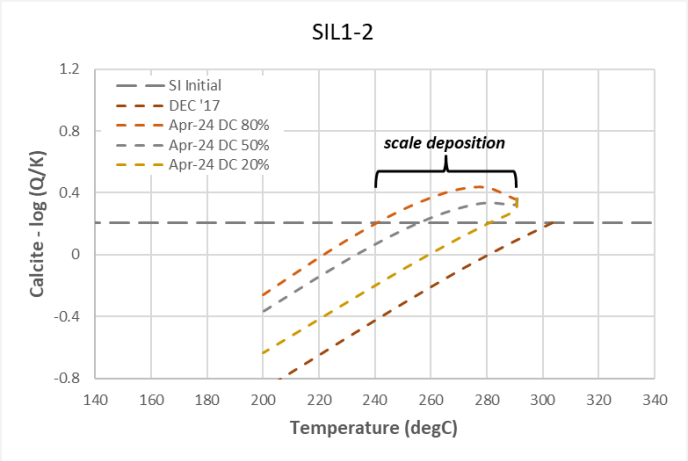

Figure 8: Post-acidizing WATCH simulation showing possible scaling deposition starting from reservoir up to wellbore conditions (or in the range of flowing temperature).

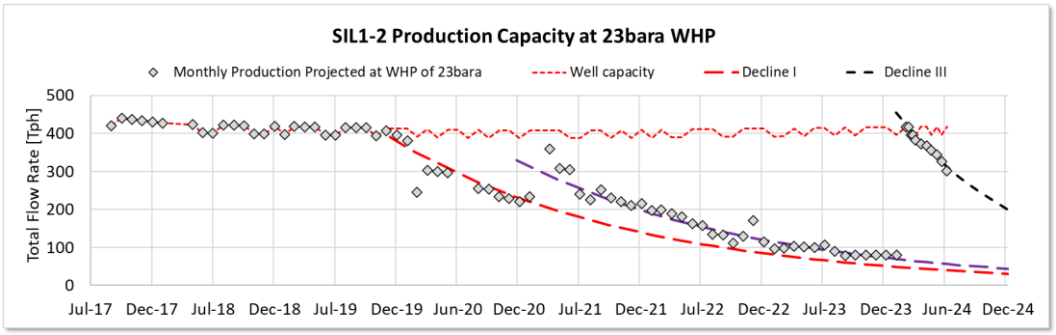

Figure 1. Updated decline trend of SIL1-2.

5. CONCLUSION

The bullhead acidizing successfully recovered the initial mass rate capacity of the SIL1-2 well. Although no methodology could confirm the permeability improvement, the combination of acid and alkali injection was considered to dissolve the calcite scale deposits in both the wellbore and the near wellbore. Further decline of the well is likely due to operating conditions and the produced reservoir fluid characteristics of which such deposition is inevitable. Though future well stimulation is expected, SIL1-2 is in an ongoing long-term observation, always fine-tuned for optimum operating conditions. Based on this result, bullhead acidizing is one methodology that has been proven in SIL and will be considered for any future well stimulations.

ABSTRACT

Geo Dipa Energi (GDE) had successfully completed Dieng 2 Drilling Campaign to prepare and supply the generation of new Dieng 2 Power Plant rated 55 MWe. The drilling campaign involved the drilling of 10 wells and additional workover operation for one well. The campaign was successfully finished within the initial planned time although the project is started lately, and one additional workover operation could be performed. In the end of the project, GDE achieved Drilling Days, Depth and Cost within plan and budget, showcasing the project's success. To achieve these targets, several improvements were continuously conducted from the first well to the last well drilled, which will be detailed in this paper. The other achievements that related to safety and drilling operation will also be described. To measure the drilling performance, GDE used ROWC (Rate of Well Completion), CPM (Cost per Meter) and NPT (Non-Productive Time) parameter. These parameters combination will demonstrate how the drilling execution was keep improving. This paper will also present a comparison of the Dieng 2 Campaign with another campaign executed by several geothermal operators in Indonesia. Moreover, valuable lessons learned and drilling strategy during the project execution, which are crucial for future drilling campaigns, will also be shared.

1. INTRODUCTION

Geo Dipa Energi (GDE) is one of the geothermal operators in Indonesia who operates two fields: Dieng and Patuha. The Dieng field currently has an electrical generation capacity of 60 MW, while Patuha has 55 MW. GDE is expanding its generation capacity by constructing a new power plant with a capacity of 55 MW in the Dieng Field. This power plant is named Dieng 2 Power Plant. To meet the steam requirements for this new power plant, 6 new production wells and 4 new injection wells are required. Therefore, GDE has successfully conducted Dieng 2 (D2) Drilling Campaign to drill wells for the Dieng 2 power plant. In addition to drilling activities, there was an additional workover operation performed for the first well drilled in the campaign. In the other hand, D2 drilling campaign is the first drilling campaign conducted by GDE as an Indonesian geothermal operator.

2. DIENG 2 DRILLING CAMPAIGN

To carry out D2 drilling campaign, GDE utilized a 1500 hp rig. Furthermore, approximately 20 service companies were involved, including directional drilling, cementing, drilling mud, casing running, and other related services. The contract system to bundle these service companies was semi-IPM contract system. Under this system, several service companies are bound by a framework contract, while others are tied to separate contracts. The typical well schematic of well drilled in D2 drilling campaign is shown by Figure 1.

2.1 Drilling Days Performance
